Preface.....	xiii
Editor .....	xv
Acknowledgments .....	xvii
Contributors .....	xix
International Advisory Board.....	xxv

## SECTION I Field Area and Control Networks

---

1 Fieldbus System Fundamentals.....	1-1
<i>Thilo Sauter</i>	
2 Networked Control Systems for Manufacturing.....	2-1
<i>James R. Moyne, Dawn M. Tilbury, and Dhananjay Anand</i>	
3 Configuration and Management of Networked Embedded Devices .....	3-1
<i>Wilfried Elmenreich and Andrea Monacchi</i>	
4 Smart Transducer Interface Standard for Sensors and Actuators .....	4-1
<i>Kang B. Lee</i>	
5 IO-Link (Single-Drop Digital Communication System) for Sensors and Actuators .....	5-1
<i>Wolfgang Stripf</i>	
6 AS-Interface .....	6-1
<i>Tilman Schinke</i>	
7 HART over Legacy 4–20 mA Signal Base.....	7-1
<i>Mark Nixon, Wally Pratt, and Eric Rotvold</i>	
8 HART Device Networks .....	8-1
<i>Mark Nixon and Deji Chen</i>	
9 Common Industrial Protocol (CIP <sup>TM</sup> ) and the Family of CIP Networks .....	9-1
<i>Viktor Schiffer</i>	

10	Modbus Protocol .....	10-1
	<i>Rudy Belliard and Ralf Neubert</i>	
11	PROFIBUS .....	11-1
	<i>Ulrich Jecht, Wolfgang Stripf, and Peter Wenzel</i>	
12	PROFINET .....	12-1
	<i>Peter Wenzel</i>	
13	Sercos® Automation Bus.....	13-1
	<i>Scott Hibbard, Peter Lutz, and Ronald M. Larsen</i>	
14	FOUNDATION Fieldbus .....	14-1
	<i>Salvatore Cavalieri</i>	
15	INTERBUS .....	15-1
	<i>Jürgen Jasperneite</i>	

---

## SECTION II Industrial Ethernet

16	Switched Ethernet in Automation .....	16-1
	<i>Gunnar Prytz, Per Christian Juel, Rahil Hussain, and Tor Skeie</i>	
17	Real-Time Ethernet for Automation Applications .....	17-1
	<i>Max Felser</i>	
18	Ethernet for Control Automation Technology .....	18-1
	<i>Gianluca Cena, Stefano Scanzio, Adriano Valenzano, and Claudio Zunino</i>	
19	Ethernet POWERLINK.....	19-1
	<i>Federico Tramarin and Stefano Vitturi</i>	
20	IEEE 802.1 Audio/Video Bridging and Time-Sensitive Networking .....	20-1
	<i>Wilfried Steiner, Norman Finn, and Matthias Posch</i>	

---

## SECTION III Fault-Tolerant Clock Synchronization in Industrial Automation Networks

21	Clock Synchronization in Distributed Systems Using NTP and PTP .....	21-1
	<i>Reinhard Exel, Thilo Sauter, Paolo Ferrari, and Stefano Rinaldi</i>	

---

## SECTION IV Accessing Factory Floor Data

22	Linking Factory Floor and the Internet.....	22-1
	<i>Thilo Sauter</i>	
23	MTConnect .....	23-1
	<i>Dave Edstrom</i>	

24	Standard Message Specification for Industrial Automation Systems .....	24-1
	<i>Karlheinz Schwarz</i>	
25	Extending CEA-709 Control Networks over IP Channels .....	25-1
	<i>Dietmar Loy and Stefan Soucek</i>	
26	Web Services for Embedded Devices .....	26-1
	<i>Vlado Altmann, Hendrik Bohn, and Frank Golatowski</i>	

---

## SECTION V Safety Technologies in Industrial Networks and Network Security

---

27	PROFIsafe .....	27-1
	<i>Wolfgang Stripf and Herbert Barthel</i>	
28	SafetyNET p Protocol.....	28-1
	<i>Marco Cereia, Jochen Streib, and Reinhard Sperrer</i>	
29	Security in Industrial Communications .....	29-1
	<i>Thilo Sauter and Albert Treyl</i>	

---

## SECTION VI Wireless Industrial Networks

---

30	Wireless LAN Technology for the Factory Floor.....	30-1
	<i>Andreas Willig</i>	
31	WirelessHART .....	31-1
	<i>Alessandra Flammini and Emiliano Sisinni</i>	
32	ISA100.11a .....	32-1
	<i>Stig Petersen and Simon Carlsen</i>	
33	Comparison of WirelessHART and ISA100.11a for Wireless Instrumentation.....	33-1
	<i>Stig Petersen and Simon Carlsen</i>	
34	IEC 62601: Wireless Networks for Industrial Automation–Process Automation (WIA-PA) .....	34-1
	<i>Ivanovitch Silva and Luiz Affonso Guedes</i>	
35	Wireless Extensions of Real-Time Industrial Networks.....	35-1
	<i>Gianluca Cena, Adriano Valenzano, and Stefano Vitturi</i>	
36	Wireless Sensor Networks for Automation .....	36-1
	<i>Tomas Lennvall, Jan-Erik Frey, and Mikael Gidlund</i>	
37	Design and Implementation of a Truly Wireless Real-Time Sensor/Actuator Interface for Discrete Manufacturing Automation .....	37-1
	<i>Guntram Scheible, Dacfey Dzung, Jan Endresen, and Jan-Erik Frey</i>	

38	IPv6 over Low-Power Wireless Personal Area Networks (6LoWPAN) and Constrained Application Protocol (CoAP) .....	38-1
	<i>Guido Moritz and Frank Golaowski</i>	

## SECTION VII Time-Triggered Communication

---

39	Concepts of Time-Triggered Communication.....	39-1
	<i>Roman Obermaisser</i>	
40	Time-Triggered Protocol (TTP/C) .....	40-1
	<i>Roman Obermaisser and Michael Paulitsch</i>	
41	Time-Triggered CAN.....	41-1
	<i>Roland Kammerer and Roman Obermaisser</i>	
42	Time-Triggered Ethernet.....	42-1
	<i>Wilfried Steiner and Michael Paulitsch</i>	

## SECTION VIII Avionics and Aerospace

---

43	MIL-STD-1553B Digital Time Division Command/Response Multiplex Data Bus.....	43-1
	<i>Chris deLong</i>	
44	ASCB .....	44-1
	<i>Michael Paulitsch</i>	
45	ARINC Specification 429 Mark 33 Digital Information Transfer System .....	45-1
	<i>Daniel A. Martinec and Samuel P. Buckwalter</i>	
46	ARINC 629 .....	46-1
	<i>Michael Paulitsch</i>	
47	Commercial Standard Digital Bus.....	47-1
	<i>Lee H. Harrison</i>	
48	SAFEbus.....	48-1
	<i>Michael Paulitsch and Kevin R. Driscoll</i>	
49	Dimensioning of Civilian Avionics Networks.....	49-1
	<i>Jean-Luc Scharbarg and Christian Fraboul</i>	

## SECTION IX Automotive Communication Technologies

---

50	In-Vehicle Communication Networks.....	50-1
	<i>Nicolas Navet and Françoise Simonot-Lion</i>	

51	Standardized Basic System Software for Automotive Embedded Applications.....	51-1
	<i>Thomas M. Galla</i>	
52	Protocols and Services in Controller Area Networks .....	52-1
	<i>Gianluca Cena and Adriano Valenzano</i>	
53	FlexRay Communication Technology.....	53-1
	<i>Roman Nossal-Tueyeni and Dietmar Millinger</i>	
54	The LIN Standard.....	54-1
	<i>Antal Rajnák and Anders Kallerdahl</i>	

---

## SECTION X Building Automation

55	State of the Art in Smart Homes and Buildings .....	55-1
	<i>Wolfgang Kastner, Lukas Krammer, and Andreas Fernbach</i>	
56	Fundamentals of LonWorks®/CEA-709 Networks.....	56-1
	<i>Dietmar Loy and Stefan Soucek</i>	
57	BACnet.....	57-1
	<i>Frank Schubert</i>	
58	KNX: A Worldwide Standard Protocol for Home and Building Automation .....	58-1
	<i>Michele Ruta, Floriano Scioscia, Giuseppe Loseto, and Eugenio Di Sciascio</i>	
59	Future Trends in Smart Homes and Buildings.....	59-1
	<i>Wolfgang Kastner, Markus Jung, and Lukas Krammer</i>	

---

## SECTION XI Energy and Power Systems

60	Protocols for Automatic Meter Reading .....	60-1
	<i>Klaas De Craemer, Geert Deconinck, and Matthias Stifter</i>	
61	Communication Protocols for Power System Automation .....	61-1
	<i>Peter Palensky, Friederich Kupzog, Thomas Strasser, Matthias Stifter, and Thomas Leber</i>	
62	IEC 61850: A Single Standard for the Engineering, Protection, Automation, and Supervision of Power Systems on All Voltage Levels .....	62-1
	<i>Karlheinz Schwarz</i>	
63	Fundamentals of the IEC 61400-25 Standard.....	63-1
	<i>Federico Pérez, Elisabet Estévez, Isidro Calvo, Darío Orive, and Marga Marcos</i>	

---

## **SECTION XII Communication Networks and Services in Railway Applications**

---

- 64** Communication in Train Control ..... **64-1**  
*Heinz Kantz, Stefan Resch, and Christoph Scherrer*
- 65** Ethernet Extensions for Train Communication Network ..... **65-1**  
*Stephan Rupp and Reiner Gruebmeyer*

---

## **SECTION XIII Semiconductor Equipment and Materials International**

---

- 66** Semiconductor Equipment and Materials International Interface  
and Communication Standards ..... **66-1**  
*Kiah Mok Goh, Lay Siong Goh, Geok Hong Phua, Aik Meng Fong, Yan Guan Lim,  
Ke Yi, and Oo Tin*

---

## **SECTION XIV Emerging Protocols and Technologies**

---

- 67** Brain ..... **67-1**  
*Michael Paulitsch, Brendan Hall, and Kevin R. Driscoll*

# Preface

---

The first edition of the *Industrial Communication Technology Handbook* was published almost a decade ago, in 2005. It gave a fairly comprehensive picture of the specialized communication networks used in diverse application areas. Solutions and technologies proposed for and deployed in process automation and on the factory floor dominated the volume. Not surprisingly, the late 1980s and the 1990s were the years when a large number of frequently competing solutions and technologies were introduced by major automation vendors and industry consortia. At the end of the 1990s, the Ethernet emerged as a contender for real-time applications, including safety-critical ones—largely on the factory floor. The Ethernet was also viewed as a potential solution for the vertical integration of functional layers of the industrial automation architectures, as it enabled a seamless data/command flow between the factory floor and upper layers. Another emerging area of research and development embarked upon at that time by the control and automation industry sector was the use of commercial wireless technologies in the automation of plants and on the factory floor.

But plant and factory automation were not the only application areas for specialized communication networks. The automotive industry has been exploring from the mid-1980s the possibility of the use of dedicated networks to automate different car functions and domains, aiming to replace mechanical or hydraulic systems with electrical/electronic ones. Production models released from the beginning of the 1990s integrated a range of networks to support different car functions and domains.

Building automation and control (BAC) is aimed at reducing energy consumption. As early as the mid-1990s, research and development activities commenced in Japan and in the United States to come up with a system to control light and temperature (coupled, particularly close to window areas) in office buildings to save energy and provide “personal comfort.” Due to the highly distributed nature of the systems involved, using specialized communication networks was a necessity.

The use of specialized communication networks in avionics was a world of its own. At the time when the first edition was published, any technical publications were seldom available to the broad engineering profession. Most technical details were confined to technical reports, sometimes available for a substantial fee.

The last ten years or so have seen a remarkable success of Ethernet-based solutions adopted, and standardized, for real-time applications—some safety-critical. (The automotive industry began evaluating IEEE 802.1 TSN/AVB for the driver assistance.) The vertical integration of industrial enterprises no longer poses major technical obstacles. This is due to the emergence of Ethernet-based solutions with real-time capabilities. But, perhaps, the most remarkable development affecting control and automation of plants and factories has been the introduction of the WAN- and PAN-based wireless technologies, stand-alone networks, and hybrid wireline-wireless solutions. It was the control and automation industry sector that saw the introduction and deployment on the factory floor of sophisticated large-scale wireless sensor networks, to mention WISA, the ABB proprietary solution. The industrial control and automation sector invested in the development and standardization of

new wireless solutions (WirelessHART, ISA 100.11a, and WIA-PA), aiming at process automation to support noncritical monitoring and control functions with the prospect of addressing safety-critical applications in future releases.

The need to manage electrical power systems to conserve energy and optimally distribute electric energy during periods of excessive demand mandated development of new solutions and technologies for automatic meter reading in order to integrate commercial and domestic energy consumption into the energy demand management decision systems.

The rapid evolution of some technologies and development of new ones called for a new edition of this handbook. It is hoped that the new edition will be useful to a broad spectrum of professionals involved in the conception, design and development, standardization, and the use of specialized communication networks. It will also have the potential to be adopted by academic instructors. The industry demand for practical knowledge of specialized communication networks, as well as hands-on exposure to the equipment, is on the rise. Academic institutions engaged in engineering education and vocational training have an important role in adequately preparing future engineering graduates to enter the profession equipped with the practical knowledge sought by the industry.

The book offers a comprehensive treatment of specialized communication networks, with chapters segregated by industry sectors and application domains. The basics of communication networks, and some aspects relevant to industrial applications that are widely available in numerous professional journals, magazines, and technical books, have been omitted to keep the new edition at a reasonable size. Certain technologies covered in the first edition have been omitted in the second edition as they are either no longer maintained or have a small user base.

Half of the contributions to the second edition are from major technology vendors, or industry consortia, involved in the technology creation, maintenance, and standardization—making this edition an authoritative volume. The other half is from governmental and private research establishments—contributors are researchers from leading academic institutions with distinguished publication records in the areas of their expertise.

This new edition, with twice as many chapters as the first one, adds new sections on industrial Ethernet, wireless industrial networks, time-triggered communication, networks in avionics and aerospace, fault-tolerant clock synchronization in industrial automation networks, networks in energy and power systems, and emerging protocols and technologies. The other sections have been updated and expanded substantially.

The second edition of the *Industrial Communication Technology Handbook* is divided into 14 sections consisting of 67 chapters and covers the following topics: field area and control networks, industrial Ethernet, fault-tolerant clock synchronization in industrial automation networks, accessing factory floor data, safety technologies in industrial networks and network security, wireless industrial networks, time-triggered communication, automotive communication technologies, networks in avionics and aerospace, networks in building automation and control, networks for energy and power systems, communication networks and services in railway applications, SEMI, and emerging protocols and technologies.

To ensure the integrity of the content, there is some overlap among selected chapters. Some chapter titles specifically refer to the technology presented in that chapter; others have more general titles, covering a range of technologies. There is a table of contents on the first page of each chapter to guide the reader. IEEE 802.15.1/Bluetooth and IEEE 802.15.4/ZigBee do not have dedicated chapters but are discussed extensively in the chapters on WISA (36 and 37), WirelessHART (31 and 36), and ISA 100 (32 and 36). CAN, which was developed specifically for automotive applications, and is also used in industrial control and automation, is discussed in Section IX, Automotive Communication Technologies, and also in Section VII, Time-Triggered Communication.

# Editor

---

**Richard Zurawski**, a fellow of the Institute of Electrical Electronics Engineers (USA), is with ISA Group, San Francisco, California. He has over 35 years of academic and industrial experience, including a regular professorial appointment at the University of Tokyo and a full-time R&D advisory position with Kawasaki Electric, Tokyo. He provided consulting services to Kawasaki Electric, Ricoh, and Toshiba Corporations, Japan. He has also participated in a number of Japanese Intelligent Manufacturing Systems programs.

Dr. Zurawski is the editor of two book series: The Industrial Information Technology series and the Embedded Systems series—both published by CRC Press/Taylor & Francis Group. He is the former editor in chief of the *IEEE Transactions on Industrial Informatics* (2007–2010). He served as editor at large of the *IEEE Transactions on Industrial Informatics* (2006) and as associate editor of the *IEEE Transactions on Industrial Electronics* (1994–2005), *Real-Time Systems*, and *The International Journal of Time-Critical Computing Systems* (Kluwer Academic Publishers, 1997–2003).

Dr. Zurawski was a guest editor of a special issue of the prestigious *Proceedings of the IEEE* dedicated to industrial communication systems. He was also invited by the *IEEE Spectrum* to contribute an article on Java technology to “Technology 1999: Analysis and Forecast Issue.” He was a guest editor of three special sections in the *IEEE Transactions on Industrial Electronics* on factory automation and factory communication systems.

Dr. Zurawski served as a vice president of the Industrial Electronics Society (1994–1997), chairman of the IES Factory Automation Council (1994–1997), and chairman of the IES Technical Committee on Factory Automation (2005–2010). He was also on the steering committee of the ASME/IEEE *Journal of Microelectromechanical Systems*. In 1996, he received the Anthony J. Hornfeck Service Award from the IEEE Industrial Electronics Society.

Dr. Zurawski was the editor of six major handbooks: *The Industrial Information Technology Handbook*, CRC Press (2004); *The Industrial Communication Technology Handbook*, CRC Press (2005); *Embedded Systems Handbook*, CRC Press/Taylor & Francis Group (2005, 2014); *Integration Technologies for Industrial Automated Systems*, CRC Press/Taylor & Francis Group (2008); *Embedded Systems Design and Verification*, vol. 1, *Embedded Systems Handbook*, 2nd edition (2009) and *Networked Embedded Systems*, vol. 2, *Embedded Systems Handbook*, 2nd edition (2009), CRC Press/Taylor & Francis Group; and *Electrical Engineering Technology and Systems Handbook* (seven volume set, 2015), CRC Press/Taylor & Francis.

Dr. Zurawski received an M.Eng. in electronics, and a Ph.D. in computer science.

# Acknowledgments

---

I would like to thank all contributing authors, particularly authors from industry and industry consortia whose job priorities usually are different from writing chapters in books. I wish to acknowledge the work of Dr. Ronald Schoop of Schneider Electric, who passed away before finishing his contribution. I am grateful to the members of the *Handbook's* Advisory Board for so generously taking part in the making of this book.

I also wish to thank at CRC Press, Nora Konopka, publisher of this book; Michele Smith, Jessica Vakili, and Richard Tressider, production editor.

## 1.1 Introduction

---

Few developments have changed the face of automation so profoundly as the introduction of networks did. Especially, fieldbus systems—networks devised for the lowest levels of the automation hierarchy—had an enormous influence on the flexibility and performance of modern automation systems in all application areas. However, fieldbus systems were not the result of some *divine spark*; they emerged in a continuous and often cumbersome evolution process. Today, many applications areas are unthinkable without them: not only factory automation, distributed process control, building and home automation, substation automation, and more generally energy distribution, but also in-vehicle networking, railway applications, and avionics. All these fields heavily rely on the availability of appropriate networks accounting for the special demands of the individual application.

But what exactly is a fieldbus? Even after a quarter of a century of fieldbus development, there exists no clear-cut definition for the term. The *definition* given in the IEC 61158 fieldbus standard is more a programmatic declaration or a least common multiple compromise than a concise formulation [1]: “A fieldbus is a digital, serial, multidrop, data bus for communication with industrial control and instrumentation devices such as – but not limited to – transducers, actuators and local controllers.” It comprises some important characteristics, but is far from being complete. On the other hand, it is a bit too restrictive.

A more elaborate explanation is given by the Fieldbus Foundation, the user organization supporting one of the major fieldbus systems [2]: “A Fieldbus is a digital, two-way, multidrop communication

link among intelligent measurement and control devices. It serves as a Local Area Network (LAN) for advanced process control, remote input/output and high speed factory automation applications.” Again, this is a bit restrictive, for it limits the application to process and factory automation, the primary areas where the Foundation Fieldbus is being used.

The lack of a clear definition is mostly due to the complex evolution history of fieldbuses. In most cases, bus systems emerged primarily to break up the conventional star-type point-to-point wiring schemes connecting simple digital and analog input and output devices to central controllers, thereby laying the grounds for the implementation of really distributed systems with more intelligent devices. As was declared in the original mission statement of the IEC work

the Field Bus will be a serial digital communication standard which can replace present signalling techniques such as 4-20 mA ... so that more information can flow in both directions between intelligent field devices and the higher level control systems over shared communication medium... [3,4].

Still in more recent publications, this aspect is seen as the only *raison d'être* for fieldbus systems [5], which is however shortsighted and does not do the fieldbus justice.

Today, fieldbus systems comprising communication networks and devices can also be regarded as networked embedded systems. In the 1980s, when their era began, this term was still unknown. Yet, their main features and development stimuli are comparable:

- *Focused solutions.* Fieldbus systems were no general-purpose developments, even if they were said to be. They were always developed with a concrete application field in mind and designed to meet the respective boundary conditions (like not only temporal behavior, efficiency, and reliability, but also cost) in the best possible way.
- *Smart devices.* An essential objective for embedded systems and fieldbuses alike is to bring more intelligence to the field, that is, to the end devices. Like in embedded systems, fieldbus developers also used the technological building blocks available at the time where possible, such as standard microcontrollers to keep costs low. However, if special needs were to be met, also dedicated solutions were devised.
- *Limited resources.* Embedded applications and fieldbus system both share the fundamental problem that resources are limited. No matter what the state of art in microelectronics is, embedded devices (and field devices) are less powerful than standard computers. Communication (sub)systems usually have less available bandwidth than computer networks, and power consumption is an issue.
- *Comprehensive concepts.* Fieldbus systems are not just networks. Communication is only part of a distributed automation concept with comprehensive application software and tool chains. In some advanced cases, fieldbuses were embedded into special frameworks exhibiting many characteristics of distributed operating systems.
- *Distribution.* A network is the prerequisite of distributed systems; many data processing tasks can be removed from a central controller and placed directly in the field devices if they are sufficiently smart and the interface can handle reasonably complex ways of communication.
- *Flexibility and modularity.* A fieldbus installation like any other network can be extended much more easily than a centralized system, provided the limitations of addressing space, cable length, etc., are not exceeded. For the special case of fieldbuses, simplification of the parameterization and configuration of complex field devices is an additional benefit making system setup and commissioning easier.
- *Maintainability.* Monitoring of devices, applying updates, and other maintenance tasks are easier, if at all possible, via a network.

These aspects are not just theoretical contemplations but actual user demands that influenced the development from the beginning on [4]. However, as the application requirements in the various

automation domains were quite different, so were the solutions, and that makes it so difficult to find a comprehensive definition. The purpose of this chapter thus is to give an overview of the nature of fieldbus systems. It briefly reviews the evolution from the historical roots up to the tedious standardization efforts. It discusses in detail typical characteristics that distinguish fieldbuses from other types of networks. Current activities aiming at using Ethernet in automation are reviewed, and evolution prospects are given. It appears that fieldbus systems have reached their climax and that future years will bring a mix of Ethernet-/Internet-based solutions and still-to-be-developed, new field-level networks.

## 1.2 What Is a Fieldbus?

---

As mentioned in Section 1.1, fieldbus systems have to be seen as an integrative part of a comprehensive automation concept and not as standalone solutions. The name is therefore programmatic and evocative. Interestingly enough, not even the etymology of the term itself is fully clear. The English word *fieldbus* is definitely not the original one. It appeared around 1985 when the fieldbus standardization project within IEC TC65 was launched [4] and seems to be a straightforward literal translation of the German term *Feldbus*, which can be traced back until about 1980 [6]. Indeed, the overwhelming majority of early publications in the area is available only in German. The word itself was coined in process industry and primarily refers to the process field, designating the area in a plant where lots of distributed field devices, mostly sensors and actuators, are in direct contact with the process to be controlled. Slightly after the German expression and sharing its etymological root, the French word *réseau de terrain* (or *réseau d'instrumentation*, instrumentation network) emerged. This term was not specifically targeted at the process industry but refers also to large areas with scattered devices. The connection of such devices to the central control room was traditionally made via point-to-point links, which resulted in a significant and expensive cabling need. The logical idea, powered by the advances of microelectronics in the late 1970s, was to replace this star-like cabling in the field by a party-line, bus-like installation connecting all devices via a shared medium—the fieldbus [7,8].

Given the large dimensions of process automation plants, the benefits of a bus are particularly evident. However, the concept was not undisputed when it was introduced. The fieldbus approach was an ambitious concept: a step toward decentralization, including the preprocessing of data in the field devices, which both increases the quality of process control and reduces the computing burden for the centralized controllers [9]. Along with it came the possibility to configure and parameterize the field devices remotely via the bus. This advanced concept, on the other hand, demanded increased communication between the devices that goes far beyond a simple data exchange. This seemed infeasible to many developers, and still in the mid-1980s, one could read statements like [10] “The idea of the fieldbus concept seems promising. However, with reasonable effort it is not realizable at present.”

The alternative and somewhat more conservative approach was the development of the so-called *field multiplexers*, devices that collect process signals in the field, serialize them, and transfer them via one single cable to a remote location where a corresponding device demultiplexes them again [11]. For quite some time, the two concepts competed and coexisted [12], but ultimately the field multiplexers mostly disappeared, except for niches in process automation, where many users still prefer such *Remote I/O* systems despite the advantages of fieldbus solutions [13]. The central field multiplexer concept of sampling I/O points and transferring their values in simple data frames also survived in some fieldbus protocols especially designed for low-level applications.

The desire to cope with the wiring problem getting out of hand in large installations was certainly the main impetus for the development of fieldbus systems. Other obvious and appealing advantages of the concept are modularity, the possibility to easily extend installations, and the possibility to have much more intelligent field devices that can communicate not just for the sake of process data transfer, but also for maintenance and configuration purposes [14,15]. A somewhat different viewpoint that led to different design approaches was to regard bus systems in process control as the spine of distributed real-time systems [16]. While the wiring optimization concepts were in many cases

rather simple bottom-up approaches, these distributed real-time ideas resulted in sophisticated and usually well-investigated top-down designs.

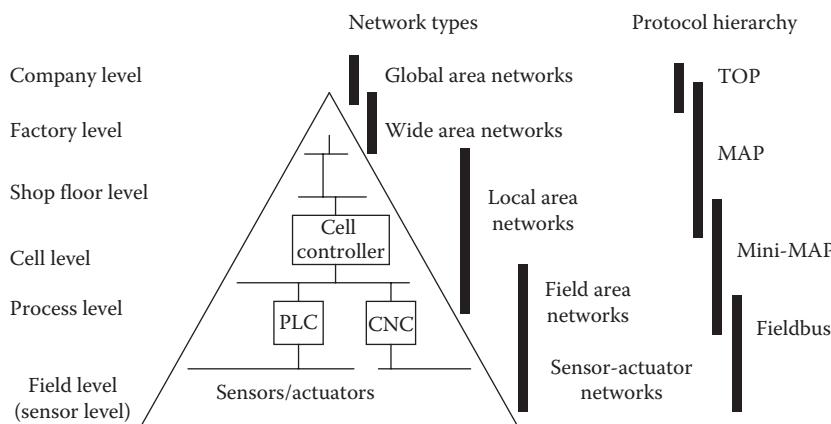

An important role in the fieldbus evolution has been played by the so-called automation pyramid. This hierarchical model was defined to structure the information flow required for factory and process automation. The idea was to create a transparent, multilevel network—the basis for computer-integrated manufacturing (CIM). The numbers vary, but typically this model comprised up to five levels, sometimes more [17]. While the networks for the upper levels already existed by the time the pyramid was defined, the field level was still governed by point-to-point connections. Fieldbus systems were therefore developed also with the aim of finally bridging this gap. The actual integration of field-level networks into the rest of the hierarchy was in fact considered in early standardization [4]; for most of the proprietary developments, however, it was never the primary intention.

In the automation pyramid, fieldbuses actually populate two levels: the field level and the cell/process level. For this reason, they are sometimes further differentiated into two classes:

1. Sensor-actuator buses or device buses have very limited capabilities and serve to connect very simple devices with, for example, programmable logic controllers (PLCs). They can be found exclusively on the field level.
2. Fieldbuses connect control equipment like PLCs and PCs as well as more intelligent devices. They are found on the cell level and are closer to computer networks.

This distinction may seem reasonable but is in fact problematic. There are only few fieldbus systems that can immediately be allocated to one of the groups, most of them are being used in both levels. Therefore, it should be preferable to abandon this arbitrary differentiation.

How do fieldbus systems compare to computer networks? The classical distinction of the different network types used in the automation pyramid hinges on the distances the networks span. From top down, the hierarchy starts with global area networks (GANs), which cover long, preferably intercontinental distances, and nowadays mostly use satellite links. On the second level are wide area networks (WANs). They are commonly associated with telephone networks (no matter if analog or digital). Next come the well-known LANs, with Ethernet as the most widely used technology today. They are the classical networks for office automation and cover only short distances. The highest level of the model shown in Figure 1.1 is beyond the scope of the original definition, but is gaining importance with the availability of the Internet. In fact, Internet technology is penetrating all levels of this pyramid all the way down to the process level. And since IP has reached a dominating position as worldwide networking technology, the discussion about how to distinguish GANs, WANs, and LANs is today mostly only of academic interest.

**FIGURE 1.1** Hierarchical network levels in automation and protocols originally devised for them.

From GANs to LANs, the classification according to the spatial extension is evident. One step below, on the field level, this criterion fails, because fieldbus systems or field area networks (FANs) can cover even larger distances than LANs. Yet, as LANs and FANs evolved nearly in parallel, some clear distinction between the two network types seemed necessary. As length is inappropriate, the classical border line drawn between LANs and FANs relies mostly on the characteristics of the data transported over these networks. LANs have high data rates and carry large amounts of data in large packets. Timeliness is not a primary concern, and real-time behavior is not required. Fieldbus systems, by contrast, have low data rates. Since they transport mainly process data, the size of the data packets is small, and real-time capabilities are important.

For some time, these distinction criteria between LANs and FANs were sufficient and fairly described the actual situation. Recently, however, drawing the line according to data rates and packet sizes is no longer applicable. In fact, the boundaries between LANs and fieldbus systems have faded. Today, there are fieldbus systems with data rates well above 10 Mbit/s, which is still standard in older LAN installations. In addition, more and more applications require the transmission of video or voice data, which results in large data packets.

On the other hand, Ethernet as *the* LAN technology is becoming more and more popular in automation and is bound to replace some of today's widely used mid-level fieldbus systems. The real-time extensions developed during the last years tackle its most important drawback and will ultimately permit the use of Ethernet also in low-level control applications. However, it seems that industrial Ethernet will not make the lowest-level fieldbuses fully obsolete. They are much better optimized for their specific automation tasks than the general-purpose network Ethernet. But the growing use of Ethernet results in a reduction of the levels in the automation hierarchy. Hence the pyramid gradually turns into a flat structure with at most three, maybe even only two levels.

Consequently, a more appropriate distinction between LANs and FANs should be based on the functionality and the application area of these networks. According to this pragmatic argumentation, a fieldbus is simply a network used in automation, irrespective of topology, data rates, protocols, or real-time requirements. Consequently, it need not be confined to the classical field level; it can be found on higher levels (provided they still exist) as well. A LAN, on the other hand, belongs to the office area. This definition is loose, but mirrors the actual situation. Only one thing seems strange at first: Following this definition, industrial Ethernet changes into a fieldbus, even though many people are inclined to associate it with LANs. However, this is just another evidence that the boundaries between LANs and FANs are fading.

## 1.3 History

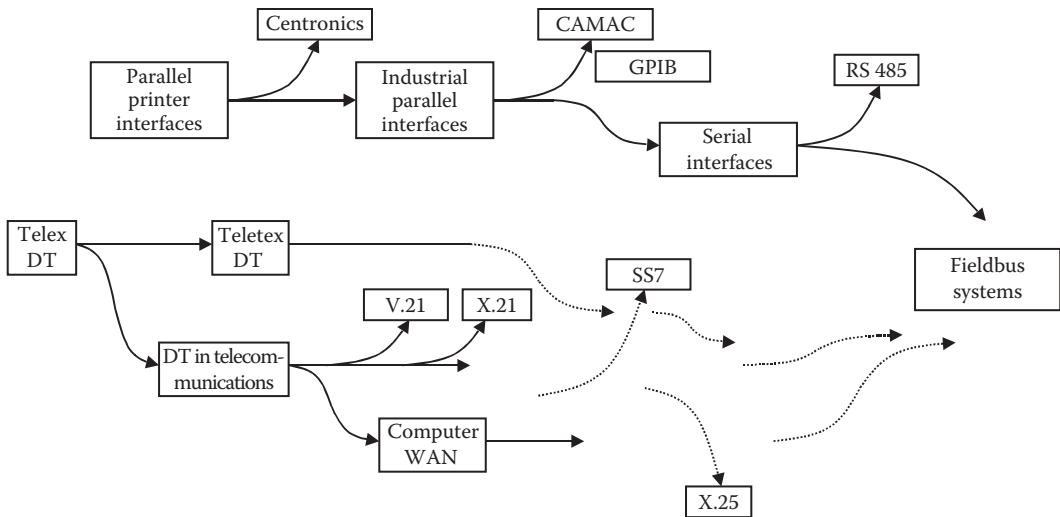

---

The question of what constitutes a fieldbus is closely linked to the evolution of these industrial networks. The best approach to understanding the essence of the concepts is to review the history and the intentions of the developers. This review will also falsify one of the common errors frequently purported by marketing divisions of automation vendors: that fieldbus systems were a revolutionary invention. They may have revolutionized automation; there is hardly any doubt about it. However, they themselves were only a straightforward evolution that built on preexisting ideas and concepts.

### 1.3.1 Roots of Industrial Networks

Although the term *fieldbus* appeared only about 30 years ago, the basic idea of field-level networks is much older. Still, the roots of modern fieldbus technology are mixed. Both classical electrical engineering and computer science have contributed their share to the evolution, and we can identify three major sources of influence:

1. Communication engineering with large-scale telephone networks
2. Instrumentation and measurement systems with parallel buses and real-time requirements
3. Computer science with the introduction of high-level protocol design

**FIGURE 1.2** Historical roots of fieldbus systems.

This early stage is depicted in Figure 1.2. One foundation of automation data transfer has to be seen in the classic telex networks and also in standards for data transmission over telephone lines. Large distances called for serial data transmission, and many of these comparatively early standards still exist, like V.21 (data transmission over telephone lines) and X.21 (data transmission over special data lines). Various protocols have been defined, mostly described in state machine diagrams and rather simple because of the limited computing power of the devices available at that time. Of course, these communication systems have a point-to-point nature and therefore lack the multidrop characteristic of modern fieldbus systems, but nevertheless they were the origin of serial data transmission. Talking about serial data communication, one should notice that the engineers who defined the first protocols often had a different understanding of the expressions *serial* and *parallel* than we have today. For example, the *serial* Interface V.24 transmits the application data serially, but the control data in a parallel way over separate control lines.

In parallel to the development of data transmission in the telecommunication sector, hardware engineers defined interfaces for standalone computer systems to connect peripheral devices such as printers. The basic idea of having standardized interfaces for external devices was soon extended to process control and instrumentation equipment. The particular problems to be solved were the synchronization of spatially distributed measurement devices and the collection of measurement data from multiple devices in large-scale experimental setups. This led to the development of standards like CAMAC (in nuclear science) and GPIB (later also known as IEEE 488). To account for the limited data processing speed and real-time requirements for synchronization, these bus systems had parallel data and control lines, which is also not characteristic for fieldbus systems. However, they were using the typical multidrop structure.

Later on, with higher integration density of integrated circuits and thus increased functionality and processing capability of microcontrollers, devices became smaller and portable. The connectors of parallel bus systems were now too big and clumsy, and alternatives were sought [18]. The underlying idea of developments like I<sup>2</sup>C [19] was to extend the already existing serial point-to-point connections of computer peripherals (based on the RS 232) to support longer distances and finally also multidrop arrangements. The capability of having a bus structure with more than just two connections together with an increased noise immunity due to differential signal coding eventually made the RS 485 a cornerstone of fieldbus technology up to the present day.

Historically the youngest root of fieldbus systems, but certainly the one that left the deepest mark was the influence of computer science. Its actual contribution was a structured approach to the design of high-level

communication systems, contrary to the mostly monolithic design approaches that had been sufficient until then. This change in methodology had been necessitated by the growing number of computers used worldwide and the resulting complexity of communication networks. Conventional telephone networks were no longer sufficient to satisfy the interconnection requirements of modern computer systems. As a consequence, the big communication backbones of the national telephone companies gradually changed from analog to digital systems. This opened the possibility to transfer large amounts of data from one point to another. Together with an improved physical layer, the first really powerful data transmission protocols for WANs were defined, such as X.25 (packet switching) or SS7 (common channel signaling). In parallel to this evolution on the telecommunications sector, LANs were devised for the local interconnection of computers, which soon led to a multitude of solutions. It took nearly a decade until Ethernet and Transmission Control Protocol (TCP)/IP finally gained the dominating position they have today.

### 1.3.2 Evolution of Fieldbuses

The preceding section gave only a very superficial overview of the roots of networking, which laid the foundations not only of modern computer networks but also of those on the field level. But let us now look more closely at the actual evolution of the fieldbus systems. Here again, we have to consider the different influences of computer science and electrical engineering. First and foremost, the key contribution undoubtedly came from the networking of computer systems, when the ISO/ open system interconnection (OSI) model was introduced [20,21]. This seven-layer reference model was (and still is) the starting point for the development of many complex communication protocols.

The first application of the OSI model to the domain of automation was the definition of manufacturing automation protocol (MAP) in the wake of the CIM idea [22]. MAP was intended to be a framework for the comprehensive control of industrial processes covering all automation levels, and the result of the definition was a powerful and flexible protocol [23]. Its complexity, however, made implementations extremely costly and hardly justifiable for general-purpose use. As a consequence, a tightened version called MiniMAP and using a reduced model based on the OSI layers 1, 2, and 7 was proposed to better address the problems of the lower automation layers [24]. Unfortunately, it did not have the anticipated success either. What did have success was Manufacturing Message Specification (MMS). It defined the cooperation of various automation components by means of abstract objects and services and was later used as a starting point for many other fieldbus definitions [25]. The missing acceptance of MiniMAP as well as the inapplicability of the original MAP/MMS standard to time-critical systems [26] were finally the reasons for the IEC to launch the development of a fieldbus based on the MiniMAP model, but tailored to the needs of the field level. According to the original objectives, the higher levels of the automation hierarchy should be covered by MAP or PROWAY [22].

Independent of this development in computer science, the progress in microelectronics brought forward many different integrated controllers, and new interfaces were needed to interconnect the ICs in an efficient and cheap way. The driving force was the reduction of both the interconnect wires on the printed circuit boards and the number of package pins on the ICs. Consequently, electrical engineers—without the knowledge of the ISO/OSI model or similar architectures—defined simple buses like the I<sup>2</sup>C. Being interfaces rather than fully fledged bus systems, they have very simple protocols, but they were and still are widely used in various electronic devices.

Long before the *invention* of board-level buses, the demand for a reduction of cabling weight in avionics and space technology had led to the development of the MIL STD 1553 bus, which can be regarded as the first *real* fieldbus. Introduced in 1970, it showed many characteristic properties of modern fieldbus systems: serial transmission of control and data information over the same line, master–slave structure, the possibility to cover longer distances, integrated controllers, and it is still used today. Later on, similar thoughts (reduction of cabling weight and costs) resulted in the development of several bus systems not only in the automotive industry but also in the automation area. A characteristic property of these fieldbuses is that they were defined in the spirit of classical interfaces, with a focus on the lower two

protocol layers, and no or nearly no application layer definitions. With time, these definitions were added to make the system applicable to other areas as well. Controller area network (CAN) is a good example of this evolution: For the originally targeted automotive market, the definition of the lowest two OSI layers was sufficient. Even today, automotive applications of CAN typically use only these low-level communication features because they are easy to use and the in-vehicle networks are usually closed. For applications in industrial automation, however, where extensibility and interoperability is an important issue, higher-level functions are important. So, when CAN was found to be interesting also for other application domains, a special application layer was added. The lack of such a layer in the original definition is the reason why there are many different fieldbus systems (like CANopen, Smart Distributed System (SDS), and DeviceNet) using CAN as a low-level interface.

From today's point of view, it can be stated that all fieldbuses that still have some relevance were developed using the *top-down* or *computer science–driven* approach, that is, a proper protocol design with abstract high-level programming interfaces to facilitate usage and integration in complex systems. The fieldbuses that followed the *bottom-up* or *electrical engineering–driven* approach, that is, that were understood as low-level computer interface, did not survive due to their inflexibility and incompatibility with modern software engineering, unless some application layer functions were included in the course of the evolution.

From the early 1980s on, when automation made a great leap forward with PLCs and more intelligent sensors and actuators, something like a gold rush set in. The increasing number of devices used in many application areas called for a reduced cabling, and microelectronics had grown mature enough to support the development of elaborated communication protocols. This was also the birth date for the fieldbus as an individual term. Different application requirements generated different solutions, and from today's point of view, it seems that creating new fieldbus systems was a trendy and fashionable occupation for many companies in the automation business. Those mostly proprietary concepts never had a real future, because the number of produced nodes could never justify the development and maintenance costs. Figure 1.3 depicts the evolution timeline of fieldbus systems and their environment [27]. The list of examples is of course not comprehensive; only systems that still have some significance have been selected. Details about the individual solutions are summarized in the tables in the appendix.

As the development of fieldbus systems was a typical *technology push* activity driven by the device vendors, the users first had to be convinced of the new concepts. Even though the benefits were quite obvious,

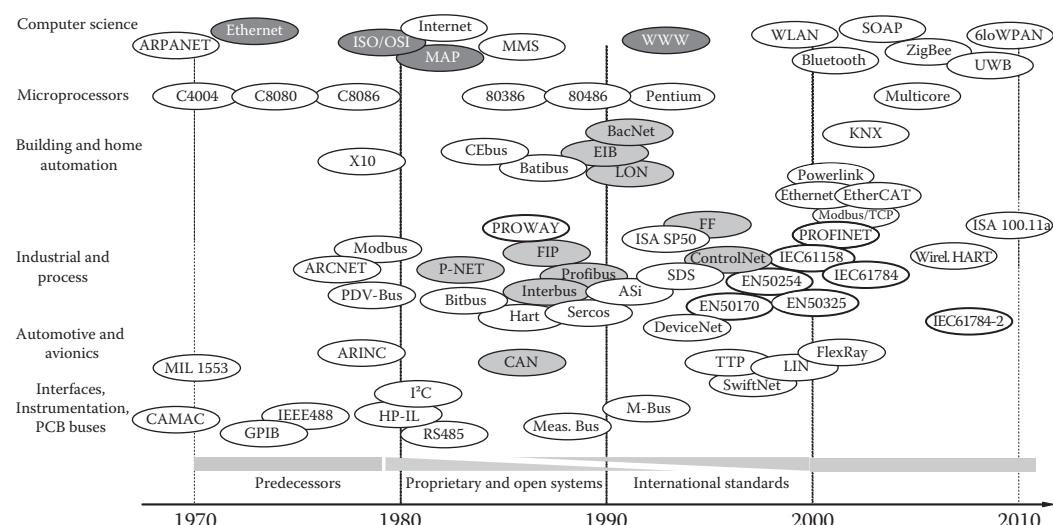

FIGURE 1.3 Milestones of fieldbus evolution and related fields.

the overwhelming number of different systems appalled rather than attracted the customers, who were used to perfectly compatible current-loop or simple digital inputs and outputs as interfaces between field devices and controllers and were reluctant to use new concepts that would bind them to one vendor. What followed was a fierce selection process where not always the fittest survived, but often those with the highest marketing power behind them. Consequently, most of the newly developed systems vanished or remained restricted to small niches. After a few years of struggle and confusion on the user's side, it became apparent that proprietary fieldbus systems would always have only limited success and that more benefit lies in creating *open* specifications so that different vendors may produce compatible devices, which gives the customer back their freedom of choice [8]. As a consequence, user organizations were founded to carry on the definition and promotion of the fieldbus systems independent of individual companies. It was this idea of open systems that finally paved the way for the breakthrough of the fieldbus concept.

The final step to establish the fieldbus in the automation world was international standardization. The basic idea behind it is that a standard establishes a specification in a very rigid and formal way, ruling out the possibility of quick changes. This attaches a notion of reliability and stability to the specification, which in turn secures the trust of the customers and, consequently, also the market position. Furthermore, a standard is vendor-independent, which guarantees openness. Finally, in many countries, standards have a legally binding position, which means that when a standard can be applied (e.g., in connection with a public tender), it *has to* be applied. Hence a standardized system gains a competitive edge over its nonstandardized rivals. This position is typical for, for example, Europe (see [28] for an interesting US-centric comment). It is therefore no wonder that after the race for fieldbus developments, a race for standardization was launched. This was quite easy on a national level, and most of today's relevant fieldbus systems soon became national standards. Troubles started when international solutions were sought. The fieldbus standardization project of IEC, which was started in the technical subcommittee SC65C in 1985, had the ambitious objective of creating one single, universally accepted fieldbus standard for factory and process automation [16,27,29]. Against the backdrop of a quickly evolving market and after 14 years of fierce technical and increasingly political struggles, this goal was abandoned with the multiprotocol standards IEC 61158 and IEC 61784-1 [30–32]. In other application domains, other standards were defined, so that the fieldbus world today consists of a sumptuous collection of well-established approaches.

## 1.4 Communication Fundamentals: The OSI Model

---

It has been stated before that the definition of the OSI model was as essential cornerstone for the development of fieldbus systems. The attempts at creating a reference model for data communication arose from the fact that at the time, there were a series of computer networks all of which were incompatible with one another. The expansion of these networks was therefore limited to a specific circle of users. Data transmission from one network to another was possible only with great investment in specialized hardware and software solutions. It was the aim of the OSI model to counteract this development. ISO introduced the concept of an *open system*. Such systems consist of hardware and software components that comply with a given set of standards. These standards guarantee that systems from different manufacturers are compatible with one another and can easily communicate.

To alleviate handling the rather complex task of data communication, it was decided in the committee to partition it into a strictly hierarchical, layered model. All relevant communication functions were counted up and ordered into overlying groups building on one another. On that basis, a reasonable degree of modularization was sought, and seven layers seemed a feasible compromise. In fact, there is no other significance or mystery in the number of layers. The great significance of the OSI model and its value for practical use came about due to the consistent implementation of three essential concepts:

1. *Protocol.* The term *protocol* denotes a set of rules that govern the communication of layers on the same level. If layer N of open system 1 wishes to contact layer N of open system 2, both systems must adhere to specific rules and conventions. Together, these rules make up the protocol of layer N. Layers lying on the same level are also called peer layers.

2. *Service*. This represents any service made available by one layer (called *service provider*) to the layer directly above it (called *service user*). It is important to notice that for the services of a layer, the OSI model defines only their functionality and not how they are actually implemented.
3. *Interface*. There is an interface between every two layers. This clearly defined interface specifies which services are offered by the lower layer to the upper layer, that is, how the service user can access the services of the service provider, what parameters need to be transferred, and what the expected results are.

It is a common misconception to think that the OSI model describes or prescribes actual implementations. It establishes only the effects of each of the layers. Suitable standards were additionally worked out for the layers. These standards are not part of the reference model and were later published in their own right.

### 1.4.1 Layer Structure

The clear distinction between horizontal and vertical communication was the key to the definition of interconnectable systems. Figure 1.4 shows the layer structure and how the data are passed from one process to another. A system application initiates a transmission via layer 7 of its communication stack. To fulfill this task, layer 7 prepares data for its peer layer on the receiving side, packages this, and requests services of layer 6 to transmit these data. Layer 6 does the same. It prepares data for the peer layer 6' to fulfill its task and requests services from the next lower layer 5, and so on all the way down to layer 1, which actually transmits the data. On the way down the layers, the data of the application process are augmented by layer-specific data needed to execute the respective protocols. These data are typically address and control information that is mostly combined in a protocol header. In addition, the data may be segmented into individual packets to match the allowed maximum packet size for a given layer. This way, the number of bits being actually transmitted can be significantly larger than the pure user data provided by the application process, and the communication overhead can be substantial. On the receiving side, the peer layers strip all this additional information to recover the user data for the application process. The basic functions of the individual layers are briefly described in the following text.

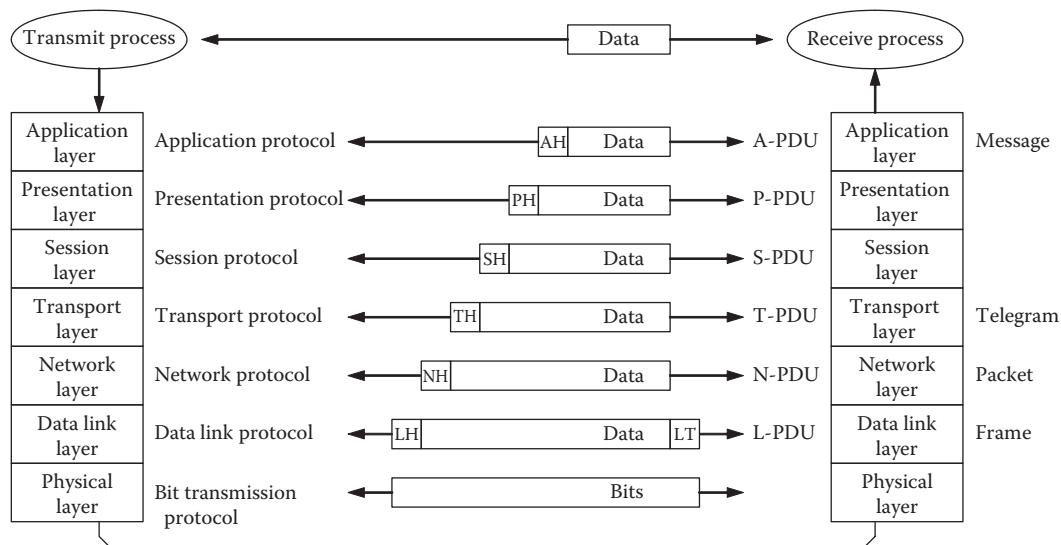

FIGURE 1.4 Layer structure of the OSI model and data frame formation.

#### 1.4.1.1 Layer 1 (Physical Layer)

As the name suggests, this layer describes all mechanical, physical, optical, electrical, and logical properties of the communication system. This includes, for example, definition of the connector type, impedances, transmission frequencies, admissible line lengths, line types, the type of coding of individual bits (such as NRZI: nonreturn to zero inverted, RZ: return to zero, Manchester coding), simultaneous transmission of energy and data, signal energy imitations for intrinsically safe applications, and the like. One of the most widely used standards for layer 1 in fieldbus technology is the RS 485 interface, which naturally forms only a small part of a complete layer-1 definition. Essentially, layer 1 presents to its upper layer all that is needed to transfer a given data frame.

#### 1.4.1.2 Layer 2 (Data Link Layer)

This layer is a pure point-to-point connection with the task of guaranteeing transmission between two network nodes. This firstly involves the formation of the data frame (Figure 1.4), which typically contains a header with control and address information and the actual data. The second task of the data link layer is the coding and checking of the frame (e.g., via CRC: cyclic redundancy check), to allow transmission errors to be detected or even corrected. This also includes the checking of timeouts or verification that the corresponding responses and confirmations are received from the opposite side. The data link layer thus provides the following service to the above lying layer 3: setup of a logic channel to an opposite end device without intermediate nodes or the transmission of a data frame between two end points. In practice, layer 2 becomes too overloaded with functions to allow for a straightforward implementation. Therefore, it is usually subdivided into the logical link control (see IEEE 802.2), which sets up the connection to layer 3 (to which the error detection mechanism is assigned) and the medium access control (MAC) to link to layer 1 (this generally controls who is able to transmit when).

#### 1.4.1.3 Layer 3 (Network Layer)

If there are nodes between the end points of an end-to-end connection, packets must be routed. In layer 3, the paths between origin and destination are established via the specified target addresses. This is easy if the corresponding path lists are available in the nodes. It becomes more complicated when the paths are to be optimized on the basis of various criteria such as cost, quality, load, and delay times if the path conditions change during a transmission, packets need to take different paths due to bandwidth considerations, or the packet size is unsuitable for certain paths. The task of layer 3 is by no means a trivial one, especially when there are various physical transmission media within the network with different transmission speeds. It is also necessary to ensure that congestion does not occur along the paths, which would cause the maximum delay times to be exceeded.

A differentiation is made between connectionless and connection-oriented services. In the case of a connectionless service (datagram service), there is no allocation of fixed channels; every transmitted package must include the complete address and is sent as an independent unit. With a connection-oriented service (virtual circuit service), a virtual channel is made available, which from the point of view of the user offers the advantage that the data packets need not include any addresses. One of the first protocols of this type to be implemented and which is still in use today is the X.25 (ISO 8473). For fieldbus systems, such virtual circuits (and therefore connection-oriented layer-3 services) do not play any practical role. In any case, layer 3 presents to its upper layer a valid path through the network for one individual data packet.

#### 1.4.1.4 Layer 4 (Transport Layer)

The transport layer sets up an end-to-end connection. This means that the receiver does not route the data further, but passes them on to layer 5, already prepared. There are various mechanisms available in layer 4. If the data to be transmitted are too big, layer 4 can split them up and transmit each piece individually. If the transmission times are long or there are a number of possible transmission paths, it is useful to number the split packets. The receiver station must then recombine the individual packets

in the right order. On layer 4, connection-oriented and connectionless protocols are available as well. The most popular examples are TCP for connection-oriented and User Datagram Protocol (UDP) for connectionless data transmission. They originated in the Internet world but are becoming increasingly important in the field-level networking domain.

#### 1.4.1.5 Layer 5 (Session Layer)

The main task of layer 5 is to bring together several end devices into a session and to synchronize the *conversation*. This also involves identification or authentication (e.g., password check) and the handling of very large messages. Close cooperation between this layer and the operating system is of vital significance. For this reason, layers 6 and 7 are implemented in fieldbus practice with high transparency for these particular layer-5 functions or a separate channel is created to bypass them. It is also the task of layer 5 to introduce any necessary synchronization markers, so that it knows when to resume after a breakdown in communication.

#### 1.4.1.6 Layer 6 (Presentation Layer)

The presentation layer interprets the incoming data and codes the data to be transmitted. This means that level 6 carries out syntactic and semantic tasks. These include, for example, the meaning of the sequence of bits of a character, to be interpreted as a letter, interpretation of currency as well as physical units, and cryptographic tasks. For encoding, ISO defined the standards Abstract Syntax Notation 1 or Basic Encoding Rules, which are frequently used.

#### 1.4.1.7 Layer 7 (Application Layer)

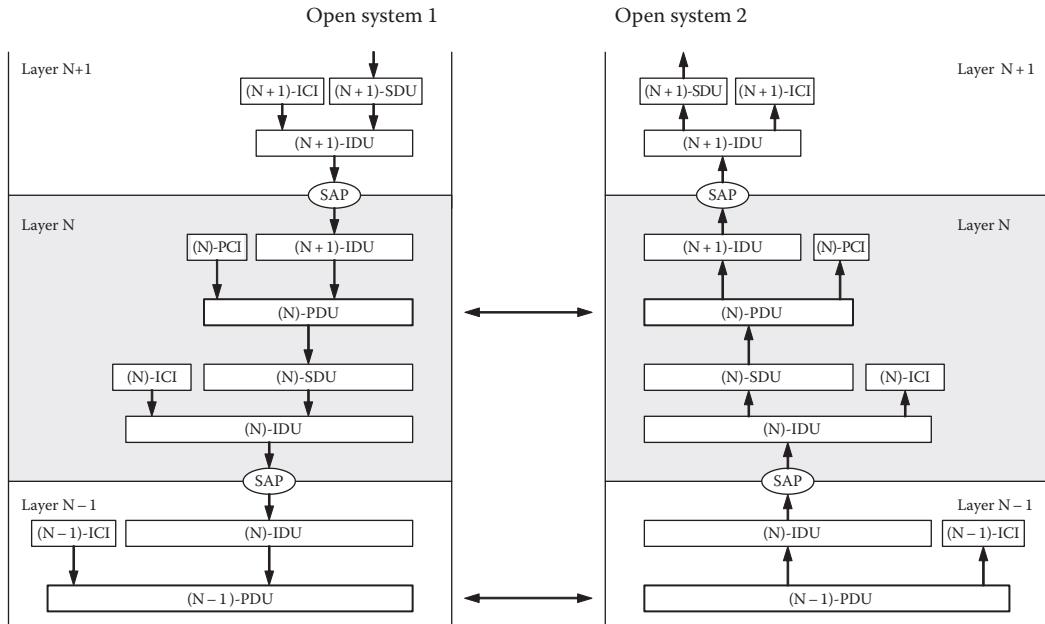

Layer 7 is a boundary layer (interface to the application) and with that occupies a special position. It forms the interface between the application and the communication unit. In this level, the procedures or protocol processes of various application functions are defined, for calling up data, file transfer, etc. The purpose of layer 7 is a transparent representation of the communication. If, for example, a system accesses databases via the communication unit, layer 7 must be designed so that it does not require any knowledge of the individual tasks of the underlying layers. With that, an efficient communications system allows a database that is distributed among various different locations to be viewed as a single interconnected database. An intelligent switch that transmits information via an OSI communication unit, such as *turn light on*, does not need to know anything about the actual communication protocol; it simply knows the *name* of the lights as well as the functions *turn light on*, *turn light off*, or *dim light by 40%*, etc.

Based on these definitions, it is possible to set up complex communication systems in a structured way. Moreover, the strictly hierarchical layout of the model allows interconnection of heterogeneous systems on different layers. Through the use of repeaters, one can overcome the limitations of a given physical layer. The interconnecting device shares a common data link layer. Bridges interconnect different networks by translating data and protocols on layer 3. Routers link networks on layer 4, whereas gateways (or more precisely, application layer gateways) interconnect entirely different communication systems on the application layer.

### 1.4.2 Communication Services

Figure 1.5 shows in greater detail how data are exchanged between service user and service provider or between two peer layers. The interface between two neighboring layers is called service access point (SAP). The vertical and horizontal communication is made up of two important units:

1. *Service Data Unit*, SDU. Communication of layer N + 1 with the underlying layer N occurs via its services, or more accurately via the interfaces of these services. For layer N, the transferred data represents pure user data that is passed on to the next lowest layer for further processing.

**FIGURE 1.5** Communication in the OSI model.

2. *Protocol Data Unit, PDU.* Communication between two peer layers is implemented via so-called protocol data units. These represent the core element of the rule set that can be understood and correctly interpreted only by the peer layers. A PDU consists of the transmitted user data supplemented with parameters of the interface (interface control information, ICI) and unique control information (protocol control information, PCI).

The exact procedure is highlighted in Figure 1.5. The user data of layer N that are to be transmitted to its peer layer are put into an SDU. The interface process of layer N adds an ICI to the message header (the SDU header), whereby the ICI and SDU together form the interface data unit (IDU). The IDU is then transferred via the SAP. In the underlying layer, the ICI is now decoded, and a corresponding process is initiated. The following process (execution of a protocol) should be viewed as a logic process, except in the lowest layer, the physical layer. In the procedure initiated by the ICI, layer N – 1 packs the SDU into a PDU. This involves adding a PCI to the SDU. The assembled PDU is now transmitted, which means that layer N – 1 in turn uses the lower layers and itself now behaves as a service user. Only layer 1 actually physically transmits the information.

In even more detail, the interaction between the individual layers is governed by a series of operations defined in the OSI model. These operations are called service primitives. There are basically four different service primitives: Request, req; indication, ind; confirmation, con; and response, res. Each service primitive that is called up by the service user is termed a request. With the request, layer N receives the order to execute a specific task. The respective task and corresponding data are converted into a corresponding PDU. In accordance with the OSI model, the service provider uses the services of the underlying layer N – 1, in order to carry out its task. This interaction continues until the lowest layer entrusts the data to the physical medium. On the receiver side, the peer layer is activated via an indication (or sometimes even a whole series of indications). After the remote layer N has decoded the PDU and extracted the control information, the user data are passed on to the above lying layer (i.e., the layer directly above or, in the case of the application layer, the actual user process) also by means of an indication. The way back from the receiver side is composed of responses generated by the service users and confirmations issued by the service providers. However, services need not always comprise

each of these four service primitives. There are many possible and practically used combinations with varying degrees of reliability, as the following examples show:

1. *Locally confirmed service.* A locally confirmed service (Figure 1.6) comprises a request, an indication, and a confirmation. In this case, layer N of the sender then receives a confirmation from local layer N – 1. Based on the parameters transmitted, the service provider can tell whether its underlying layer was able to accept and process the request accordingly. After a brief preprocessing, this local confirmation is also made known to the service user by means of a confirmation service primitive. As the name suggests, a locally confirmed service gives no guarantee that the remote user receives the information transmitted. The confirmation can be omitted at all, which leads to an unconfirmed service.
2. *Confirmed service.* This type of service also consists of a request, an indication, and a confirmation. With a confirmed service however, the peer layer generates an acknowledgment immediately after receiving the indication (Figure 1.7). The acknowledgment is returned to the sender via a service primitive of the remote layer N – 1 and signaled to the service provider via an indication of local layer N – 1. Note that contrary to the procedure outlined in point 1, the transmitted parameters and data come from the partner side. From the indication, layer N can conclude whether or not the service requested by layer N – 1 was executed without error. If necessary (i.e., if errors have occurred), this service is used again. This depends on the protocol used in layer N. In all cases,

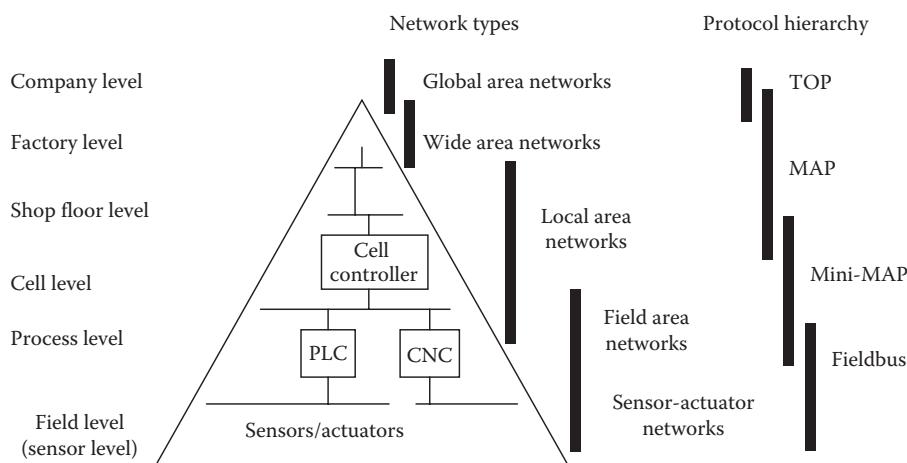

FIGURE 1.6 Locally confirmed service.

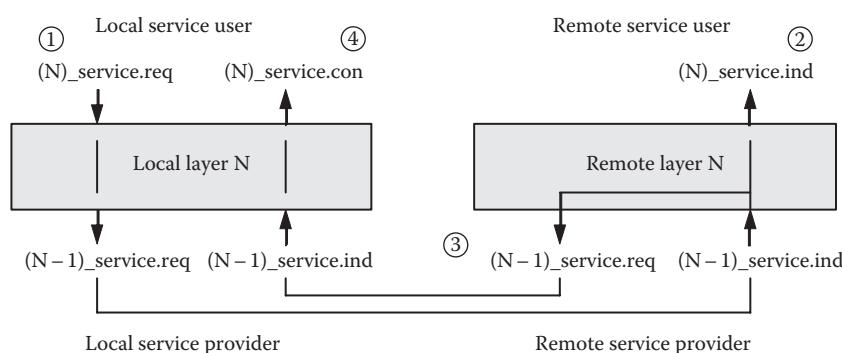

FIGURE 1.7 Confirmed service.

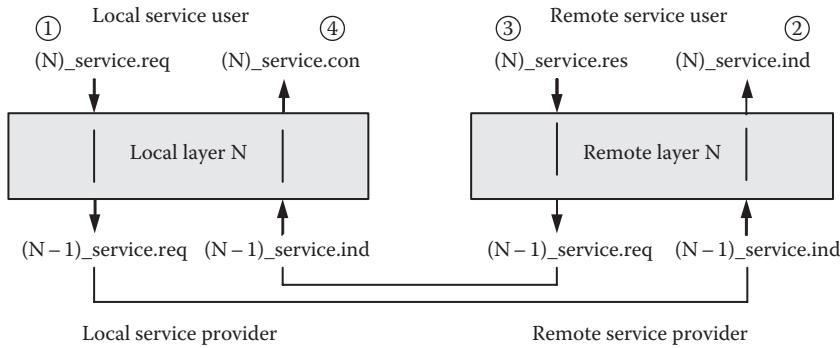

FIGURE 1.8 Answered service.

the service user is informed of the output with a suitable confirmation (positive or negative). From this confirmation, it is possible to derive whether or not the originally requested service has been satisfactorily fulfilled by layer N.

3. *Answered service.* This represents the fully fledged use case of all service primitives (Figure 1.8). Here, after an indication on the partner side, a response is generated by the remote service user. The response is transmitted via a service primitive of layer N – 1 and passed on to the service user from which the original service request came as a confirmation. This mechanism permits data traffic in both directions. Contrary to the other two services, an answered service always consists of request, indication, response, and confirmation.

*In short:* Request and response are always called up by the service user; the resulting confirmation and indication originate from the corresponding layer. The interaction between the individual layers is best understood if one imagines that the layers lying on top of one another are primarily inactive. The service provider is *awoken* only after a request from the service user. In order to perform this service, it in turn activates the underlying layer by calling up the appropriate service primitive. This interaction continues down to the lowest layer, which then accesses the transmission medium. On the remote side, the indication of a low-lying layer informs the layer lying directly above that a service is to be executed. This indication is then processed in accordance with the service type—it causes either a confirmation or a response.

## 1.5 Fieldbus Characteristics

The application areas of fieldbus systems are manifold; hence, many different solutions have been developed in the past. Nevertheless, there is one characteristic and common starting point for all those efforts. Just like today's embedded system networks, fieldbus systems were always designed for efficiency, with two main aspects:

1. Efficiency concerning data transfer, meaning that messages are rather short according to the limited size of process data that must be transmitted at a time.
2. Efficiency concerning protocol design and implementation, in the sense that typical field devices do not provide ample computing resources.

These two aspects, together with characteristic application requirements in the individual areas with respect to real-time, topology, and economical constraints, have led to the development of concepts that still are very peculiar of fieldbus systems and present fundamental differences to LANs. In the previous section, the general differences in the context of the OSI model were already sketched. This section will discuss some more peculiarities in greater detail.

### 1.5.1 Traffic Characteristics and Requirements

The primary function of a fieldbus is to link sensors, actuators, and control units that are used to control a technical process. Therefore, the consideration of the typical traffic patterns to be expected in a given application domain was in most cases the starting point for the development of a new fieldbus. Indeed, the characteristic properties of the various data types inside a fieldbus system differ strongly according to the processes that must be automated. Application areas like manufacturing, process, and building automation pose different *timing* and *consistency* requirements that are not even invariant and consistent within the application areas [16].

As regards timing, there are two essential philosophies to look at the technical process in a black-box form and describe (and thus convey within the network) its behavior. One is a state-based approach focusing on the status of the process defined by its internal state variables together with its inputs and outputs. These variables are continuously sampled and transmitted in discrete-time fashion and form the basis for continuous process control and monitoring (like temperature, pressure, etc.).

The other philosophy is an event-based one, that is, data are transmitted only in case of state changes. This approach is well suited for processes or subprocesses that have a somewhat discrete nature and can be modeled as a state machine. Switches obviously lend themselves to such an interpretation. But also in continuous processes, it may be reasonable to transmit process data only if they exceed certain pre-defined limits. This naturally requires the implementation of control functions locally in the network nodes rather than in a remote control unit.

As far as consistency is concerned, there are on the one hand process data that are continuously updated and on the other hand parameterization data that are transferred only upon demand. In case of error, the former can easily be reconstructed from historical data via interpolation (or simply be updated by new measurements). The system-wide consistency of configuration data, on the other hand, is an important requirement that cannot be met by mechanisms suitable for process data.

Trying to find an abstract and comprehensive classification scheme for all possible fieldbus traffic patterns, we arrive at the traffic types shown in Figure 1.9 and are described in the following text.

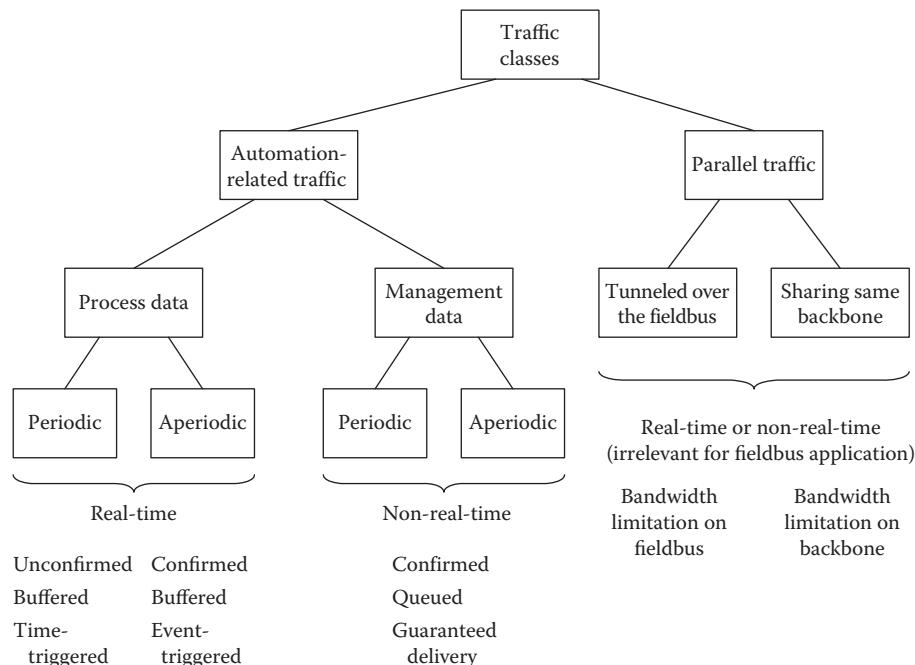

FIGURE 1.9 Traffic classes and typical properties.

In theory, data traffic generation is exclusively a question of the application process and should be seen independently of the underlying communication system. In practice, however, the communication protocol and the services provided therein heavily influence the possible traffic types—it is one of the peculiarities of fieldbus systems that the two cannot be properly disentangled.

### 1.5.1.1 Process Data

This type is sometimes also called *cyclic* or *identified* traffic because the communication relations must be known once the application is specified. Depending on the characteristics of the process, such data can be periodic or aperiodic. Periodic traffic mostly relates to the state of a process and is typically handled by some sort of time-slot-based communication strategy, where each variable is assigned a dedicated share of the network bandwidth based on the a priori known sampling time or generation rate of the data source. The frequency or data update rate may also be adaptive, so as to dynamically change according to the current state of the process (e.g., alarm conditions may require a more frequent sampling of a state variable).

*Aperiodic, acyclic, or spontaneous* traffic is generated on demand in an event-based manner and transmitted according to the availability of free communication bandwidth. If the predominating data transfer scheme is time slot based, there may be spare slots or some idle time in the periodic traffic explicitly reserved for this purpose.

From an application point of view, process data typically are real-time data and require timely delivery. For both periodic and aperiodic data, this means that they should be transmitted (and received) within a limited time window to be meaningful for the purpose of process control. For aperiodic data, there is the additional restriction that the service ought to be reliable, that is, data loss should not occur or at least be detected by some appropriate mechanism.

### 1.5.1.2 Management Data

This type is also called *parameterization* or *configuration* data and generally refers to all data that are needed to set up and adjust the operation of the automation system as such. Settings of distributed application processes (such as control functions localized in the network nodes), communication and network parameters, and more general all network management data belong to this class. Management data typically are aperiodic as they occur infrequently depending on the state of the complete system. Traditionally, they are therefore often transmitted in some dedicated parameter channels that use a small amount of communication bandwidth left over by the (mostly periodic) process data.

In some cases, management data may also be needed periodically or quasi-periodically, for example, to update session information after a certain time, to exchange authentication information after a given number of messages, or to change communication parameters on a routine basis. Nevertheless, the communication mechanisms for such periodic management messages likely do not differ from the aperiodic ones; they are simply invoked on a periodic basis.

Contrary to process data, management data are mostly not real-time data, which means that timely delivery is not that important. What is more important, however, is guaranteed and correct delivery, which influences the communication services that are used for this type of data. Confirmed services are mandatory.

### 1.5.1.3 Parallel Traffic

This traffic type does not belong to the applications processes concerned with the actual control of the technical process. Rather, it is generated by independent parallel processes and shares the communication medium. In traditional fieldbus systems, which were closed environments, this type of traffic did not exist. With growing interconnection of automation networks, however, it becomes relevant, either because external traffic (such as IP traffic) may be routed or tunneled through the fieldbus or because fieldbus traffic may be routed through a shared backbone network [33,34]. In particular, this is an issue for industrial Ethernet solutions, which in general foresee some sort of general-purpose IP channel for devices not belonging to the automation system.

From the viewpoint of the automation process, care must be taken that the fieldbus traffic is not negatively influenced. This needs to be done by appropriate quality-of-service arrangements that guarantee reasonable bandwidth and latency to the fieldbus application traffic in case a shared backbone is used. In the other case, the fieldbus network management must ensure that the parallel traffic cannot consume an arbitrary amount of communication resources or block other processes.

#### 1.5.1.4 Implications for the Fieldbus

The various traffic types have also implications for the way communication in fieldbus systems is handled, both from a protocol and from an implementation point of view. Data that are exchanged on a cyclic basis are usually sent via connectionless services. The reason behind this is that for periodically updated process data, it makes no sense to require a confirmation. If a message containing process data gets lost, resending it is not sensible because by the time the data might arrive at the receiver, they are outdated, anyway, and new data might already be available. With respect to practical implementation, the handling of such data, especially at the receiver side, is mostly implemented by means of buffers. In these buffers, the latest data always overwrite older values, even when they are basically implemented in a first in, first out (FIFO) structure. In this case, the *FIFO full* signal is suppressed, so that always the most recent values are in the buffer.

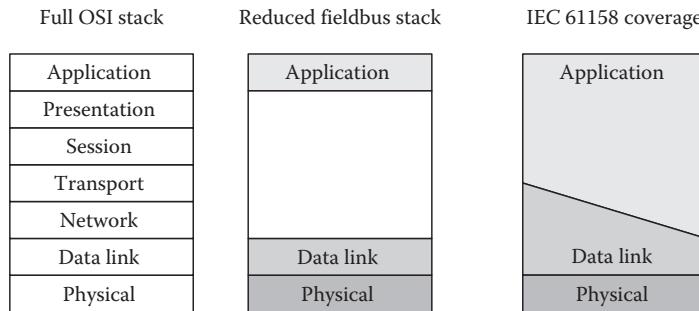

On the contrary, acyclic data need special precautions, irrespective of whether they are related to process variables or management data. Loss of such data is not desirable and might be detrimental to the overall application (e.g., if alarm events are not received). Hence, mechanisms involving some sort of acknowledgment must be used to allow for retransmissions in case of data loss. These mechanisms can be implemented on the lower communication layers or the application level, depending on the basic communication services a fieldbus offers. In terms of actual implementation, such messages are typically handled in queues. As opposed to buffers, messages are not overwritten. If the queue is full, no new messages are accepted until earlier entries have been consumed and deleted. This ensures that no messages are lost before they are processed by the node.

Stimulated by the different ways of looking at and handling data exchange in fieldbus systems (and embedded systems in general), two opposing paradigms have been established in the past and have ignited a long, partly fierce debate: the *time-triggered* and the *event-triggered* paradigm [140]. The time-triggered approach is specifically suited for periodic real-time data, and many fieldbus systems actually use it in one form or another. The event-triggered approach was designed following the idea that only changes in process variables are relevant for transmission. An additional aspect behind it was that such events should be broadcast in the network, so that every node potentially interested in the data can receive them. This makes extension of the network fairly easy by just adding new nodes if the message identifiers they need for their application are known.

#### 1.5.2 Fieldbus Systems and the OSI Model

Like all modern communication systems, fieldbus protocols are essentially modeled according to the ISO/OSI model. However, in most cases, only layers 1, 2, and 7 are actually used [14]. This is in fact a tribute to the lessons learned from the MAP failure, where it was found that a full seven-layer stack requires far too many resources and does not permit an efficient implementation. For this reason, the MiniMAP approach and based on it the IEC fieldbus standard explicitly prescribe a three-layer structure consisting of physical, data link, and application layer. But what about the other layers and the functions defined therein?

The reduced and simplified protocol stack reflects the actual situation found in many automation applications pretty well, anyway. Many fieldbuses are single-segment networks with limited size, and extensions are realized via repeaters or, at most, bridges. Therefore, network and transport layer—which contain routing functionality and end-to-end control—are simply not necessary. The same applies to the upper layers. Originally, fieldbus systems were not meant to be very sophisticated. Fully implemented

**FIGURE 1.10** Layer structure of a typical fieldbus protocol stack as defined by the IEC 61158.

session and presentation layers are therefore not needed, either. Still, certain functions from the layers 3 to 6 might be needed in reduced form. Rudimentary networking aspects could be required or specific coding rules for messages that are better suited for the limited resources available in typical fieldbus nodes. In such cases, these functions are frequently included in the layer 2 or 7. For the IEC 61158 fieldbus standard [1], the rule is that layer 3 and 4 functions can be placed either in layer 2 or layer 7, whereas layer 5 and 6 functionalities are always covered in layer 7 (Figure 1.10).

It would nevertheless be deceptive to think that all fieldbus systems just consist of a physical, data link, and application layer. There are several examples where other layers were explicitly defined. Particularly in the building automation domain, the situation is different. Owing to the possibly high number of nodes, these fieldbus systems must offer the capability of hierarchically structured network topologies, and a reduction to three layers is not sensible. For instance, European Installation Bus (EIB) and KNX use also the network and transport layers to implement routing through the hierarchical network as well as connection-oriented and connectionless end-to-end communication functions. BACnet uses the network layer as well, which is especially important as BACnet was devised as higher-layer protocol to operate on different lower-layer protocols and links such as Ethernet, MS/TP (master-slave/token passing as inexpensive data-link layer protocol based on the RS 485 standard for the physical layer), and LonTalk. For such a heterogeneous approach, a uniform network layer is essential.

The probably most elaborate protocol structure in the fieldbus world is exhibited by LonWorks. Even though it is today chiefly used in building automation, it was in fact designed as a general-purpose control network (LON stands for local operating network) without any particular application area in mind; hence, it resembles much more a LAN than a conventional highly efficient fieldbus. In the LonTalk protocol, all seven OSI layers are defined, even though layer 6 is rather thin in terms of functionality. Specific characteristics are a rich layer 3 that supports a variety of different addressing schemes and advanced routing capabilities, the support of many different physical layers (a common aspect in all building automation networks), and a large number of various communication objects not just for process data exchange and network management, but also for advanced functions like file transfer.

Among the fieldbus systems mainly used in industrial and process automation, ControlNet and P-NET are particular in that they implement also layers 3 and 4. An outstanding characteristic of P-NET is its capacity for multinetwork structures, where the so-called multiport masters can link multiple segments to any arbitrary structure. Layer 3 provides a source routing mechanism (where the path through the network must be defined inside the packet) to manage transmission even in meshed networks. Layer 4 is called service layer and actually contains definitions and processing rules for communication objects that go beyond the usual end-to-end functionality of the OSI transport layer.

An essential part of fieldbus protocol stacks are comprehensive application layers. They are indispensable for open systems and form the basis for interoperability. Powerful application layers offering abstract functionalities to the actual applications, however, require a substantial software implementation effort that can negatively impact the protocol processing time and also the costs for a fieldbus interface. This is why in some cases (like Interbus, PROFIBUS-DP/PA, or CAN), an application layer was

originally omitted. While the application areas were often regarded as limited in the beginning, market pressure and the desire for flexibility finally enforced the addition of higher-layer protocols, and the growing performance of controller hardware facilitated their implementation. CAN is a good example for this because a plethora of protocols (like CANopen, SDS, and DeviceNet) appeared in the course of time on the basis of the original CAN layers 1 and 2.

A further vital aspect of any network is an appropriate network management. This includes tasks like incorporating new end devices into an existing network and combining them with other end devices to form functional units. In addition, a modern network management also offers mechanisms for the analysis and diagnosis of systems that are already up and running. Network management was not foreseen in the original OSI model; rather it was put into a dedicated OSI Network Management Framework. It is to be understood as existing in parallel to the OSI layers as it affects all of them:

*Physical and datalink layers.* All end devices must, for example, have the same channel configuration.

This involves certain parameters that determine transmission on the underlying medium. In this connection, the applicable bit rate is of particular interest. Network management also concerns the repeaters operating on layer 1 and bridges (implemented in layer 2), because they can also be used to link subnetworks with different channel configurations.

*Network layer.* Every end device or group of end devices must be provided with a unique address.

With the help of intelligent routers, it is possible to form subnetworks and with that reduce the network load. These devices too can be contacted and then configured by the commands made available through the network management (such as loading of new routing tables).

*Transport and session layers.* These layers are mainly responsible for the service quality that is offered by the underlying network. Corresponding configuration possibilities, which can be carried out with the network management, are therefore closely linked to the term *quality*.

*Presentation layer.* Common syntax is a basic prerequisite for interoperability. Network management must inform two communicating end devices of the syntax of the matching data types.

*Application layer.* Here, network management is concerned with the carrying out of tasks that relate to applications. It should be possible not only to load applications and define their specific configurations but also to load and modify tables describing the communication relationships of applications.

Inside fieldbus protocols, network management is traditionally not very highly developed. This stems from the fact that a fieldbus normally is not designed for the setup of large, complex networks. There are again exceptions, especially in building automation, which consequently need to provide more elaborated functions for the setup and maintenance of the network. In most cases, however, the flexibility and functionality of network management are adapted to the functionality and application area of the individual fieldbus. There are systems with comparatively simple (ASi, Interbus, P-NET, and J1939) and rather complex management functions (WorldFIP, CANopen, LonWorks, KNX, and BACnet). The latter systems are typically more flexible in their application range but need more efforts for configuration and commissioning. In any case, network management functions are normally not explicitly present (in parallel to the protocol stack as suggested by the OSI model), but rather directly included in the protocol layers (mostly the application layer).

### 1.5.3 Network Topologies

One important property of a fieldbus is its topology. Developers of fieldbus systems have been very creative in the selection and definition of the best suited physical layout of the network. Again, this selection was typically influenced by the target application area as well as by the available interface technologies that are used to build the fieldbus. Figure 1.11 shows the most relevant topologies for wired automation networks. It should be noted that the physical layer of a fieldbus has to meet quite demanding requirements like robustness, immunity to electromagnetic disturbances, intrinsic safety

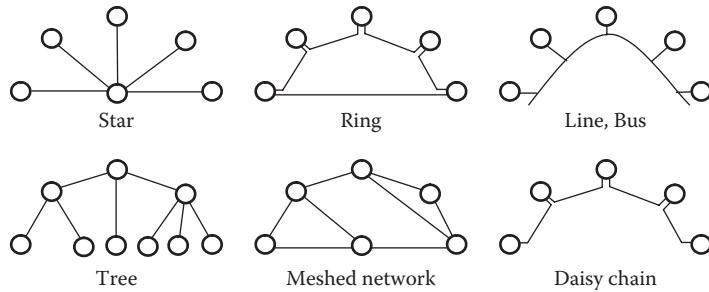

FIGURE 1.11 Topological network structures typically used in fieldbus systems.

for hazardous areas, or costs. The significance of the physical layer is underpinned by the fact that this area was the first that reached (notably undisputed) consensus in standardization.

The *star* topology was the typical wiring in automation before the introduction of the fieldbus. The PLC was the center, attached to the distributed I/O elements with dedicated lines. The obvious cabling overhead was one of the main reasons to develop serial bus systems. With the adoption of switched Ethernet also for automation purposes, the star topology returned. Today, the central element is the Ethernet switch, and all Ethernet nodes are connected by means of a structured cabling, that is, a dedicated link to each network node. Another application of the star topology is for fieldbus systems using optical fibers as transmission medium. Here, the center is an active star coupler linking the fibers (as in byteflight). Unless the coupler is a fully fledged node (i.e., addressable by the fieldbus protocol), this star topology is logically equivalent to a line structure.

Another simple topological form is the *ring*. Here, each node has two network interfaces (an input and a separate, independent output), and the nodes are arranged one after another in the form of a chain. In its entirety, the ring can be viewed as one large shift register, and it is usually also operated in this way (the most prominent example is INTERBUS). As there is no need to address the nodes explicitly, it is a very fast method to exchange data and also a very deterministic one with low jitter (this is why SERCOS uses this topology for the interconnection of drives). A variant of the ring topology, actually a daisy-chain structure, was introduced with industrial Ethernet. Here, each node contains a small switch, and the nodes are not connected in a star topology, but cascaded like a string of pearls. This layout is used, for example, in PROFINET.

The *line*, often referred to simply as *bus* (although this term is not unique), is the most successful and most commonly used network topology in the fieldbus world. It was the logical and most efficient replacement for the former star-like point-to-point cabling in that one single line should connect all network nodes (just as in the original concepts of Ethernet with the famous yellow cable and other types of coax cables). In many cases, the line topology is based on the RS 485 interface. This is an inexpensive, fully differential, multipoint interface standard using a shielded twisted pair cable with 120 Ohm characteristic impedance. Maximum cable length is 1200 m, and the maximum achievable data rate is 10 Mbit/s. The maximum number of nodes per segment depends on the electrical characteristics of the driver circuits and was originally limited to 32 (termed unit loads). Enhanced transceivers with higher input impedance meanwhile allow up to 256 nodes per segment. Beyond this, repeaters are necessary to regenerate the data signals. Some fieldbus systems (like CAN and all CAN-based systems) use RS 485 transceivers in a modified way (i.e., by essentially applying the data signal not to the actual data input but the output enable used to switch the output to a high-impedance state) to generate asymmetric bit patterns supporting a special form of medium access. A crucial aspect in practice is the proper electrical termination of the bus line in order to avoid signal reflections disturbing the data transfer. Wrong or missing termination is the most frequent problem leading to communication failures. A variant of the line topology used for P-NET therefore requires that the ends of the cable be connected, so as to form a closed loop. Nevertheless, electrically, this structure is still a bus.

The *tree structure* is a composite network structure and characterized by one or more substations being dependent on a root node. Each substation can in turn be a root node for a lower-level segment. In many cases, the actual connections between the stations are regular point-to-point connections or lines. In automation technology, tree structures are the usual way to build hierarchical, relatively complex networks. The root nodes usually have routing capabilities, so that the data traffic can at least partly be confined to individual areas of the network. This however requires caution in the planning phase of the network when defining communication relations between end nodes. Nodes exchanging lots of information should be kept in common subnets to avoid congestion on the backbone links. Tree structures are very common in building automation networks like EIB, LonWorks, or BACnet.

Some fieldbus systems permit *free topologies* where nodes can be connected in a multipoint fashion without restrictions. Essentially, this is a variant of the line topology because the nodes are electrically interconnected. Contrary to the standard line topology, however, there are no stringent limitations concerning line length, the length of stubs, or branches that would cause severe signal degradation. This makes cabling very convenient for the installer, but poses a substantial challenge for the signal processing in the nodes and their transceivers. Fieldbus systems using such free topologies are, for example, LonWorks (where the free topology transceiver is the most widely used because of its robustness even in cases where conventional RS 485 transceivers would be sufficient) or ASi, which was designed for utmost simplicity and ease of handling in harsh industrial environments.

*Mesh* networks, where multiple paths through the network exist, play only a subordinate role in fieldbus systems because they require appropriate routing strategies to keep messages from circling in the network and causing congestion. LonWorks and P-NET offer the possibility for building meshes.

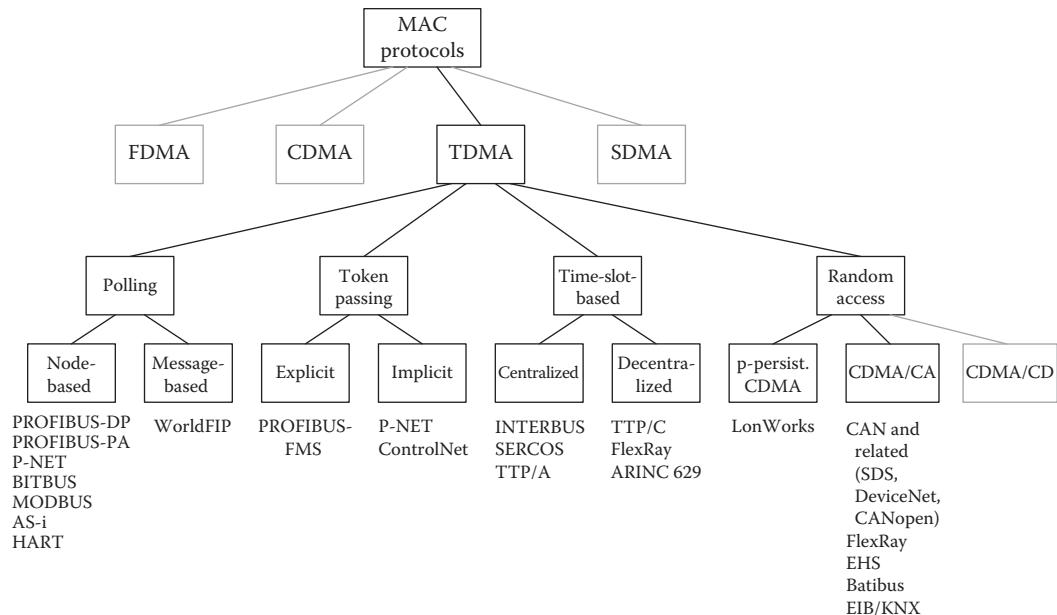

The general topology used by the fieldbus also influences the way access to the medium is being handled. As a matter of fact, topologies were often selected according to the desired MAC method, or vice versa.

#### 1.5.4 Medium Access Control

Fieldbus designers have been very creative in what concerns allocation of the available communication bandwidth to the individual nodes. On the data link layer, virtually all medium access principles also known from LANs are used, plus many different subtypes, refinements, and hybrid solutions (Figure 1.12). This has to be understood against the backdrop of desired efficiency. Resources in terms of both computing power in the nodes and available data rate and thus bandwidth in the network were very limited at the time most fieldbus systems were invented. Hence, developers wanted to get the most out of what was at hand, and they found that a straightforward application of the medium access strategies used in computer networks were not efficient enough. So, they started designing new, more efficient methods tailored to individual application areas and optimized for the particular type of traffic and communication models they had in mind. In fact, the efficiency or overhead in the sense of how many bits must be transmitted over the network to convey a given amount of user data was a very common parameter to compare (and market) fieldbus systems—even though the significance of such a parameter alone was and is more than questionable.

An important classification for the way the data transfer is controlled is the distinction between single- and multimaster systems. The single-master (or master-slave) approach reflects the tradition of centralized, PLC-based automation systems and is typically used for fieldbus systems in the lowest levels of the automation pyramid where the roles of the nodes in the network can be clearly distributed. Such networks typically have a limited size and a simple, mostly single-segment structure. The master either retrieves data from the slaves in direct request-response communication or explicitly synchronizes time slots that are then used by the slaves to send their data.

The alternative strategy is the multimaster approach, where all nodes are basically equal and must share the communication medium in a democratic and fair way. Such networks can have more complex structures, including hierarchical ones with large numbers of nodes, and are found mostly on

**FIGURE 1.12** Medium access control strategies in fieldbus systems and examples.

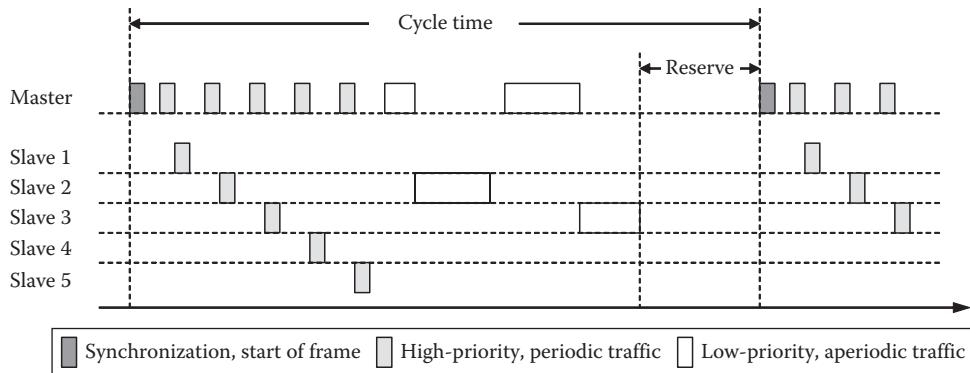

the middle level of the automation pyramid (the cell level) and in building automation. Historically, multimaster fieldbus systems originated from the wish to have truly distributed systems for process control, and in many cases, such fieldbus systems were more than pure communication networks—they were embedded in comprehensive operating-system-like software frameworks.

As far as the actual MAC strategies are concerned, all fieldbus systems use a time division multiple access (TDMA) strategy in the sense that the bandwidth is shared in the time domain, that is, the network nodes use the communication line sequentially. Other multiplexing methods known in particular from telecommunications, such as frequency division multiple access, code division multiple access, or space division multiple access, play no or only subordinate roles in the fieldbus world. More precisely, medium access is managed either in a centralized fashion by polling or time-slot-based techniques, or it is done in a decentralized way by TP or random access methods. Within these basic methods, which will be briefly reviewed later, various variants and blends are in use.

#### 1.5.4.1 Polling

Polling is a master–slave access scheme and foresees that a slave node is allowed to send data only when explicitly told so by a central master (sometimes also called arbiter or arbitrator). On the network, there is a constant alternation between poll messages from the master to each slave and response messages from the slaves back. In its purest form, polling is strictly cyclic, which means that the master polls the entire list of slaves one by one and then restarts the cycle. The polling rate might be adapted (in theory even dynamically) if individual nodes have more data to transmit than others [35], but this is rarely done in practice.

Evidently, polling is perfectly suited for periodic traffic where all process variables need equidistant sampling (Figure 1.13). Since the traffic is strictly controlled by one node, the cycle time can be kept constant provided that slaves implement antijammer mechanisms so that they cannot block the medium in the case of failure. Likewise, jitter can be kept low. Simple polling is employed in typical sensor–actuator bus systems like AS-i, HART, MODBUS, or lower-level fieldbus systems like BITBUS, PROFIBUS-DP, and PROFIBUS-PA. Polling can also be used as an underlying bus access mechanism in a multimaster system, such that the permission to access the slaves is rotated between several master nodes. This strategy is used, for example, by PROFIBUS-FMS or P-NET.

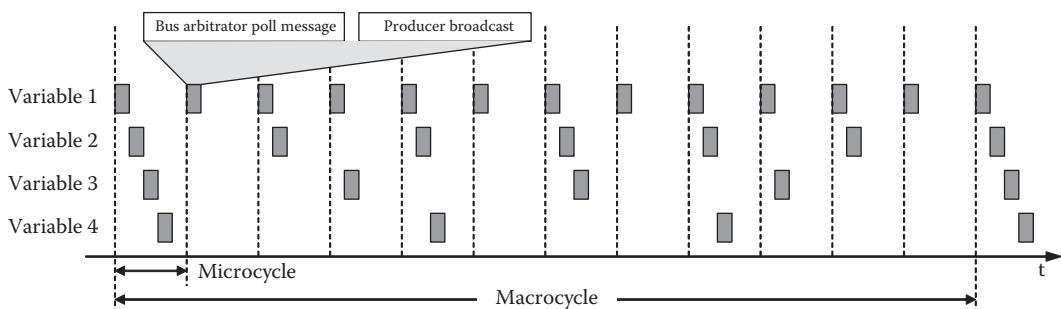

**FIGURE 1.13** Bus cycle with cyclic polling and room for aperiodic traffic (PROFIBUS-DP V2).

A distinction between different flavors of polling can be made depending on the way data are addressed. The classical master–slave polling in the examples listed earlier uses explicit node addressing, that is, the communication approach is device-centric. Another possibility is to identify the desired data by name, meaning that the request from the master concerns not a device, but a certain process variable. This is an approach employed by the producer/consumer model in WorldFIP, where the bus arbitrator polls a variable and the node generating (*producing*) it then sends it onto the network, or in LIN, where the master retrieves data from the slaves by polling the message identifiers. The link active scheduler in Foundation Fieldbus performs a similar function by prompting devices to send their scheduled data to the consumers. This polling variant is sometimes called central polling. From the network traffic point of view, the two approaches are equal; each consists of a request–response pair of messages per variable exchange.

A peculiarity of the bus arbitration in WorldFIP, however, is that the polling mechanism accounts for different periodicity requirements of the individual variables. To this end, the polling cycle (here called macrocycle) is compiled at configuration time from several elementary cycles or microcycles in a static schedule to ensure that each variable will be sampled as often as needed under the constraint that the total data rate originating from this scheduled traffic is at any given time lower than the maximum data rate of the bus. The number of elementary cycles a macrocycle must have is essentially defined by the least common multiple of the periodicities divided by the highest common denominator of the periodicities (Figure 1.14).

In strict polling, there is no room for aperiodic traffic, which is a severe drawback for fieldbus systems designed to be more than simple sensor–actuator buses. Therefore, most fieldbus systems foresee some possibility for the master to handle sporadic data exchange for configuration data or process variables that require transfer only on an event basis. The important constraint is that this type of traffic must

**FIGURE 1.14** Bus cycle in WorldFIP.

not interfere with the periodic one. In practice, this is done by reserving some bandwidth in addition to the scheduled periodic messages for a priori unknown aperiodic data transfer. PROFIBUS-DP/PA and many Ethernet-based automation networks (such as PROFINET) use a dedicated portion of the bus cycle after the periodic traffic for aperiodic traffic. In order to keep the cycle period constant, there is usually some spare time after this window to account for possible retransmissions of messages. In WorldFIP, aperiodic traffic can be scheduled in the empty slots of the elementary cycles, so that the macrocycle need not be extended.

Another disadvantage of polling is that slaves cannot become active by themselves. If all of a sudden, a slave—for instance, in the event of an alarm condition—needs to transmit additional data, it first has to signal this alarm condition to the master to initiate an aperiodic request. In most cases (like in WorldFIP), the slaves have the possibility to set a flag in the ordinary cyclic data exchange messages to indicate the need for additional service (in the old CAMAC system, this flag had the descriptive name *look at me*). The master then typically starts a handshake procedure to retrieve these data, possibly by first requesting information about their amount so as to allocate an appropriate time slot for the transfer (also with respect to other pending requests). This basic mechanism can be further extended to allow a communication among slaves. Again, two possibilities exist: The first is to handle it indirectly via the master, which gets the message from the sending slave and forwards it to the addressee (as done in the Measurement Bus). This permits the master to maintain full control over the bus. The alternative is that the master delegates the bus access to the slave for a while until the slave has sent all its data and returns the access right to the master (as in WorldFIP, Foundation Fieldbus, or PROFIBUS-DP-V2). In this case, the master has to implement some timeout mechanism to ensure that the procedure is properly terminated.

#### 1.5.4.2 Token Passing

One way to coordinate medium access between several peer stations in a network is TP. In this method, the right to control the network is represented by a special piece of information called token, which is passed on from node to node. Only a node possessing this token may initiate data transfer. A set of rules ensures that the token is passed in a fair manner and that errors such as lost tokens or duplicate tokens are detected and resolved. Compared with time-slot mechanisms, TP has the advantage that if a node has no data to send, it will hand over the token to the next station immediately, which saves time. Essentially, there are two ways of implementing the token: either explicitly by means of a dedicated short message or implicitly by distributed, synchronized access counters (ACs) in all nodes. TP is often combined with an underlying master-slave mechanism to control a subset of nodes.

The explicit form of TP is employed by PROFIBUS, both FMS and DP/PA (Figure 1.15). Even though PROFIBUS-DP in its basic variant is a single-master system, several DP networks may coexist on the

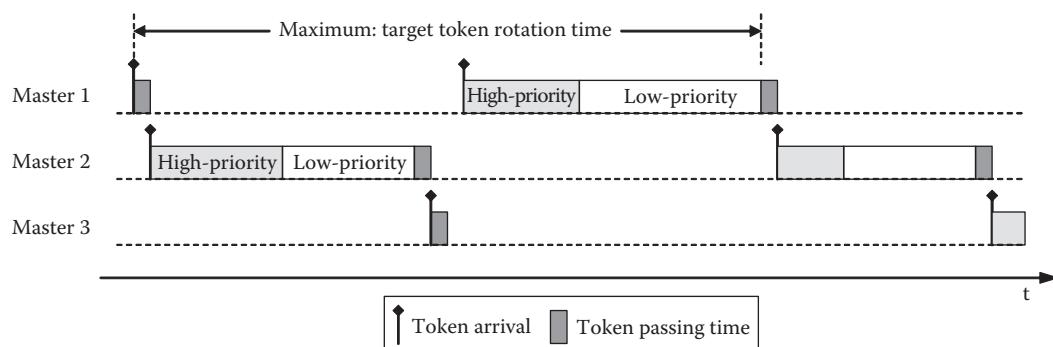

FIGURE 1.15 Token passing in PROFIBUS.

same bus. A crucial point here is the correct setting of a timing parameter called target token rotation time  $T_{TR}$ . This parameter indirectly determines how long a master may occupy the bus. When a master receives the token, it starts a timer to measure the real token rotation time. When it receives the token the next time, it is allowed to exchange messages with other masters and slaves only while the timer has not reached the  $T_{TR}$ . As soon as this happens, the token must be handed over to the next master in the list. If a master receives the token after the timer is expired, it may send just one high-priority message before having to pass on the token again. The time available for each master therefore also depends on the amount of time all the other masters in the network hold the token, and it might vary from round to round if aperiodic data have to be sent or retransmissions of individual frames are necessary. Periodicity of individual process variables is therefore less exact as with polling, and jitter may be larger. Still, the total time of a token rotation cycle can be upper bounded so as to support real-time requirements. In any case, careful selection of the  $T_{TR}$  value must be done based on an a priori analysis of the expected network traffic and is essential to ensure optimal use of the available communication bandwidth.

The implicit form of TP is used by P-NET. This fieldbus uses a hybrid approach together with polling. In order to keep the overhead of the volume of information that needs to be transferred on the bus to the absolute minimum, the token is simulated by two counters, included in every master, and is not actually passed around the bus (Figure 1.16). The *Idle Bus Bit Period Counter* (IC) is incremented every bit period as long as the bus is free and is reset as soon as some node sends data. The AC is incremented whenever the IC reaches the values 40, 50, 60 ... 360. If the AC status matches the address of a master, this means that the master has the token and is therefore able to access the bus for one single request-response data exchange with some other node. To ensure that the token is not passed on, there are maximum values for the time a master can wait before sending a request to a slave and also for the time a slave may take until it starts its response. If the master has no data to send, it remains silent, and after a further 10 increments, the token is handed over. Once the AC reaches the number of masters contained within the bus system, up to a maximum of 32, it is reset to the value 1. To avoid loss of synchronization due to the freely running system clocks in the nodes during long idle periods, a master has to send at least a synchronization message if the IC value reaches 360. Since the data exchange per master is strictly limited, the token rotation time is upper bounded, even though it is likely not constant.

A similar implicit method is employed by ControlNet. A node possessing the token may transmit one single data frame possibly containing several link layer packets. All nodes monitor the source address of this frame, and at the end of the frame, increment this address in an internal implicit token register. If the value of this register matches the address of a node, it possesses the token and may send its own data. If there are no data to be sent, the node must send an empty frame so that the token can be passed on. This mechanism is used both for scheduled and for unscheduled traffic with two different tokens.

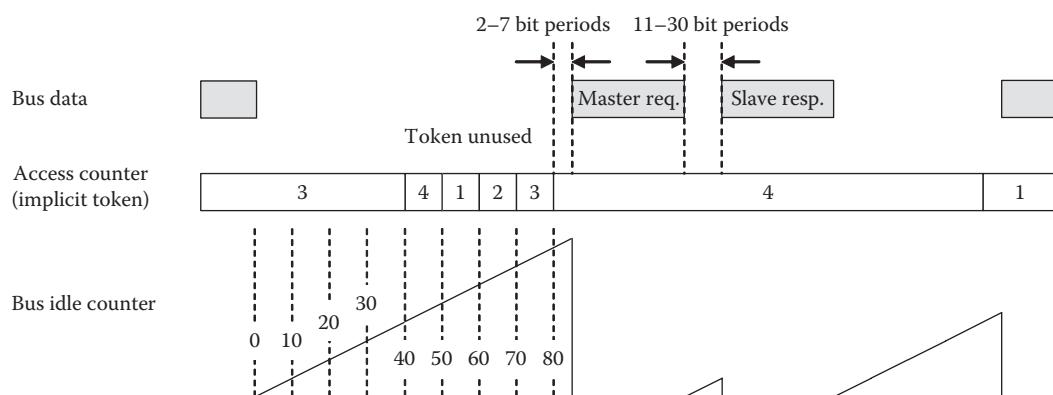

FIGURE 1.16 P-NET polling mechanism.

While every node with scheduled traffic will have a guaranteed bus access every network cycle, the access right for unscheduled traffic changes in a round-robin fashion, that is, the first node to get bus access for unscheduled traffic is rotated every cycle.

#### 1.5.4.3 Time-Slot-Based Access

In time-slot-based methods, the available transmission time on the medium is divided into distinct slots that are assigned to the individual nodes. During its time slot, a node may then access the medium. The difference to cyclic polling strategies—which in fact also come down to partitioning the polling cycle into time windows—is that the nodes are not requested by a central station to send their data; they can do it by themselves. Therefore, time-slot-based methods are mostly also called TDMA (in a narrower sense). The slots need not have the same size; they may be different. Likewise, they may be dynamically distributed to the nodes according to the amount of data they wish to send. This way, aperiodic traffic can be incorporated, whereas TDMA in general favors periodic traffic. A strictly equal distribution of the slots is also called synchronous TDMA and is particularly known from telecommunications technology, where each end device is assigned a time window in which, for example, the correspondingly digitized voice data can be transmitted. There, such systems are referred to as *synchronous bus systems*. The case where time slots are dynamically distributed is called asynchronous TDMA. Contrary to the synchronous version where the position of the time slot within the cycle implicitly identifies the sending nodes, some address information must be sent in the case of asynchronous TDMA.

The fact that nodes may access the medium without prior explicit request does not mean that TDMA methods are generally multimaster or peer-to-peer techniques. Whether they are depends on the way the synchronization of the time slots is achieved. Evidently, if no handshake procedures are implemented for data transfer, all nodes must be properly synchronized so that only one node at a time accesses the bus. This can be done in a centralized or decentralized way.

The simpler version is to have one dedicated bus master sending some sort of synchronization message at the start of the cycle. After that, the nodes exchange their data in their previously assigned time slots. Such a strategy is used, for example, by SERCOS, which is therefore regarded as a master-slave fieldbus (Figure 1.17). In this particular case, the time slots for the slaves are all equal in length, and the master has a larger time window to send its data to the slaves afterward. A similar method is also used by TTP/A. Here, a bus master (apart from having the possibility for simple polling) sends a synchronization message in the first time slot of a round to start the cyclic data transfer from all other nodes. In byteflight, a node (the sync master) sends a periodic synchronization signal to start the data exchange round (in byteflight called slot), and the others initialize slot counters to determine the position of

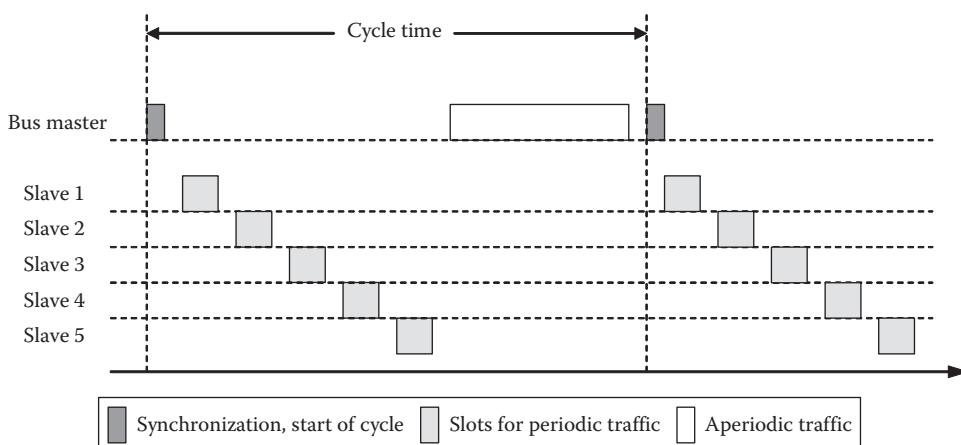

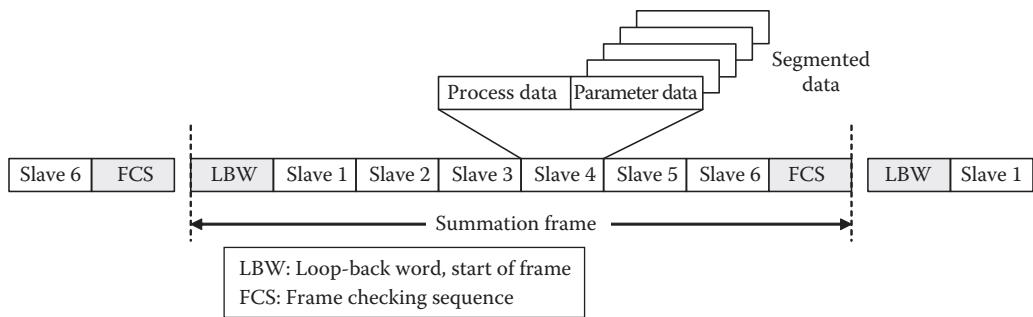

FIGURE 1.17 Centralized TDMA scheme (example SERCOS).

**FIGURE 1.18** Summation frame of INTERBUS.

their predefined microslot. If a node has no data to send, the respective microslot is shortened. In this respect, the bus access mechanism resembles an implicit TP method. The spare time of unused microslots becomes available for aperiodic or lower-priority traffic towards the end of the round.

Related to the centralized TDMA approaches is the summation frame protocol of INTERBUS (Figure 1.18). As noted in the previous section, the system is based on a ring structure and acts like a large shift register. Each slave has a predefined slot in the data frame that is selected in accordance with its position in the ring. Output data from the master to the slave and input data from the slave back are exchanged in the respective slot as the frame is shifted through the ring. Thus, one data frame is sufficient for the cyclic updating of all end devices. A clever arrangement of buffers furthermore ensures that despite the ring structure with its inherent delays, all I/Os at the slaves are updated at the same time, so that synchronous operation with respect to the process variables is guaranteed. Aperiodic traffic can be introduced in this rather rigid scheme through a so-called parameter channel. Larger amounts of data are transferred in small packets in this channel without affecting the exchange of cyclic process data.

The second method of managing the time slots is a decentralized one. In this case, there is no dedicated node to initiate the cycle; rather, all devices synchronize themselves either by explicit clock synchronization mechanisms or by a set of timers that settle bus operation down to a stable steady state. Fieldbus systems relying on such distributed mechanisms have a high degree of fault tolerance because there is no single point of failure as in centralized approaches. Therefore, they are well suited for safety-critical applications (such as TTP/C, FlexRay, or ARINC 629), provided that they are designed to have real-time capabilities. Nevertheless, the underlying algorithms are relatively complex, which is why such systems have attracted a lot of scientific interest. The distributed nature of bus access requires proper error containment mechanisms to avoid faulty nodes (babbling idiots) from blocking the medium and jeopardizing real-time behavior.

The real-time properties of time-slot mechanisms also led to the introduction of such approaches in fieldbus systems that originally use different access control methods. As a prominent example, CAN was enhanced in this way by superimposing TDMA structures like in time-triggered CAN (TT-CAN) or flexible time-triggered CAN (FTT-CAN). Last but not least, it should be noted that the boundaries between TDMA and other MAC techniques are sometimes blurred. For instance, the access control method of ControlNet is called Concurrent Time Domain Multiple Access, although it is rather an implicit TP strategy. The Flexible Time Domain Multiple Access of byteflight also has some similarity to TP.

#### 1.5.4.4 Random Access

Random access basically means that a network node tries to access the communication medium whenever it wants to—without limitations imposed, for instance, by any precomputed access schedule. This principle is called carrier sense multiple access (CSMA); it was first implemented in the ALOHA network in 1970 and since then has been modified in various ways. Obviously, it is perfectly suited for

spontaneous peer-to-peer communication. Its conceptual simplicity comes at the expense of a severe drawback: collisions inevitably occur when several nodes try to access the network at the same time, even if they first check if the line is idle. The variants of CSMA therefore have one common goal—to deal with these collisions in an effective way without wasting too much communication bandwidth and thereby avoiding excessive communication delays.

The best known CSMA variant is CSMA-CD (collision detection) used in Ethernet, more precisely in its original version with shared medium. Here, collisions are immediately detected by the sending nodes that monitor the bus while sending. After CD, the nodes abort the data transfer and wait for a random time before trying again. In fieldbus systems, this variant is not very common because despite its stochastic component, there is a high probability that collisions remain if the source data rates are too high. In practice, the effectively attainable throughput is limited to values well below 50% of the maximum data rate, which was always deemed insufficient for automation networks. It should be noted, though, that things changed with the introduction of switched Ethernet.

A variant where the backoff time (the time a node waits before a retry) is not just random, but adaptable is called predictive  $p$ -persistent CSMA and is used in LonWorks. Here,  $p$  denotes the probability that the node will try again in a certain time interval after the collision. This probability can be adapted by each node based on an estimation of its backlog and the monitored network load. In high-load conditions, the nodes reduce their probability for starting a medium access, which in turn reduces the probability for collisions. LonWorks additionally has a number of high-priority *time slots* with differing probabilities for medium access, so that messages with a higher priority still have a better chance to be sent without long delays.

The most widely used CSMA strategy in the fieldbus world, however, uses asymmetric symbols for coding the bits on the bus line, so that when two different bits are sent at a time, one of them wins over the other. In this case, there is no actual collision, bus access is nondestructive, and this is why this strategy is called CSMA-CA (collision avoidance), sometimes also called CSMA-BA (bitwise arbitration). The first fieldbus to use this method was CAN, and this example will be used in the sequel to explain the idea in more detail.

The bus line is designed as an open collector bus so that the low level is *dominant* and the high level remains *recessive*. This means that a “1” sent from an end device can be overwritten by a “0.” CAN uses message-based addressing, and after sending a synchronization bit, the nodes write the identifier of their message to the bus bit by bit and at the same time observe the current bus level. If the bits sent and read back differ, arbitration is lost, and the node stops sending. In the end, the remaining node is the one whose message has the lowest identifier (Figure 1.19). The BA method brings with it a major disadvantage: The propagation time of the signals on the line must be short compared with the bit time to yield quasi-simultaneity for all nodes. With the highest bit rate of 1 Mbit/s, this means a maximum bus length of only 40 m. In motor vehicles (the original application field of CAN), this restriction is of lesser importance, but in industrial automation technology, it can lead to a reduction in the data transfer rate.

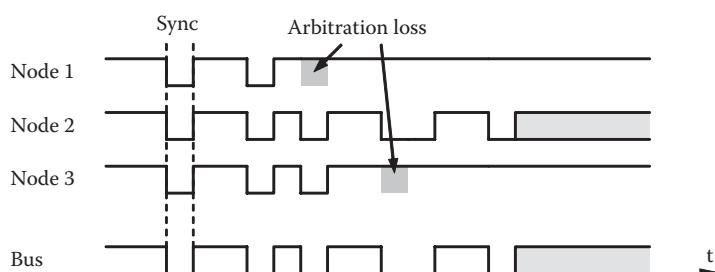

FIGURE 1.19 Bitwise arbitration method with CAN.

As with decentralized TDMA, faulty nodes may infinitely block the bus. To prevent this situation, CAN nodes contain error counters that are incremented whenever the node detects transmit or receive errors and are decremented after successful transmit or receive procedures. The counter status reflects the reliability of the node and determines if the node may fully participate in bus traffic or only with certain restrictions. In the extreme case, it is completely excluded from the bus.

BA was so successful that it was used in several other fieldbus systems in similar form. Examples are building automation networks like EIB, BATIBUS, or EHS, as well as in other automotive networks like VAN and FlexRay (for aperiodic traffic). But CAN was also used as a basis for further extension. CAN as such originally only defined layers 1 and 2 in the OSI model. Although this was sufficient for the exchange of short messages within a closed network, it was insufficient for automation technology. For this reason, the CAN-in-Automation user group defined the CAN application layer and then the CANopen protocol. Other protocols for automation technology, also based on CAN, are DeviceNet and SDS. The CAN Kingdom protocol has been specially developed for machine controls and safety-critical applications. These higher-level protocols offer the possibility of exchanging larger volumes of data and of synchronizing end devices. Network management functions solve the problems of node configuration and identifier specification.

CSMA-CA has one inherent problem: Even in the absence of babbling idiots, the highest priority object can practically block the bus, and messages with lower priorities seldom get through. Therefore, quality-of-service guarantees can only be given in a strict sense for the message with the highest priority if no additional measures are taken. A number of solutions have been proposed to overcome this problem. One of them is to limit the frequency of the messages such that after a successful transmission, a node has to wait a certain amount of time before being able to send again. Another possibility is to introduce mechanisms in the upper protocol layers to exchange identifiers cyclically within specific priority classes in addition to restrictions in access frequencies. This is a network management function used, for example, in CANopen. The third method of improving fairness (and thus real-time capabilities) is to superimpose time-slot mechanisms at least for some message and traffic classes. This strategy is being employed by TT-CAN and FTT-CAN.

### 1.5.5 Communication Paradigms

It was stated before that there are many diverse types of traffic to be considered in fieldbus systems, and there are many different services that a fieldbus should provide to the user application. Apart from basic functions like reading and writing variables, management of objects is required. This includes updates of device configurations, starting and stopping tasks running on nodes, up- or downloading of program, triggering and synchronization of events, establishment and termination of connections between nodes, and access control to node data, to name just of few. In general terms, fieldbus services need to handle objects by identifying them, the actions to be performed on them, as well as the appropriate parameters for the actions. These services must be defined and provided by the upper layers of the protocol stack, in most cases by the application layer.

Communication and cooperation between different application layers and applications in a fieldbus system is based on a basic set of two or three different models [36]. These models again represent different philosophies of the type of information that is exchanged between two or more entities. One approach is to build the cooperation on actions or functions into which a more complex process is decomposed. The responsibility for interpretation of the information is largely concentrated on the sender's side. This is the philosophy behind the client-server model. The other approach is a data-oriented one. Here, not actions but data are exchanged, and the responsibility for their interpretation is with the receiver (which then might take according actions). This is the idea behind the publisher-subscriber model and the producer-consumer model. The most relevant properties of these three are summed up in Table 1.1.

The overview shows that communication paradigms need to be supported by the medium access mechanism of the data link layer to achieve optimal performance.

**TABLE 1.1** Properties of Communication Paradigms

	Client–Server Model	Producer–Consumer Model	Publisher–Subscriber Model
Communication relation	Peer-to-peer	Broadcast	Multicast
Communication type	Connection-oriented	Connectionless	Connectionless
Master–slave relation	Monomaster, multimaster	Multimaster	Multimaster
Communication service	Confirmed, unconfirmed, acknowledged	Unconfirmed, acknowledged	Unconfirmed, acknowledged
Application classes	Parameter transfer, cyclic communication	Event notification, alarms, error, synchronization	State changes, event-oriented signal sources (e.g., switches)

### 1.5.5.1 Client–Server Model

In the client–server paradigm, two entities cooperate in the information exchange. The entity providing a service or data is called server, and the one requesting the service is called client. In general, the server may become active only upon request from the client, which means that this model is better suited for state-based data traffic handled in some scheduled manner. Events, that is, spontaneous traffic, can be handled only if they occur at the client (which may solely initiate communication). If they occur at the server, they cannot be handled in a spontaneous way at all; the server has to postpone the transmission until it receives an appropriate request from the client.

Client–server communication is based on confirmed services with appropriate service primitives (request, indication, response, and confirm) as defined in the OSI model (Figure 1.20a). This is the classical implementation used by many fieldbus systems that derive their application layer protocols essentially from the MMS standard. Examples are PROFIBUS-FMS (DP and PA in reduced form as well), WorldFIP, INTERBUS, or P-NET. The MMS model proposed comprehensive services that are usually only partly implemented in the fieldbus application layers. For the example of PROFIBUS-FMS (in similar form, they exist also in Foundation Fieldbus and WorldFIP), the services comprise the following groups: variable access (read, write), transmission of events, execution of programs, domain management (up- or download of large amounts of data), context management (administration of communication relationships), and object dictionary management (administration of the list of all objects in a device). Depending on the actual service requested, the semantics of the information exchanged obviously differ.

In some cases, and deviating from the standard model described before, a client–server communication can also be built from two unconfirmed services (Figure 1.20b). This means that the response generated by the server is not related to the request by means of the underlying protocols (i.e., it does not generate a confirmation on the local application layer). Rather, the client application has to keep track of the request and needs to relate the indication generated by the response on its own. This mechanism reduces the implementation efforts on the protocol side at the expense of the application complexity. Another—nonstandard—variant of the client–server model may have several responses from the server answering a single request [36]. Such an approach can be beneficial if the service execution on the

**FIGURE 1.20** Communication services used in the client–server model. (a) Normal and (b) Based on unconfirmed services.

server side takes a long time, so that partial results are reasonable or at least indications about the status of the execution. This may help to circumvent problems with, for example, hard-coded timeouts in legacy client applications by means of some keep-alive signal. Somewhat related to this and resembling a publisher–subscriber-type operation is a multiresponse from a server following one single request from the client. This can be useful if strictly periodic data transmissions from the server are required. Contrary to a cyclic client–server polling strategy, which always is affected by network and software delay, the server can control the sampling and transmission period of the data to be sent in a better and more accurate way.

As far as the interrelation of the client–server model and MAC strategies is concerned, it should be noted that basically, a client–server-type communication can be implemented in both mono- and multimaster systems. In the latter cases (which may be based on CSMA, TDMA, or TP), every master can take on the role of a client, whereas in mono-master systems (polling-based or centralized TDMA), this position is reserved for the bus master. Consequently, the client–server paradigm is used mainly for master–slave systems (as represented by PROFIBUS, ASI, MODBUS, P-NET, BITbus, and INTERBUS) and for reliable data transfer on application level (e.g., for parameterization data, file transfer, network, and device management). In particular for management functions, the client–server model is widely used also within fieldbus systems that organize their regular data transfer according to the publisher–subscriber model, such as WorldFIP, EIB, CANopen, DeviceNet, ControlNet, or LonWorks.

### 1.5.5.2 Publisher–Subscriber Model

The basic idea of the publisher–subscriber model is that certain nodes (the publishers) produce information that they post into the network. The subscribers are typically groups of nodes that listen to information sources. Relating publishers and subscribers can be done at runtime. The producer–consumer model uses very similar mechanisms; the only difference is that broadcast services are being employed instead of multicast communication as in the case of the publisher–subscriber model. However, this distinction is rather subtle and not very relevant in practice.

Depending on how the information exchange is initiated, two different subtypes of the publisher–subscriber paradigm can be distinguished [16]. In the pull model, the publishing action is triggered by a centralized publishing manager (Figure 1.21). Upon receiving the request from the manager, the publisher broadcasts the respective response to the network. Filtering of the message, which determines if the service is a broadcast or multicast, is done locally by the subscribers who listen to the network for message identifiers they subscribe to. It should be noted that the subscriber group may as well consist of just one node, such that the communication relation is effectively a one-to-one relationship.

In terms of communication services, the pull publisher–subscriber model uses a confirmed request/response service for the interaction between manager and publisher. The peculiarity of this service however is that while the request is unicast (i.e., has only one recipient), the response from the publisher is multicast to the publishing manager *and* the subscribers and already contains the information to be published. It is the task of the underlying protocol layers to ensure that the appropriate addressing scheme is used to transform the unicast into a multicast message. For the subscribers, the communication then may look like an unconfirmed service (i.e., they receive only an indication that a subscribed object has been transmitted) although it is actually a confirmed one from the viewpoint of the manager.

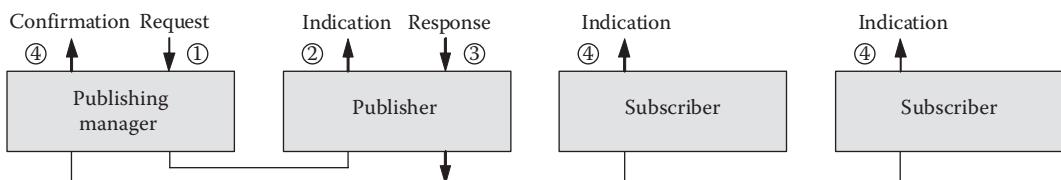

FIGURE 1.21 Pull-type publisher–subscriber model.

Still, there might be subtle differences in the way the request itself is handled. On the one hand, the manager might know the identifier of a variable and requests publication of this specific variable without caring about producer. This method is being used, for example, in WorldFIP. On the other hand, the manager might know the device address of the publisher and send the request directly to this node. This is typically done in fieldbus systems that normally rely on node addressing for data exchange and thus a client-server model. In such fieldbus systems, a publisher-subscriber transaction is the exception rather than the rule, as in PROFIBUS-DP V2. In master-slave systems, this type of communication—although not strictly publisher-subscriber—may also be used to implement a direct communication possibility between slaves under the direct control of the master. This shows that an application layer service for reading data based on the pull model comes very close to a read service implemented according to the client-server model. The essential difference is that the response is directed to a group of receivers instead of only one—the manager.

The second subtype of the publisher-subscriber paradigm is the push model (Figure 1.22) in which the publishers become active by themselves without prior request from a centralized station and distribute their information to the subscribers when they consider it necessary, for example, triggered by the expiration of a timer (as in TDMA systems) or by an external event. In terms of communication services, the publishing of information is implemented by means of unconfirmed (or locally confirmed) services on the publisher's side. Like in the pull variant, the subscribers receive an indication that new data have arrived and do not answer or acknowledge receipt of the message.

A necessary step in either of the two variants is the subscription of the subscribers with the publisher. This is a typical network management or configuration action that can be accomplished statically during system setup and commissioning or dynamically during runtime. As the underlying communication mechanism of the publisher-subscriber model is a multicast to a defined group of nodes, it must be ensured that a node subscribing to a given message or object joins the correct communication group. This is therefore mainly done using client-server-type communication based on confirmed services.

Processes with mostly event-based communication can get along very well with publisher-subscriber- or producer-consumer-type communication systems. Depending on the fundamental layer-2 communication methods, real-time requirements may be more (in the case of TDMA methods or centralized polling) or less met (with pure random access methods). The obvious advantage is that all connected devices have direct access to the entire set of information since the broadcasting is based on identification of messages rather than nodes. Reaction times on events can be very short due to the absence of slow polling or token cycles. Generally, publisher-subscriber-type systems (or subsystems) are mostly multimaster systems because every information source (producer) must have the possibility to access the bus. The selection of relevant communication relationships is solely based on message filtering at the subscriber's side. Such filter tables are typically defined during the planning phase of an installation. It is no wonder that this communication model is being widely used in fieldbus systems, as, for instance, WorldFIP, Foundation Fieldbus, CAN, CANopen, DeviceNet, ControlNet, LIN, EIB, or LonWorks.

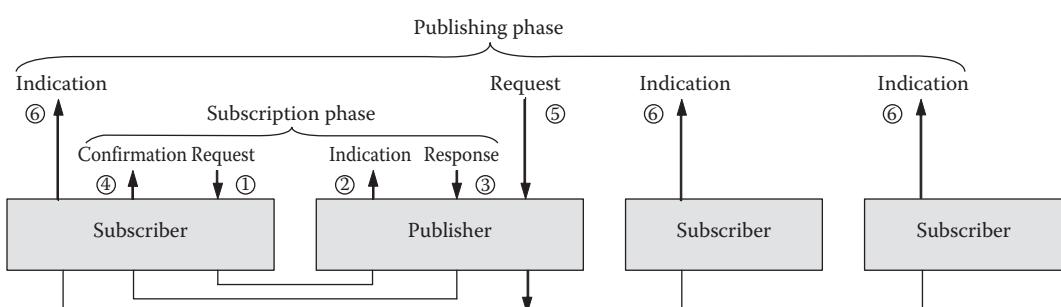

FIGURE 1.22 Push-type publisher–subscriber model.

Still, there is an inherent problem. As both paradigms are message based and therefore connectionless on the application layer, they are not suited for the transmission of sensitive, nonrepetitive data such as parameter and configuration values or commands. Connectionless mechanisms can inform the respective nodes about communication errors on layer 2, but not about errors on application layer. Particularly for fieldbus systems devised for safety-critical applications (such as TTP), additional mechanisms have been developed to enable atomic broad- and multicasts. Atomic in this context means that the communication is successful only if all subscribers receive the distributed information correctly. Only in this case will actions associated with the transaction be executed; otherwise, they are cancelled.

### 1.5.6 Above the OSI Layers: Interoperability and Profiles

A key point for the acceptance of fieldbus systems was their openness. The availability of publicly available specifications and finally standards made it possible to set up the so-called multivendor systems, where components developed by different manufacturers work together to achieve a common functionality. This possibility was the evidence for interoperability and still is an important argument in fieldbus marketing. The standardization of fieldbuses was originally thought to be sufficient for interoperable systems, but reality quickly showed that it was not. Standards (interoperability standards, to be precise) define the rules that the system components must comply with in order to be able to work with other components, but they often leave room for interpretation, and actual implementations may vary. Certification of the devices is a suitable way to reduce the problems, but by no means a guarantee. Another reason for troubles is that the semantics of data objects are not precisely defined. In fact, there are various degrees of interoperability, as defined by the IEC TC65 SC65C WG7 within the scope of the IEC *Interoperability Definitions* (Figure 1.23) [37]. These definitions relate to application functionalities that can be achieved, that is, the degree to which devices and applications can actually work together.

**Incompatible:** The two communication partners have no common ground, and their connection, if physically possible, could result in damage. The connectors, voltage levels, and modulation methods can be different.

**Compatible:** The most fundamental requirement is that both devices use the same communication protocol. They can be connected and may exchange data packets. Still, compliance

Access to the data						
Protocol (layer 1–7)						

FIGURE 1.23 Application functionalities within the interoperability definitions.

with the protocol (as verified, e.g., by conformity tests according to ISO 9646) alone does not guarantee meaningful cooperation between the applications as they cannot make sense of the received packets.

*Interconnectable:* The partners have the same methods of accessing the data, and they mutually understand the addressing methods used by the partner. This is important because the exact way in which data are made available in the network is not defined by the protocol layers; they just offer a number of services for data transmission. Being interconnectable, the partners can recognize whether received messages were addressed to them, and they are capable of extracting the data (or encoding them in the opposite direction). Furthermore, they use the application layer services in the same way and have a common understanding of data types used for their applications.

*Interworkable:* Applications share the same definitions of data and use the same variable types. Therefore, they can correctly exchange data using a common way of coding. As an example, a sensor can send its value in long\_int format, and a controller can correctly receive and process this value. Usually, the development tools offer support for this level. If the tools are designed for distributed systems, errors violating interworkability can already be detected in an early development phase.

*Interoperable:* On this level, the semantics of the data play an important role. Variables take on physical relevance; they do not have just a data type but also a physical unit that needs to be known to the partners. Furthermore, accuracy ranges, meaning, and purpose of variables are defined. If a device produces a larger data set, it is known how the individual data can be distinguished. Interoperable nodes can be used immediately without additional description, their network interfaces are unique, and also the functional behaviors match. It is precisely defined what happens to the data that are sent across the network and which actions or sequence of actions they trigger.

*Interchangeable:* Even the temporal behavior of two nodes is the same with respect to the needs of the application. Typically, such requirements are maximum reaction times to events or commands. If such constraints are not equal, the overall behavior of the entire network can fundamentally change even if a device replacing another is functionally equivalent.

The problem of interoperability has been disregarded in many cases until recently. In fact, it is not a problem of the fieldbus itself, but of the application. Consequently, it must be tackled beyond the ISO/OSI model. The definition of appropriate *profiles* addresses this problem. A profile defines which variables carry which data, how they are coded, what physical units they have, etc. By virtue of this profile, it is possible to subject devices, which are claimed to satisfy this profile, to a corresponding conformity test. The compatibility of a device is generally also tested when used within a multivendor system.

The creation of profiles originated from the recognition that the definition of the protocol layers alone is not sufficient to allow for the implementation of interoperable products, because there are simply too many degrees of freedom. Therefore, profiles limit the top-level functionality and define specialized subsets for particular application areas [38,39]. Likewise, they specify communication objects, data types, and their encoding. So they can be seen as an additional layer on top of the ISO/OSI model, which is why they have also been called *Layer 8* or *User Layer*. One thing to be kept in mind is that nodes using them literally form islands on a fieldbus, which contradicts the philosophy of an integrated decentralized system. Different profiles may coexist on one fieldbus, but a communication between the device groups is normally very limited or impossible at all.

The concept of profiles has many names. In MMS, they are termed Companion Standards. In P-NET, they are equivalent to the Channel concept. Function blocks in Foundation Fieldbus essentially pursue the same idea. In LonWorks, there are the Standard Network Variable Types, and in EIB, interoperability is achieved by means of the EIB Interworking Standards.

From a systematic viewpoint, profiles can be distinguished into communication, device, and branch. A bus-specific *communication profile* defines the mapping of communication objects onto the services offered by the fieldbus. A *branch profile* specifies common definitions within an application area concerning terms, data types, their coding, and physical meaning. *Device profiles* finally build on communication and branch profiles and describe functionality, interfaces, and in general the behavior of entire device classes such as electric drives, hydraulic valves, or simple sensors and actuators.

The work of defining profiles is scattered among different groups. Communication profiles are usually in the hands of fieldbus user groups. They can provide the in-depth know-how of the manufacturers, which is indispensable for bus-specific definitions. Device and branch profiles are increasingly a topic for independent user groups. For them, the fieldbus is just a means to an end—the efficient communication between devices. What counts more in this respect is the finding and modeling of uniform device structures and parameters for a specific application. This forms the basis for a mapping to a communication system that is generic within a given application context.

The ultimate goal is the definition of fieldbus-independent device profiles. This is an attempt to overcome on a high level the still overwhelming variety of systems. Finally, such profiles are also expected to facilitate the employment of fieldbus systems by the end user who normally is only concerned about the overall functionality of a particular plant—and not about the question which fieldbus to use. The methods used to define data types, indices, default values, coding and meanings, identification data, and device behavior are based on functional abstractions and general modeling techniques [40].

### 1.5.7 Fieldbus Management

Owing to the different capabilities and application areas of fieldbus systems, the management of a fieldbus shows varying complexity, and its solutions are more or less convenient for the user. It has already been stated that the various fieldbuses offer a wide range of network management services with grossly varying levels of sophistication. Apart from the functional boundary conditions given by the protocols, fieldbus management always strongly relies on the tool support provided by the manufacturers. This significantly adds to inhomogeneity of the fieldbus world in that entirely different control concepts, user interfaces, and implementation platforms are being used. Furthermore, a strict division between communication and application aspects of fieldbus management is usually not drawn.

Typical *communication-related* management functions are network parameter settings like address information, data rate, or timing parameters. These functions are rather low level and implicitly part of all fieldbus protocols. The user can access them via software tools mostly supplied by the device vendor. *Application-related* management functions concern the definition of communication relations, system-wide timing parameters (such as cycle times), priorities, or synchronization. The mechanisms and services offered by the fieldbus systems to support these functions are very diverse and should be integrated in the management framework for the application itself (e.g., the control system using the fieldbus).

As a matter of fact, a common management approach is still not available despite all interoperability achievements, and vendor-specific solutions are preferred. From the user's point of view (which includes not only the end users, but also system integrators), this entails significantly increased costs for the build-up and maintenance of know-how because they must become acquainted with an unmanageable variety of solutions and tools. This situation actually revives one of the big acceptance problems that fieldbus systems originally had among the community of users: the missing interoperability. Communication interoperability (as ensured by the fieldbus standards) is a necessary but not sufficient precondition. For the user, *handling interoperability* of devices from different vendors is equally important [41]. What is needed are harmonized concepts for configuration and management tools. More than that, tools should also be consistent for different aspects of the life cycle of an installation, like planning, configuration, commissioning, test, and diagnosis or maintenance. An increasingly important topic on the overall enterprise level is asset management, which also includes field-level data [42]. Such tools require functionality-oriented abstract views. A major disadvantage of today's tool variety is that they operate in

many cases on incompatible data bases, which hampers system integration and is likely to produce consistency problems. More advanced concepts build on unified data sets that present consistent views to the individual tools with well-defined interfaces. The data structures are nevertheless still specific for each fieldbus.

With the increasing importance of LAN and Internet technologies in automation, new approaches for fieldbus management appeared that may be apt to introduce at least a common view at various fieldbuses. All these concepts aim at integrating fieldbus management into existing management applications of the higher-level network, which is nowadays typically IP based. One commonly employed high-level network management protocol is SNMP, which can be used to access also fieldbus data points [43,44]. Another approach involves the use of directory services [45]. These two solutions permit the inclusion of a large number of devices in specialized network management frameworks. An alternative that has become very popular is the use of web technology, specifically HTTP tunneled over the fieldbus, to control device parameters. This trend is supported by the increasing availability of embedded web servers and the use of XML as device description language [46]. The appealing feature of this solution is that no special tools are required and a standard web browser is sufficient. However, web pages are less suitable for the management of complete networks and rather limited to single-device management. Nevertheless, this approach is meanwhile pursued by many manufacturers.

In the context of management and operation frameworks, the unified description of device and system properties becomes of eminent importance. To this end, device description languages were introduced. Over the years, several mutually incompatible languages and dialects were developed [47]. Originally, they were tailored to individual fieldbus systems (e.g., HART DDL, PROFIBUS GSD, CANopen EDS, and FF DDL) and laid the foundation for user-friendly configuration and engineering tools. In recent years, the diversity of description languages is being addressed by the increased usage of universal languages like XML [48], which is also the basis for the electronic device description language standardized in IEC 61804.

For a fieldbus-independent access to the field devices and their data (not necessarily covering the entire life cycle), several solutions have been proposed. They mostly rely on a sort of middleware abstraction layer using object-oriented models. Examples are OPC or Java. Such platforms can ultimately be extended through the definition of suitable application frameworks that permit the embedding of generic or proprietary software components in a unified environment spanning all phases of the life cycle. A popular approach is, for example, the Field Device Tool [47,49]. Typical for all approaches is that they start from a comprehensive, consistent description of the devices and their parameters and filter this data base depending on the life cycle phase. The user therefore gets access only to a specific subset coinciding with his role in the life cycle. The latest trend is to use web services as actual middleware because of their platform independence [50,51] and workflows to describe processes [52]. To gain even more flexibility, ontologies are being used to introduce semantic information about processes [53], and all together leads to the booming field of service-oriented architectures [54–56]. Special attention deserves OPC, which is currently the most widely used solution for data exchange between the field-level and higher-level applications, for example, SCADA systems [57]. Also inside the field level, OPC as interoperable data exchange middleware is a de facto standard [58]. In its most recent version OPC UA (Unified Architecture), web services are used as one technological basis.

## 1.6 Industrial Ethernet: The New Fieldbus

---

As stated before, Ethernet has become increasingly popular in automation. And like in the early days of fieldbus systems, this boom is driven mainly by the industry—on an academic level, the use of Ethernet had been discussed decades ago. At that time, Ethernet was considered inappropriate because of its lack of real-time capabilities. With the introduction of switched Ethernet and certain modifications of the protocol, however, these problems have been alleviated. And even if there are still doubts about the predictability of Ethernet, its penetration into the real-time domain will influence the use of fieldbus-based

devices and most likely restrict the future use of fieldbus concepts [59]. Today, Ethernet already takes the place of mid-level fieldbus systems, for example, for the connection of PLCs.

Using Ethernet on the field-level one first of all has to overcome the problem of the inherent lack of determinism. For Ethernet as shared medium, and if no hard real-time behavior is requested, various types of traffic smoothing techniques have been proposed [60,61], where real-time packets are given priority over non-real-time ones. The goal is to eliminate contention within each local node and to shape non-real-time traffic so as to reduce the chance for collision with real-time packets from the other nodes. The introduction of switched Ethernet further alleviated the problem [62]. Much research work consequently focused on how to reduce the queuing delays inside the switches [63,64] and on traffic smoothing methods for switched Ethernet [65], even if also switched Ethernet per se is not fully deterministic and leaves room for further research [66].

One of the main arguments used to promote Ethernet on the field level is that because it is the same network technology as in the office world, a straightforward integration is possible, that is, both automation and office domain can in principle be connected to one single enterprise network. A quick look at reality, however, shows that things are different. Ethernet per se is but a solution for the two lower OSI layers, and as fieldbus history already showed, this is not sufficient. Even if the commonly used Internet protocol suite with TCP/UDP/IP is taken into account, only the lower four layers are covered. Consequently, there are several possibilities to get Ethernet or Internet technologies into the domain currently occupied by fieldbus systems:

- Tunneling of a fieldbus protocol over UDP/TCP/IP
- Tunneling of TCP/IP over an existing fieldbus
- Definition of new real-time-enabled protocols
- Limitation of the free medium access in standard Ethernet
- Modifications of the Ethernet hardware to achieve better real-time capabilities

All of these possibilities are actually used in practice (Figure 1.24). In the beginning, all research work carefully avoided any concepts violating the Ethernet standards. Compatibility and conformity were the primary goals. Especially those approaches already contained in the first version of the IEC 61158

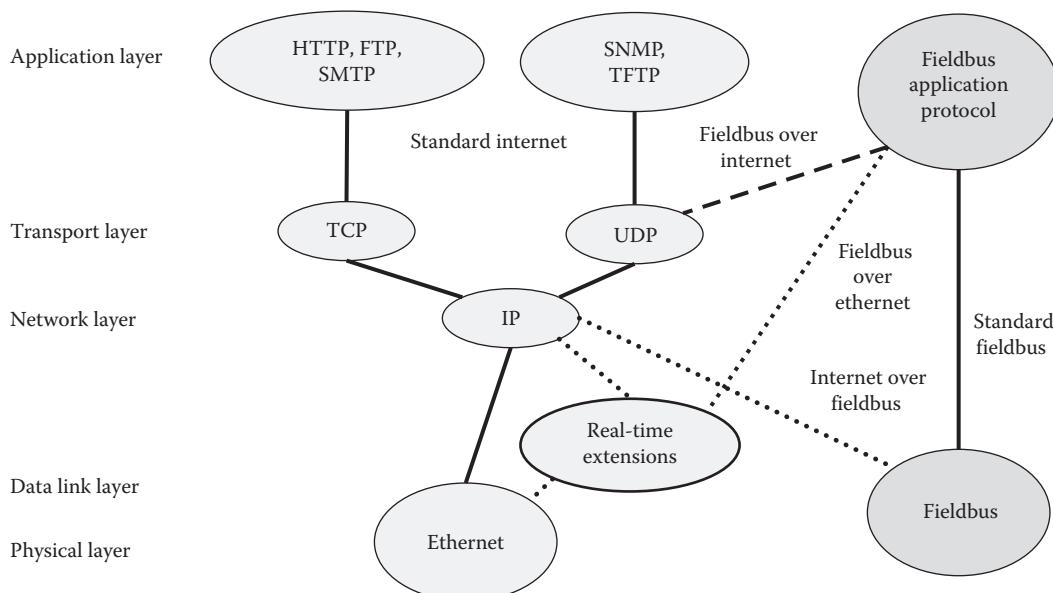

FIGURE 1.24 Structures of Ethernet and Fieldbus combinations.

standard employ existing fieldbus application layer protocols on top of IP-based transport mechanisms (TCP or UDP, respectively, depending on the services needed) that replace the lower fieldbus layers [31]. The following four examples pursue this approach:

1. The high-speed Ethernet variant of Foundation Fieldbus is an application of the existing Fieldbus Foundation's H1 protocol wrapped in UDP/IP packets [67].
2. Ethernet/IP (IP in this case standing for Industrial Protocol) uses the Control and Information Protocol (CIP) already known from ControlNet and DeviceNet [68]. This application layer protocol is sent over TCP or UDP, depending on whether configuration or process data have to be transmitted.
3. Modbus/TCP is based on standard Modbus frames encapsulated in TCP frames. For more stringent real-time requirements, a real-time variant of the publisher–subscriber model was developed by IDA Group (Interface for Distributed Automation, now merged with Modbus Organization), which builds on UDP.
4. P-NET on IP defines a way to wrap P-NET messages in UDP packets.

These industrial Ethernet solutions build on Ethernet in its original form, that is, they use the physical and data link layer of ISO/IEC 8802-3 without any modifications. Furthermore, they assume that Ethernet is low loaded or fast Ethernet switching technology is used, in order to get a predictable performance. Switching technology does eliminate collisions, but delays inside the switches and lost packages under heavy load conditions are unavoidable also with switches [69]. This gets worse if switches are used in a multilevel hierarchy and may result in grossly varying communication delays. The real-time capabilities of native Ethernet are therefore limited and must rely on application-level mechanisms controlling the data throughput. For advanced requirements, like drive controls, this is not sufficient. These known limitations of conventional Ethernet stimulated the development of several alternative solutions that were more than just adaptations of ordinary fieldbus systems. These entirely new approaches were originally outside the IEC standardization process, but are now included in the RT Ethernet standard, that is, the second volume of IEC 61784 [70].

The initial and boundary conditions for the standardization work, which started in 2003, were targeted at backward compatibility with existing standards. First of all, real-time Ethernet (RTE) was seen as an extension to the industrial Ethernet solutions already defined in the communication profile families in IEC 61784-1. Furthermore, coexistence with conventional Ethernet is intended. The scope of the working document [71] states that

the RTE shall not change the overall behavior of an ISO/IEC 8802-3 communication network and their related network components or IEEE 1588, but amend those widely used standards for RTE behaviors. Regular ISO/IEC 8802-3 based applications shall be able to run in parallel to RTE in the same network.

The work program of the RTE working group essentially consists of the definition of a classification scheme with RTE performance classes based on actual application requirements [59,72]. This is a response to market needs that demand scalable solutions for different application domains. One possible classification structure could be based on the reaction time of typical applications:

- A first low-speed class with reaction times around 100 ms. This timing requirement is typical for the case of humans involved in the system observation (10 pictures/s can already be seen as a low-quality movie), for engineering, and for process monitoring. Most processes in process automation and building control fall into this class. This requirement may be fulfilled with a standard system with TCP/IP communication channel without many problems.
- In a second class, the requirement is a reaction time below 10 ms. This is the requirement for most tooling machine control systems like PLCs or PC-based control. To reach this timing behavior, special care has to be taken in the RTE equipment: Sufficient computing resources are needed to handle the TCP/IP protocol in real time or the protocol stack must be simplified and reduced to get these reaction times on simple, cheap resources.

- The third and most demanding class is defined by the requirements of motion control: To synchronize several axes over a network, a time precision well below 1 ms is needed. Current approaches to reach this goal rely on modifications of both protocol medium access and hardware structure of the controllers.

During the last years, a number of industrial solutions appeared that tackled the real-time requirements, mostly on the basis of switched Ethernet. Still, as with fieldbus systems, they were tailored to specific needs. Not even the use of standard Ethernet is really a common denominator, and above the data link layer, the approaches are completely different. Some use standard TCP/UDP/IP mechanisms for transmitting data, maybe enhanced by additional software layers to support both real-time and non-real-time communication, and some use dedicated communication stacks that bypass the entire IP suite. Figure 1.25 sketches the various appearances of the protocol stack. Manifold differences are also possible on the physical layer. Some approaches foresee redundant media (VNET/IP, TCnet), PROFINET-I/O uses dedicated built-in switches to reduce the data transmission jitter [73], and EtherCAT as well as SERCOS III need dedicated controllers [59]. Ethernet Powerlink uses the old shared Ethernet and places a master-slave scheduling system on top of it. Common to many proposed networks is that they employ clock synchronization to support real-time applications. To this end, the standard IEEE 1588 [74], which originally emerged in the instrumentation area, was officially adopted also by IEC. The specific requirements in the automation domain have led to several suggestions for improvement of the standard regarding performance or fault tolerance [75,76] that were taken into account in the subsequent revision.

Given the multitude of approaches, despite the early hope that Ethernet could be the basis for a unique industrial communication solution, the situation has not too much changed compared with the heterogeneity of the traditional fieldbus systems [70]. Interoperability between different industrial Ethernet solutions is not possible in a direct way and must be established on a higher level by means of profiles (which is actually done to allow for cooperation between *old* fieldbuses and *new* Ethernet installations) or middleware layers like OPC. In many cases, higher-layer protocols (in particular, application layer protocols) and at least data objects are compatible with classical fieldbus systems and allow for an interconnection on a relatively high level. From this compatibility viewpoint, four different classes of industrial Ethernet approaches exist:

1. Reuse of higher-layer protocols from the preexisting fieldbus solutions. This applies to MODBUS/TCP, MODBUS/RTPS, high-speed Ethernet (Foundation Fieldbus over UDP/IP), Ethernet/IP (which uses the CIP protocol common to ControlNet and DeviceNet), P-NET on IP, Vnet/IP

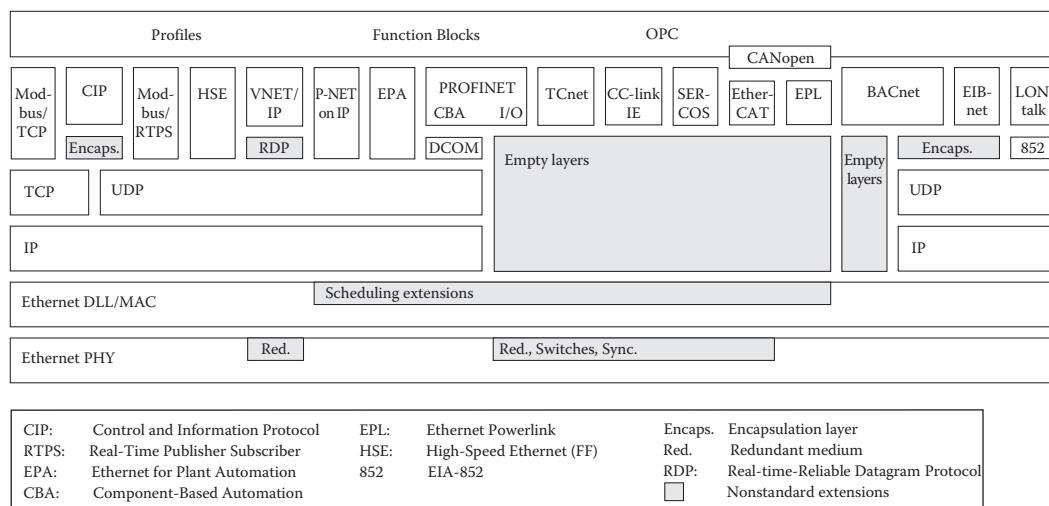

FIGURE 1.25 Protocol architecture of selected real-time Ethernet solutions proposed for IEC 61784-2.

(compatible to Vnet from Yokogawa), SERCOS III (structure of telegrams has been retained from the earlier, fiber-optics-based versions), and CC-Link IE (using the existing CC-Link protocol over Ethernet). Building automation networks take particular advantage of this architecture. BACnet, LonWorks, and EIBnet all use IP-based networks (or plain Ethernet as an alternative for BACnet) as a transport medium for the higher-layer protocols [77].

2. Compatibility of data models and objects with preexisting fieldbuses. An example is PROFINET, where proxy solutions exist to incorporate legacy PROFIBUS devices and networks.
3. Usage of application layer profiles from preexisting fieldbuses without direct protocol compatibility. This is the case for, for example, Ethernet Powerlink and EtherCAT, which use the CANopen application layer to achieve compatibility with widely used device profiles, for example, for drives.
4. Completely new industrial Ethernet developments without backward compatibility because of the lack of older fieldbus solutions. This is the case for the Asian networks Ethernet for Plant Automation and TC-Net.

Given the still large number of solutions, the only conceivable improvement compared to the classical fieldbus technology is that even with all proprietary modifications, Ethernet and, to a large extent, also the IP suite are being recognized as technological basis for the new generation of industrial communication systems. And with a view on vertical integration, the main benefit of industrial Ethernet is that all approaches allow for a standard TCP/UDP/IP communication channel in parallel to *fieldbus* communication. Even the RTE solutions (like PROFINET, Ethernet Powerlink, and EtherCAT) have such a conventional channel for configuration purposes. This is related to the IP-over-fieldbus tunneling concepts discussed earlier, but unlike the classical fieldbus systems, where such IP tunnels were introduced long after the fieldbus development and thus often had to cope with performance problems, they are now an integral part of the system concept right from the beginning on.

The separation of real-time and non-real-time traffic is accomplished on Ethernet MAC level with prioritization or TDMA schemes together with appropriate bandwidth allocation strategies. In such a parallel two-stack model, IP channels are no longer stepchildren of industrial communication, but offer sufficient performance to be used for regular data transfer. While this enables in principle the coexistence of automation and nonautomation applications on industrial Ethernet segments, the mixing of automation and office is not advisable for performance, but more important for security reasons. The value of this standard IP channel is rather to be seen in a simple direct access path to the field devices. Therefore, the currently favored solutions for configuration tools (i.e., XML, SOAP, and more generally web technology) can be used consistently. This again does not mean that industrial Ethernet solutions are interoperable or use the same configuration tools, but at least the basic principles are the same.

Actually, all this could have already been done with traditional fieldbus systems as well, and it certainly would have been done had especially the achievements of the Internet and the WWW been available in the early 1980s. So, what we see today with the rapid evolution of Ethernet in automation can in fact be regarded as a second wave of fieldbus development, which takes into account all the technological achievements of the last decade and exploits them for the field level, thereby making particularly vertical integration significantly easier.

## 1.7 Aspects for Future Evolution

Fieldbus systems have come a long way from the very first attempts of industrial networking to contemporary highly specialized automation networks. What is currently at hand—even after the selection process during the last two decades—nearly fully covers the complete spectrum of possible applications. Nevertheless, there is enough evolution potential left [17,27]. On the technological side, the communication medium itself allows further innovations. The currently most promising research field for technological evolution is the wireless domain. The benefits are obvious: (1) no failure-prone or

costly cabling and (2) high flexibility, even mobility. The problems on the other hand are also obvious: very peculiar properties of the wireless communication channel must be dealt with, such as attenuation, fading, multipath reception, temporarily hidden nodes, the simple access for intruders, and many more [78–81]. Wireless communication options do exist today for several fieldbuses [82–84]. Up to now, they have been used just to replace the conventional data cable. A really efficient use of wireless communication, however, would necessitate an entire redefinition of at least the lower fieldbus protocol layers, while the higher protocol layers might be kept compatible with fieldbus or industrial Ethernet solutions [85–88]. Evaluation of currently available wireless technologies from the computer world with respect to their applicability in automation is a first step in this direction [89,90]. Ultimately, we can expect completely new automation networks optimized for wireless communication, where wired and wireless network segments are seamlessly integrated [91] and maybe only the application layer protocol remains compatible with traditional wired solutions to achieve integration [92–95].

Driven by ever more demanding application areas, communication networks for safety-relevant systems gain importance. In special fields such as x-by-wire for vehicles and avionics, dedicated fieldbus systems were developed that specifically addressed the problem of reliable communication [96]. Examples are TTP, FlexRay, byteflight, or ARINC 629. As this domain is subject to very stringent normative regulations and thus very conservative, it was dominated for a long time (and still is) by point-to-point connections between devices. The first *older* fieldbus system to penetrate this field was the CAN-based Safety Bus [97]. It took a long time and effort for this system to pass the costly certification procedures. Nevertheless, it was finally accepted also by the users, which was by no means obvious in an area concerned with the protection of human life, given that computer networks usually have the psychological disadvantage of being considered unreliable. After this pioneering work, other approaches like the ProfiSafe profile, INTERBUS Safety, ASi Safety, and recently also Ethernet/IPsafety, WorldFIP, and SafetyLON readily followed [98]. All these traditional fieldbus systems that were originally not designed for safety-critical applications implement this particular functionality by means of dedicated profiles. In practice, they wrap additional safety protocols into the normal payload data, which foresee a set of measures to make communication more reliable: sequence numbers, additional CRCs and confirmations, timestamps, heartbeat functions, and timeouts together with safety monitors and built-in test functions for the hardware components detect residual errors and may typically achieve safety integrity level 3 according to IEC 61508, which makes them applicable for fire emergencies, alarming, traffic and transportation applications, or power plant control.

Apart from communication protocol issues, there are two major trends to be noticed. One is the growing complexity of networks and networked systems in general. This is manifested by the increasing integration of fieldbus systems in higher-level, heterogeneous networks and process control systems on the one hand and the massive use of Internet technologies to achieve simplification and possible harmonization of existing solutions on the other. This in fact drastically reduces the number of layers in the traditional network hierarchy, which only reflects the trend toward peer-to-peer networking on a protocol level [99]. The other trend is the still increasing capabilities of embedded devices, the possibility to integrate more computational resources while at the same time reducing energy consumption. Systems on Chip with on-chip memory, network interfaces, and the computing power of a complete industrial PC offer sufficient resources for smart and low-cost sensors and actuators. This evolution is on the one hand the foundation of the current boom of Ethernet in automation. On the other, it will stimulate more research in the already booming field of sensor networks [100–103]. What is likely to be seen in the future are much more ubiquitous Ethernet- and Internet-based concepts, probably optimized to meet special performance requirements on the field level but still compatible with the standards in the management area. At any rate, these concepts and protocols will have to be scalable to allow for seamless integration of low-level, highly specialized sensor/actuator networks tailored to meet the demands of low power consumption, small-footprint implementation, high flexibility, and self-organization. The next evolution step in fieldbus history is just ahead.

## Appendix

Tables 1.A.1 through 1.A.4 presented here give an overview of selected fieldbus systems, categorized by application domain. The list is necessarily incomplete, although care has been taken to include all approaches that either exerted a substantial influence on the evolution of the entire field or are significant still today. The year of introduction refers to the public availability of the specification or first products. This year is also the one used in the timeline in Figure 1.3. Note that despite careful research, the information obtained from various sources was frequently inconsistent, so that there may be an uncertainty in the figures. Where respective data could be obtained, the start of the project has been listed as well because there are several cases where the development of the fieldbus took a long time before the first release.

### 2.1 Introduction

---

Networks have become an integral part of manufacturing over the past two decades, replacing point-to-point communications at all levels. At lower levels in the factory infrastructure, networks provide higher reliability, visibility, and diagnosability and enable capabilities such as distributed control, diagnostics, safety, and device interoperability. At higher levels, networks can leverage Internet services to enable factory-wide automated scheduling, control, and diagnostics; improve data storage and visibility; and open the door to e-manufacturing.

In general, control networks can replace traditional point-to-point wired systems while providing a number of advantages. Perhaps the simplest but most important advantage is the reduced volume of wiring. Fewer physical potential points of failure, such as connectors and wire harnesses, result in increased reliability. This advantage is further accentuated in wireless networks. Another significant advantage is that networks enable complex distributed control systems to be realized in both horizontal (e.g., peer-to-peer coordinated control among sensors and actuators) and vertical (e.g., machine to cell to system-level control) directions. Other documented advantages of networks include increased capability for troubleshooting and maintenance, enhanced interchangeability and interoperability of devices, improved reconfigurability of control systems, and ease of integration of web service-based capabilities such as the cloud- and applet-based systems [48,93].

The primary application of control networks is supervisory control and data acquisition (SCADA) systems [31,53]. Networked SCADA systems often provide a supervisory-level factory-wide solution for coordination of machine and process diagnostics, along with other factory floor and operations information. However, networks are being used at all levels of the manufacturing hierarchy, loosely defined as device, machine, cell, subsystem, system, factory, and enterprise. Within the manufacturing domain, the application of networks can be further divided into subdomains of *control*, *diagnostics*, and *safety*. Control network operation generally refers to communicating the necessary sensory and actuation information for closed-loop control. The control may be time-critical, such as at a computer numeric controller (CNC) or servo drive level, or event-based, such as at a programmable logic controller (PLC) level. In this subdomain, networks must guarantee a certain level of response time determinism to be effective. Diagnostics network operation usually refers to the communication of sensory information as necessary to deduce the health of a tool, product, or system; this is differentiated from *network diagnostics*, which refers to deducing the health of the network [28,38,40,84]. Systems diagnostics solutions may *close-the-loop* around the diagnostic information to implement control capabilities such as equipment shutdown or continuous process improvement; however, the performance requirements of the system are driven by the data collection, and actuation is usually event based (i.e., not time dependent). An important quality of diagnostics networks is the ability to communicate large amounts of data, with determinism usually less important than in control networks. Issues of data compression and security can also play a large role in diagnostics networks, especially when utilized as a mechanism for communication between user and vendor to support equipment e-diagnostics [22,38,84]. Required data communication rates associated with large volumes of data, along with required data storage, data merging, data quality, and analytics capabilities collectively contribute to the *big data* problem in factories; thus, networks are an integral part of the big data solution [66]. Safety is the newest of the three network subdomains, but is rapidly receiving attention in industry [12,52]. Here, network requirements are often driven by standards, with an emphasis on determinism (guaranteed response time), network reliability, and capability for self-diagnosis [35].

Driven by a desire to minimize cost and maximize interoperability and interchangeability, there continues to be a movement to try to consolidate around a single network technology at different levels of control and across different application domains. For example, Ethernet, which was widely regarded as a high-level-only communication protocol in the past, is now frequently being utilized as a lower-level control network, with flavors of Ethernet actually being used for real-time, high-speed control [15,24,91]. The hierarchical Ethernet network infrastructure has enabled capabilities such as web-based *drill-down* (focused data access) to the sensor level [43,84]. In some situations, wireless technology can be considered as a replacement for wired networks at all levels, primarily to support diagnostics, but also to support control and even safety functionality in specific instances [13,17,101].

This movement toward consolidation, and indeed the technical selection of networks for a particular application, revolves around evaluating and balancing quality of service (QoS) parameters. Multiple components (nodes) are vying for a limited network bandwidth, and they must strike a balance with factors related to the time to deliver information end to end between components. Two parameters that are often involved in this balance are network average speed and determinism; briefly, network

speed is a function of the network access time and bit transfer rate, while determinism is a measure of the ability to communicate data consistently from end to end within a guaranteed time. Note that this QoS issue applies to both wired and wireless network applications; however, with wireless, there must be more focus on external factors that can affect the end-to-end transmission performance, reliability, and security.

Network protocols utilize different approaches to provide end-to-end data delivery. The differentiation could be at the lowest physical level (e.g., wired vs. wireless) up through the mechanism at which network access is negotiated, all the way up through application services that are supported. Protocol functionality is commonly described and differentiated utilizing the International Standards Organization–Open Systems Interconnection (ISO–OSI) seven-layer reference model [3]. The seven layers are physical, data link, network, transport, session, presentation, and application.

The network protocol, specifically the media access control (MAC) protocol component, defines the mechanism for delegating this bandwidth in such a way so that the network is *optimized* for a specific type of communication (e.g., large data packet size with low determinism vs. small data packet size with high determinism). Over the past two decades, *bus wars* (referring to sensor bus network technology) resulted in serious technical debates with respect to the optimal MAC approach for different applications [26,60,64].

Over the past 10 years, however, it has become clear that the pervasiveness of Ethernet, especially in domains outside of manufacturing control (e.g., the Internet), will result in its eventual dominance in the manufacturing control domain [19,25,39,70]. This movement has been facilitated in large part by the emergence of switch technology in Ethernet networks, which can increase determinism [59]. Ethernet has become a strong contender in the safety networking for the same reasons. In summary, Ethernet (1) has achieved dominance in the diagnostics domain primarily due to its speed, support for large data sizes, and web friendliness; (2) is achieving dominance in the control domain due mostly to the advent of switched networks and the resulting determinism, and (3) has become a strong contender in the safety domain due to the determinism capability as well as the ability to partition networks, for example, to support diagnostics, control, and safety on the same physical network [53,90].

Even more recently, there has been a strong consideration of wireless as the networking medium at all levels to support all functionalities, though it is not clear to what extent wireless will successfully supplant wired technologies. Research into characterization of wireless technologies in manufacturing environment will help to facilitate this movement to wireless [4,17]. It is the authors' opinion that a large portion of Ethernet solutions, especially at the higher levels, and in the domains of diagnostics and, to a lesser extent, control, will be replaced by wireless over the next decade [57].

The body of research around control networks is very deep and diverse. Networks present not only challenges of timing in control systems, but also opportunities for new control directions enabled by the distribution capabilities of control networks. For example, there has been a significant amount of work on networked control systems (NCSs) [5,7,16]. Despite this rich body of work, one important aspect of control networks remains relatively untouched in the research community, namely, the speed of the devices on the network. Practical application of control networks often reveals that device speeds dominate in determining the system performance to the point that the speed and determinism (network QoS parameters) of the network protocol are irrelevant [47,59,62]. Recent experimental work has shown that actual measured delays can vary significantly from manufacturer specifications [82]. Unfortunately, the academic focus on networks in the analysis of control network systems, often with assumptions of zero delay of devices, has served to further hide the fact that device speed is often the determining factor in assessing the NCS performance.

In light of the strong and diverse academic and industry focus on networks as well as the myriad of network technologies, the prospect of choosing a *best* network technology for a particular environment is ominous. The choice should be governed by a number of factors that balance upfront and recurring costs and performance to an objective function that best fits the particular environment. Thus, the best solution is necessarily application dependent [54]. A methodology is needed that supports the

application of theory, experimental results, and analytics to a particular application domain so that the trade-offs can be quantified and a best solution determined [55].

This chapter explores the application of NCSs in the domains of control, diagnostics, and safety in manufacturing [57]. Specifically, Section 2.2 explores the parameterization of networks with respect to balancing QoS capabilities. This parameterization provides a basis for differentiating industrial network types. Section 2.3 introduces common network protocol approaches and differentiates them with respect to functional characteristics. This includes a discussion of all forms of Ethernet being employed in NCSs, from switched Ethernet to real-time Ethernet (RTE) and wireless Ethernet, as well as technologies that are leveraged to support Ethernet in various NCS environments, such as time synchronization. The importance of device performance is also explored. Section 2.4 presents a method for NCS evaluation that includes theoretical, experimental, and analytical components. In Section 2.5, network applications within the domain of manufacturing are explored; these include application subdomains of control, diagnostics, and safety, as well as different levels of control in the factory such as machine level, cell level, and system level. Within this section, an example is presented of a multilevel factory networking solution that supports networked control, diagnostics, and safety. This chapter concludes with a discussion of future trends in industrial networks with a focus on the continued movement to wireless networking technology.

## 2.2 Parameterization of Industrial Networks

---

The function of a network is to transmit data from one node to another. Different types of industrial networks use different mechanisms for allocating the bandwidth on the network to individual nodes and for resolving contentions among nodes. Briefly, there are three common mechanisms for allocating bandwidth: time-division multiplexing (TDM), random access (RA) with collision detection (CD), and RA with collision avoidance (CA). In TDM, the access time to the network is allocated in a round-robin fashion among the nodes, either by passing a token (e.g., ControlNet) or having a master poll the slaves (e.g., AS-I). Because the bandwidth is carefully allocated, no collisions will occur. If RA to the network is allowed, collisions can occur if two nodes try to access the network at the same time. The collision can be destructive or nondestructive. With a destructive collision, the data are corrupted, and both nodes must retransmit (e.g., hub-based Ethernet). With a nondestructive collision, one node keeps transmitting and the other backs off (e.g., CAN); in this case, the data are not corrupted. CA mechanisms (e.g., WiFi) use random delay times to minimize the probability that two nodes will try to transmit at the same time, but collisions can still occur. Collisions can be completely avoided if the network is effectively set up in a star configuration with intelligent routing, as is done with switched Ethernet. Network collision arbitration and avoidance mechanisms, and the most common network protocols that use them, will be discussed in detail in Section 2.3.

Although any network protocol can be used to send data, each network protocol has its pros and cons. In addition to the protocol, the type and amount of data to be transmitted are also important when analyzing the network performance: Will the network carry many small packets of data frequently or large packets of data infrequently? Must the data arrive before a given deadline? How many nodes will be competing for the bandwidth, and how will the contention be handled?

The QoS of a network is a multidimensional parameterized measure of how well the network performs its function; the parameter measures include the speed and bandwidth of a network (how much data can be transmitted in a time interval), the delay and jitter associated with data transmission (time for a message to reach its destination and repeatability of this time), and the reliability and security of the network infrastructure [89]. When using networks for control, it is often important to assess determinism as a QoS parameter, specifically evaluating whether message end-to-end communication times can be predicted exactly or approximately, and whether these times can be bounded.

In this section, we will review the basic QoS measures of industrial networks, with a focus on time delays, as they are typically the most important element determining the capabilities of an industrial

control system. In Section 2.3, more detailed analysis of the delays for specific networks will be given. In Section 2.4, a methodology will be presented for evaluating the many dimensions of QoS along with other factors as they relate to the particular application environment.

### 2.2.1 Speed and Bandwidth

The *bandwidth* of an industrial network is given in terms of the number of bits that can be transmitted per second. Industrial networks vary widely in bandwidth, including CAN-based networks, which have a maximum data rate of 1 Mb/s, and Ethernet-based networks, which can support data rates upwards of 10 Gb/s,\* although most networks currently used in the manufacturing industry are based on 100 Mb/s or 1 Gb/s Ethernet. DeviceNet, a commonly used network in the manufacturing industry, is based on CAN and has a maximum data rate of 500 kb/s. The *speed* is the inverse of the data rate, thus the time to transmit 1 bit of data over the network is  $T_{\text{bit}} = 1 \mu\text{s}$  for 1 Mb/s CAN and 10 ns for 100 Mb/s Ethernet.

The data rate of a network should be considered together with the packet size and overhead. Data are not just sent across the network one bit at a time. Instead, data are encapsulated into packets, with headers specifying, for example, the source and destination addresses of the packet, and often a checksum for detecting the transmission errors. All industrial networks have a minimum packet size; for example, the minimum packet size is 47 bits for CAN and 64 bytes for Ethernet. A minimum *interframe time* between two packets is required between subsequent messages to ensure that each packet can be distinguished individually; this time is specified by the network protocol and is included herein as part of the frame.

The transmission time for a message on the network can be computed from the network's data rate, the message size, and the distance between two nodes. As most of these quantities can be computed exactly (or approximated closely), transmission time is considered a deterministic parameter in a network system. The transmission time can be written as the sum of the frame time and the propagation time:

$$T_{\text{tx}} = T_{\text{frame}} + T_{\text{prop}}$$

where

$T_{\text{frame}}$  is the time required to send the packet across the network

$T_{\text{prop}}$  is the time for a message to propagate between any two devices

As the typical transmission speed in a communication medium is  $2 \times 10^8 \text{ m/s}$ , the propagation time  $T_{\text{prop}}$  is negligible on a small scale. In the worst case, the propagation delays from one end to the other of the network cable for two typical control networks are  $T_{\text{prop}} = 67.2 \mu\text{s}$  for 2500 m Ethernet,<sup>†</sup> and  $T_{\text{prop}} = 1 \mu\text{s}$  for 100 m CAN. The propagation delay is not easily characterized because the distance between the source and destination nodes is not constant among different transmissions, but typically it is less than 1  $\mu\text{s}$  (if the devices are less than 100 m apart). Some networks (e.g., Ethernet) are not a single trunk but have multiple links connected by hubs, switches, and/or routers that receive, store, and forward packets from one link to another. The delays associated with these interconnections can dominate propagation delays in a complex network and must also be considered when determining the transmission delays [61].

The frame time,  $T_{\text{frame}}$ , depends on the size of the data, the overhead, any padding, and the bit time. Let  $N_{\text{data}}$  be the size of the data in terms of bytes,  $N_{\text{ovhd}}$  be the number of bytes used as overhead,  $N_{\text{pad}}$  be the number of bytes used to pad the remaining part of the frame to meet the minimum frame size

\* 10 Gb/s solutions are available with fiber-optic cabling.

<sup>†</sup> Because Ethernet uses Manchester biphase encoding, two bits are transmitted on the network for every bit of data.

requirement, and  $N_{\text{stuff}}$  be the number of bytes used in a stuffing mechanism (on some protocols).<sup>\*</sup> The frame time can then be expressed by the following equation:

$$T_{\text{frame}} = [N_{\text{data}} + N_{\text{ovhd}} + N_{\text{pad}} + N_{\text{stuff}}] \times 8 \times T_{\text{bit}} \quad (2.1)$$

In Ref. [45], these values are explicitly described for Ethernet, ControlNet, and DeviceNet protocols.

The effective bandwidth of a control network will depend not only on the physical bandwidth, but also on the efficiency of encoding the data into packets (how much overhead is needed in terms of addressing and padding), how efficiently the network operates in terms of (long or short) interframe times, and whether network time is wasted due to message collisions. For example, to send one bit of data over a 500 kb/s CAN network, a 47 bit message is needed, requiring 94  $\mu\text{s}$ . To send the same one bit of data over 10 Mb/s Ethernet, an 84-byte message is needed (64-byte frame size plus 20 bytes for interframe separation), requiring a 67.2  $\mu\text{s}$   $T_{\text{frame}}$ . Thus, even though the raw network speed is 20 times faster for Ethernet, the frame time is only 30% lower than CAN. This example shows that the network speed is only one factor that must be considered when computing the effective bandwidth of a network.

### 2.2.2 Delay and Jitter

The *time delay* on a network is the total time between the data being available at the source node (e.g., sampled from the environment or computed at the controller) and it being available at the destination node (received and decoded, where the decode level depends on where the delay is evaluated within the end-to-end communication). The *jitter* is the variability in the delay. Many control techniques have been developed for systems with constant time delays [21,78], but variable time delays can be much more difficult to compensate for, especially if the variability is large. Although time delay is an important factor to consider for control systems implemented over industrial networks, it generally is not well defined or studied by standards organizations defining network protocols [94].

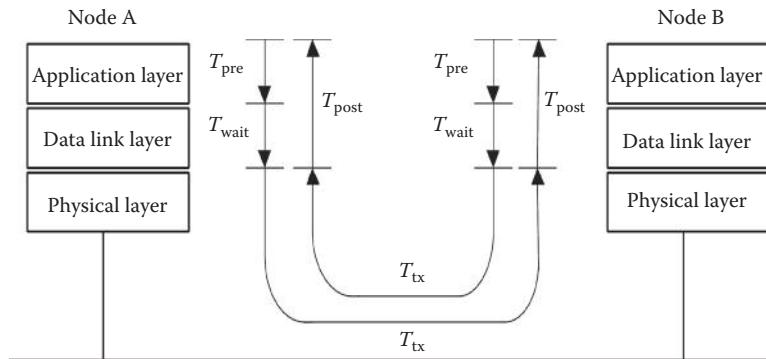

To further explain the different components that go into the time delay and jitter on a network, consider the timing diagram in Figure 2.1 showing how messages are sent across a network. The source node A captures (or computes) the data of interest. There is some preprocessing that must be done to encapsulate the data into a message packet and encode it for sending over the network; this time is denoted  $T_{\text{pre}}$ . If the network is busy, the node may need to wait for some time  $T_{\text{wait}}$  for the network to become available. This waiting time is a function of the MAC mechanism of the protocol, which is categorized as part of layer 2 of the OSI model. Then, the message is sent across the network, taking time  $T_{\text{tx}}$  as described in Section 2.2.1. Finally, when the message is received at the destination node B, it must be decoded and postprocessed, taking time  $T_{\text{post}}$ . Thus, the total time delay can be expressed by the following equation:

$$T_{\text{delay}} = T_{\text{pre}} + T_{\text{wait}} + T_{\text{tx}} + T_{\text{post}} \quad (2.2)$$

The waiting time  $T_{\text{wait}}$  can be computed based on the network traffic, how many nodes there are, the relative priority of these nodes and the messages they are sending, and how much data they send. The pre- and postprocessing times  $T_{\text{pre}}$  and  $T_{\text{post}}$  depend on the devices. Often the network encoding and decoding are implemented in software or firmware. These times are rarely given as part of device specifications. As they can be the major sources of delay and jitter in a network, a more detailed discussion of these delays is given here.

---

\* The bit-stuffing mechanism in DeviceNet is as follows: if more than 5 bits in a row are “1,” then a “0” is added and vice versa. Ethernet uses Manchester biphasic encoding and, therefore, does not require bit stuffing.

**FIGURE 2.1** Timing diagram showing time spent sending a message from a source node to a destination node.

### 2.2.2.1 Pre- and Postprocessing Times

The preprocessing time at the source node depends on the device software and hardware characteristics. In many cases, it is assumed that the preprocessing time is constant or negligible. However, this assumption is not true in general; in fact, there may be noticeable differences in processing time characteristics between similar devices, and these delays may be significant. The postprocessing time at the destination node is the time taken to decode the network data into the physical data format and output it to the external environment.

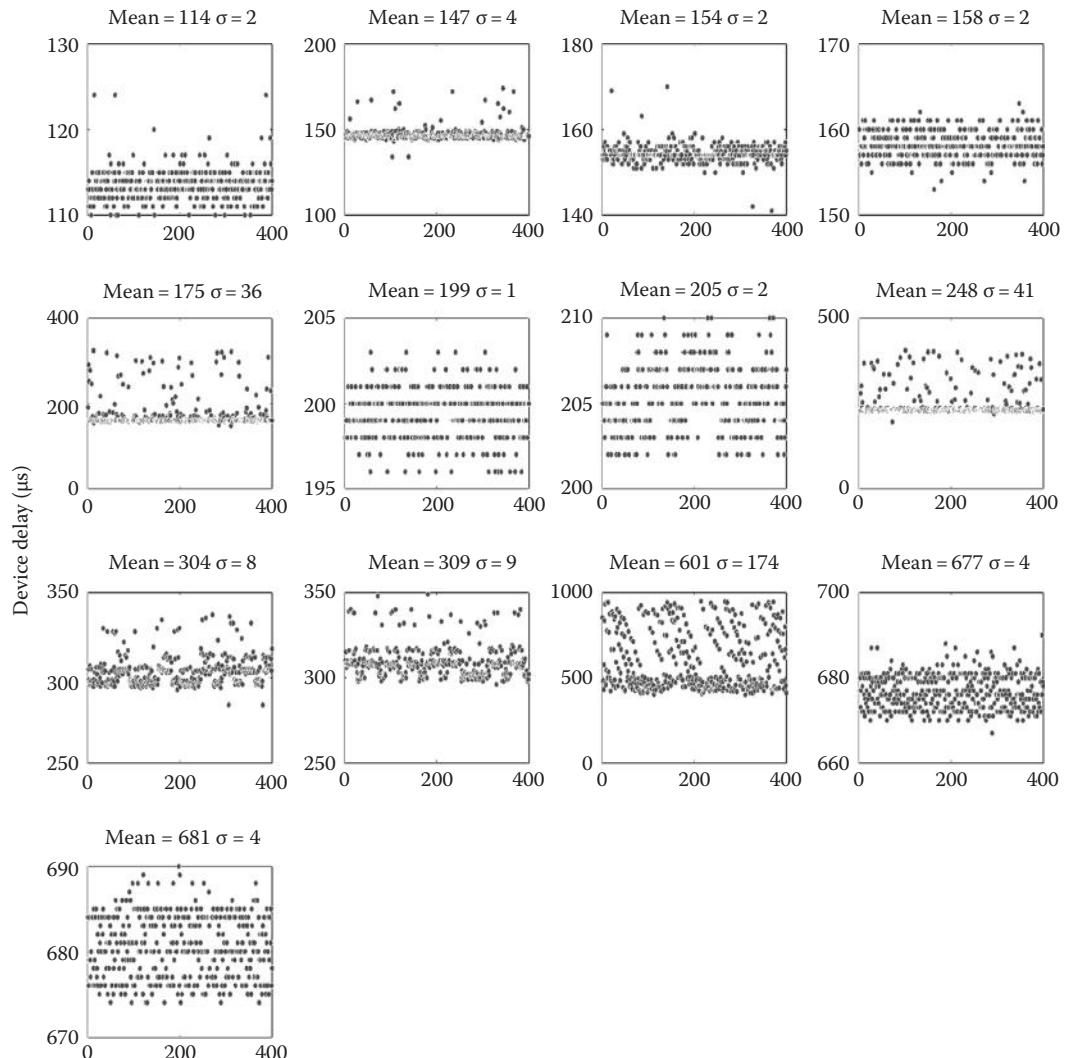

In practical applications, it is very difficult to identify each individual timing component. However, a very straightforward experiment can be run with two nodes on the network. The source node A repeatedly requests data from a destination node B and waits until it receives a response before sending another request. Because there are only two nodes on the network, there is never any contention, and thus the waiting time is zero. The request-response frequency is set low enough that no messages are queued up at the sender's buffer. The message traffic on the network is monitored, and each message is time-stamped. The processing time of each request-response pair, that is,  $T_{\text{post}} + T_{\text{pre}}$ , can be computed by subtracting the transmission time from the time difference between the request and response messages. Because the time stamps are recorded all at the same location, the problem of time synchronization across the network is avoided.

Figure 2.2 shows the experimentally determined device delays for DeviceNet devices utilizing the aforementioned setup [47,59]. Note that for all devices, the mean delay is significantly longer than the minimum frame time in DeviceNet (94  $\mu$ s), and the jitter is often significant. The uniform distribution of processing time at some of the devices is due to the fact that they have an internal sampling time, which is mismatched with the request frequency. Hence, the processing time recorded here is the sum of the actual processing time and the waiting time inside the device. The tested devices include photoeyes, input-output terminal blocks, mass flow controllers, and other commercially available DeviceNet devices.

A key point that can be taken from the data presented in Figure 2.2 is that the device processing time can be substantial in the overall calculation of  $T_{\text{delay}}$ . In fact, this delay often dominates over network delays. Thus, when designing industrial network systems to be used for control, device delay and delay variability should be considered as important factors when choosing the components. In the same manner, controller devices such as off-the-shelf PLCs typically specify scan times and interscan delays on the order of a few milliseconds, thus these controller delays can also dominate over network delays.

### 2.2.2.2 Waiting Time at Source Nodes

A message may spend time waiting in the queue at the sender's buffer and could be blocked from transmitting by other messages on the network. Depending on the amount of data the source node must send

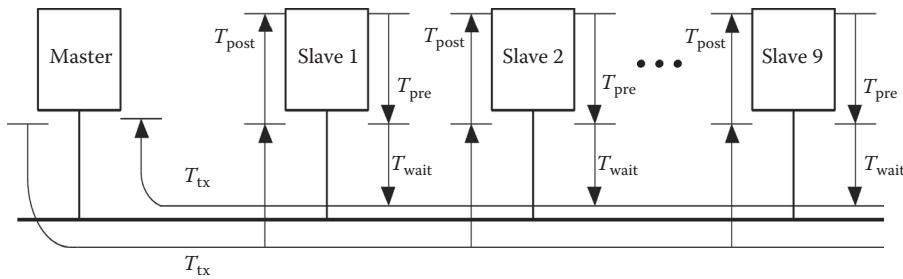

**FIGURE 2.2** Device delays for DeviceNet devices in a request-response setup as described in Section 2.2.2.1. Delays are measured with only source and destination node communicating on the network and thus focus only on device delay jitter as described in Section 2.2.2. The stratification of delay times seen in some nodes is due to the fact that the smallest time that can be recorded is 1 μs.

and the traffic on the network, the waiting time may be significant. The main factors affecting waiting time are network protocol, message connection type, and network traffic load.

For control network operation, the message connection type must be specified. In a master-slave (MS) network,\* there are three types of message connections: strobe, poll, and change of state (COS)/cyclic. In a *strobe* connection, the master device broadcasts a message to a group of devices, and these devices respond with their current condition. In this case, all devices are considered to sample new information

\* In this context, an MS network refers to operation from an end-to-end application layer perspective. Master node applications govern the method by which information is communicated to and from their slave node applications. Note that, as it will be described further in Section 2.3.1, application layer MS behavior does not necessarily require corresponding MS behavior at the MAC layer.

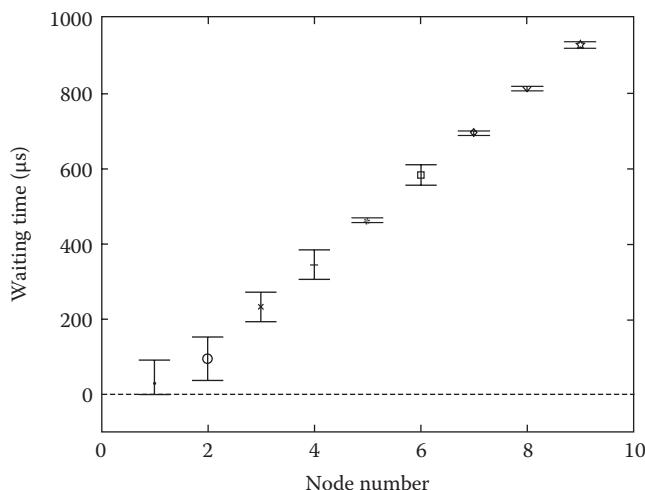

**FIGURE 2.3** Waiting time diagram for a strobe message configuration.

at the same time. In a *poll* connection, the master sends individual messages to the polled devices and requests update information from them. Devices respond with new signals only after they have received a poll message. *COS/cyclic* devices send out messages either when their status is changed (*COS*) or periodically (*cyclic*). Although the *COS/cyclic* connection seems most appropriate from a traditional control systems point of view, strobe and poll are commonly used in industrial control networks [20].

For example, consider the strobe message connection in Figure 2.3. If Slave 1 is sending a message, the other eight devices must wait until the network medium is free. In a CAN-based DeviceNet network, it can be expected that Slave 9 will encounter the most waiting time because it has a lower priority on this priority-based network. However, in any network, there will be a nontrivial waiting time after a strobe, depending on the number of devices that will respond to the strobe.

Figure 2.4 shows experimental data of the waiting time of nine identical devices with a strobed message connection on a DeviceNet network; 200 pairs of messages (request and response) were collected. Each symbol denotes the mean, and the distance between the upper and lower bars equals two standard deviations. If these bars are over the limit (maximum or minimum), then the value of the limit is used instead. It can be seen in Figure 2.4 that the average waiting time is proportional to the node number (i.e., priority). Although all these devices have a very low variance of processing time, the devices with the lowest node numbers have a larger variance of waiting time than the others, because the variance of processing time occasionally allows a lower-priority device to access the idle network before a higher-priority one.

**FIGURE 2.4** Nine identical devices with strobed message connection.

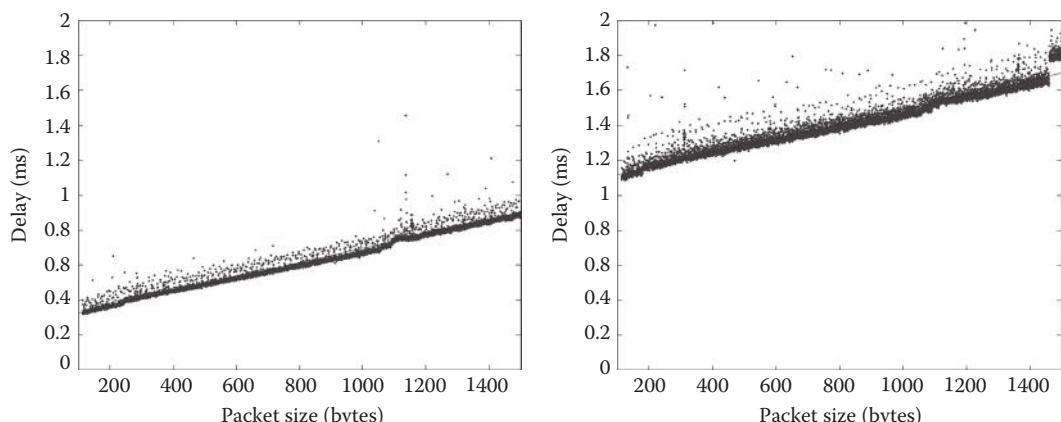

### 2.2.3 Wired and Wireless QoS Metrics

The advent of wireless has added a new dimension to the QoS metric set that focuses heavily on the QoS of the communication medium with respect to external factors. With wired networks, reliability of data transmission is an important factor to consider. For example, some networks are physically more vulnerable than others to data corruption by electromagnetic interference [4]. This issue is much more prevalent in wireless networks as there is a much higher potential exposure to external factors that can reduce the quality of the communication medium. Both wired and wireless networks can use handshaking by sending of acknowledgment (ACK) messages to increase the reliability. If no ACK message is received, the message is resent. These handshaking techniques increase the reliability of a network, but also add to the required overhead and thus decrease the overall effective bandwidth.

Wireless networks also commonly utilize techniques such as frequency hopping and transmission on multiple frequency channels to make the transmission more robust to radio frequency (RF) interference sources such as other industrial wireless networks, cell phones, and manufacturing equipment such as spot welders that generate RF noise [13,101]. These frequency hopping protocols can be quite elaborate and often distinguish the robustness of one wireless technology over another.

Security is another factor that must be considered for both wired and wireless networks. For all networked systems, security is of special concern when networks and operating systems are used that can be vulnerable to Internet-based attacks and viruses [22]. Most industrial fieldbuses were not designed to be highly secure, relying mainly on physical isolation of the network instead of authentication or encryption techniques. When some type of security is provided, the intent is more commonly to prevent accidental misuse of process data than to thwart malicious network attacks [96]. For wireless, the security issue has another dimension in that the transmissions themselves can be intercepted rather easily by a listening device that understands the transmission protocol. The most common solution to this problem is encryption of the transmission through mechanisms such as virtual private network (VPN). While VPN provides for secure keyed tunnels, mechanisms such as these also introduce transmission overhead and delay as shown in Figure 2.5. Thus, the cost of security must be considered when evaluating the (especially wireless) networked solutions.

Other QoS and related metrics such as device power requirements, distances between nodes, and desire to *not* generate interference (i.e., coexist) with other networks can weigh heavily in the choice of

**FIGURE 2.5** Example of the impact of VPN security encryption on Ethernet network performance (the figure on the left is the round-trip delay measured for user datagram protocol [UDP]\* packet transmission on a 100 Mbps switched Ethernet network; the figure on the right is the delay measured for the same system, but with VPN encryption added).

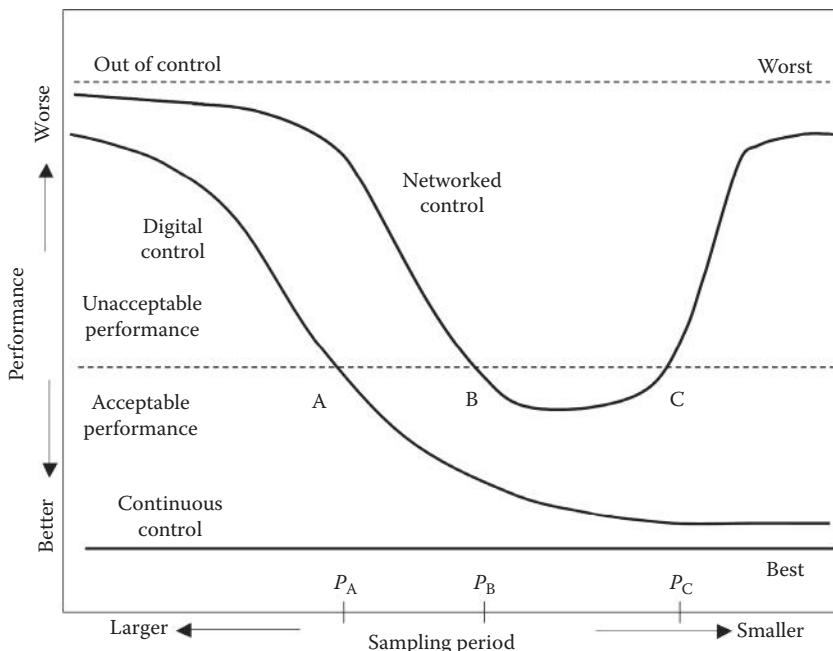

\* UDP is a relatively fast unacknowledged communication service utilized in Ethernet, often utilized as a baseline in defining Ethernet system performance.

a wireless protocol and solution [4,13,17]. The key to evaluating solutions against metrics is to be able to quantify all of the important metrics and evaluate them collectively in the application environment. This process is discussed in Section 2.4.

### 2.2.4 Network QoS versus System Performance

When a network is used in the feedback loop of a control system, the performance of the system depends not only on the QoS of the network, but also on how the network is used (e.g., sample time, message scheduling, and node prioritization) [47,49]. For example, consider a continuous-time control system that will be implemented with networked communication. Figure 2.6 shows how the control performance varies vs. sampling period in the cases of continuous control, digital control, and networked control. The performance of the continuous control system is independent of the sample time (for a fixed control law). The performance of the digital control system approaches the performance of the continuous-time system as the sampling frequency increases [30]. In an NCS, the performance is worse than the digital control system at low frequencies, due to the extra delay associated with the network (as described in Section 2.2.2). Also, as the sampling frequency increases, the network starts to become saturated, data packets are lost or delayed, and the control performance rapidly degrades. Between these two extremes lies a *sweet spot* where the sample period is optimized to the control and networking environment. Note that, as discussed in Section 2.2.2, the device delay can comprise a significant portion of the end-to-end delay; thus, the optimal sampling period can often be more a function of the device speed than the network speed, especially for faster networks with minimal collisions, such as switched Ethernet.

Typical performance criteria for feedback control systems include overshoot to a step reference, steady-state tracking error, phase margin, or time-averaged tracking error [29]. The performance criteria in Figure 2.6 can be one of these or a combination of them. Due to the interaction of the network and control requirements, the selection of the best sampling period is a compromise. More details on the performance computation and analysis of points A, B, and C in Figure 2.6 can be found in [47], including simulation and experimental results that validate the overall shape of the chart.

**FIGURE 2.6** Performance comparison of continuous control, digital control, and networked control, as a function of sampling frequency.

## 2.3 Differentiation of Industrial Networks

Networks can be differentiated either by their protocol (at any or all levels of the ISO–OSI seven-layer reference model [3]) or by their primary function (control, diagnostics, and safety). These dimensions of differentiation are somewhat related. In this section, we first define how network protocols are categorized technically with respect to timing and then discuss the different types of protocols that are commonly used in industrial networks. In Section 2.5, we describe how these different types of networks are used for different functions.

### 2.3.1 Categorization of Networks

When evaluating the network QoS parameters associated with timeliness, determinism, etc., the protocol functionality at the data link layer is the primary differentiator among network protocol types. Specifically, the MAC sublayer protocol within the data link layer describes the protocol for obtaining access to the network. The MAC sublayer thus is responsible for satisfying the time-critical/real-time response requirement over the network and for the quality and reliability of the communication between network nodes [41]. The discussion, categorization, and comparison in this section thus focus on the MAC sublayer protocols.

As noted in Section 2.2, there are three main types of medium access control used in control networks: TDM (such as MS or token-passing [TP]), RA with retransmission when collisions occur (e.g., Hub-based Ethernet and most wireless mechanisms), and RA with prioritization for collision arbitration (e.g., CAN). Implementations can be hybrids of these types; for example, switched Ethernet combines time-division multiplexed (TDM) and RA. Note that, regardless of the MAC mechanism, most network protocols support some form of MS communication at the application level; however, this appearance of TDM at the application level does not necessarily imply the same type of parallel operation at the MAC level. Within each of these three MAC categories, there are numerous network protocols that have been defined and used.

Surveys of the types of control networks used in industry show a wide variety of networks in use; see Table 2.1 and also [31,32,48,65,79,94]. Networks can be classified according to type: RA with CD, CA, or arbitration on message priority (AMP); or TDM using TP or MS.

### 2.3.2 Time-Division Multiplexing

TDM can be accomplished in one of two ways: MS or TP. In an MS network, a single master polls multiple slaves. Slaves can send data over the network only when requested by the master; there are no

**TABLE 2.1** Popular Fieldbuses

Network	Type	Users (%)	Max. Speed	Max. Devices
Ethernet TCP/IP	RA/CD	78	1 Gb/s	1024
Modbus	TDM/MS	48	35 Mb/s	32
DeviceNet	RA/AMP	47	500 kb/s	64
ControlNet	TDM/TP	39	5 Mb/s	99
WiFi (IEEE 802.11b)	RA/CA	35	11 Mb/s	Not specified
Modbus TCP	TDM/MS	34	1 Gb/s	256
PROFIBUS-DP	TDM/MS and TP	27	12 Mb/s	127
AS-I	TDM/MS	17	167 kb/s	31

Note: The maximum speed depends on the physical layer, not the application-level protocol. Note that the totals are more than 100% because most companies use more than one type of bus.

collisions, as the data transmissions are carefully scheduled by the master. ATP network has multiple masters or peers. The token bus protocol (e.g., IEEE 802.4) allows a linear, multidrop, tree-shaped, or segmented topology [100]. The node that currently has the token is allowed to send data. When it has finished sending data, or the maximum token holding time has expired, it *passes* the token to the next logical node on the network. If a node has no message to send, it just passes the token to the successor node. The physical location of the successor is not important because the token is sent to the logical neighbor. Collision of data frames does not occur, as only one node can transmit at a time. Most TP protocols guarantee a maximum time between network accesses for each node, and most also have provisions to regenerate the token if the token holder stops transmitting and does not pass the token to its successor. AS-I, Modbus, and Interbus-S are typical examples of MS networks, while PROFIBUS and ControlNet are typical examples of TP networks. Each peer node in a PROFIBUS network can also behave like a master and communicate with a set of slave nodes during the time it holds the token [74].

TP networks are deterministic because the maximum waiting time before sending a message frame can be characterized by the token rotation time. At high utilizations, TP networks are very efficient and fair. There is no time wasted on collisions, and no single node can monopolize the network. At low utilizations, they are inefficient due to the overhead associated with the TP protocol. Nodes without any data to transmit must still receive and pass the token.

Waiting time in a TDM network can be determined explicitly once the protocol and the traffic to be sent on the network are known. For TP networks, the node with data to send must first wait to receive the token. The time it needs to wait can be computed by adding up the transmission times for all of the messages on nodes ahead of it in the logical ring. For example, in ControlNet, each node holds the token for a minimum of 22.4  $\mu$ s and a maximum of 827.2  $\mu$ s.

In MS networks, the master typically polls all slaves every cycle time. Slaves cannot transmit data until they are polled. After they are polled, there is no contention for the network so the waiting time is zero. If new data are available at a slave (e.g., a limit switch trips), the slave must wait until it is polled before it can transmit its information. In many MS networks (such as AS-I), the master will only wait for a response from a slave until a timer has expired. If the slave does not respond within the timeout value for several consecutive polls, it is assumed to have dropped off the network. Also, every cycle time, the master attempts to poll an inactive slave node (in a round-robin fashion) [8]. In this way, new slaves can be added to the network and will be eventually noticed by the master.

### 2.3.3 RA with Collision Arbitration: CAN (CSMA/AMP)

CAN is a serial communication protocol developed mainly for applications in the automotive industry, also capable of offering good performance in other time-critical industrial applications. The CAN protocol is optimized for short messages and uses a carrier sense multiple access (CSMA)/AMP medium access method. Thus, the protocol is message oriented, and each message has a specific priority that is used to arbitrate access to the bus in case of simultaneous transmission. The bit stream of a transmission is synchronized on the start bit, and the arbitration is performed on the following message identifier, in which a logic zero is dominant over a logic one. A node that wants to transmit a message waits until the bus is free and then starts to send the identifier of its message bit by bit. Conflicts for access to the bus are solved during transmission by an arbitration process at the bit level of the arbitration field, which is the initial part of each frame. Hence, if two devices want to send messages at the same time, they first continue to send the message frames and then listen to the network. If one of them receives a bit different from the one it sends out, it loses the right to continue to send its message, and the other wins the arbitration. With this method, an ongoing transmission is never corrupted, and collisions are nondestructive [45].

DeviceNet is an example of a technology based on the CAN specification that has received considerable acceptance in manufacturing applications at the device level. The DeviceNet specification is based on the standard CAN with an additional application and physical layer specification [20,45].

The DeviceNet frame has a total overhead of 47 bits, which includes start of frame, arbitration (11-bit identifier), control, cyclic redundancy check (CRC), ACK, end of frame, and intermission fields. The size of a data field is between 0 and 8 bytes. The DeviceNet protocol uses the arbitration field to provide source and destination addressing as well as message prioritization.

The major disadvantage of CAN compared with the other networks is the slow data rate, limited by the network length. Because of the bit synchronization, the same data must appear at both ends of the network simultaneously. DeviceNet has a maximum data rate of 500 kb/s for a network of 100 m. Thus, the throughput is limited compared with other control networks. CAN is also not suitable for the transmission of messages of large data sizes, although it does support fragmentation of data that is more than 8 bytes into multiple messages.

### 2.3.4 Ethernet-Based Networks

The proliferation of the Internet has led to the pervasiveness of Ethernet in both homes and businesses. Because of its low cost, widespread availability, and high communication rate, Ethernet has been proposed as the ideal network for industrial automation [19,70]. Previously, some had questioned whether Ethernet would become the de facto standard for automation networks, making all other solutions obsolete [27,88]. The concerns primarily centered around the fact that standard Ethernet (IEEE 802.3) is not a deterministic protocol, and network QoS cannot be guaranteed [19,45]. Collisions can occur on the network, and messages must be retransmitted after random amounts of time. To address this inherent nondeterminism, many different *flavors* of Ethernet were proposed for use in industrial automation. Several of these add layers on top of standard Ethernet or on top of the TCP/IP protocol suite to enable the behavior of Ethernet to be more deterministic [25,27,42]. In this way, the network solutions may no longer be *Ethernet* other than at the physical layer; they may use the same hardware but are not interoperable. As noted in [48], message transmission does not always lead to successful communication: “just because you can make a telephone ring in Shanghai doesn’t mean you can speak Mandarin.” An effective and accepted solution in recent years has been the utilization of switches to manage the Ethernet bandwidth utilizing a TDM approach among time-critical nodes. Rather than repeat the survey of approaches to industrial Ethernet in [25], in this section, the general MAC protocol of Ethernet is outlined, and the general approaches that are used with Ethernet for industrial purposes are discussed.

Ethernet is an RA network, also often referred to as CSMA. Each node listens to the network and can start transmitting at any time that the network is free. Typically, once the network is clear, a node must wait for a specified amount of time (the interframe time) before sending a message. To reduce collisions on the network, nodes wait an additional random amount of time called the backoff time before they start transmitting. Some types of messages (e.g., MAC layer ACKs) may be sent after a shorter interframe time. Priorities can be implemented by allowing for shorter interframe times for higher-priority traffic. However, if two nodes start sending messages at the exact same time (or if the second node starts transmitting before the first message arrives at the second node), there will be a collision on the network. Collisions in Ethernet are destructive; the data are corrupted, and the messages must be resent.

In the remainder of this section, various flavors and concepts associated with wired Ethernet are discussed.

#### 2.3.4.1 Hub-Based Ethernet (CSMA/CD)

Hub-based Ethernet uses hub(s) to interconnect the devices on a network; this type of Ethernet is common in the office environment. When a packet comes into one hub interface, the hub simply broadcasts the packet to all other hub interfaces. Hence, all of the devices on the same network receive the same packet simultaneously, and message collisions are possible. Collisions are dealt with utilizing the CSMA/CD protocol as specified in the IEEE 802.3 network standard [9,14,92].

This protocol operates as follows: when a node wants to transmit, it listens to the network. If the network is busy, the node waits until the network is idle; otherwise, it can transmit immediately (assuming an interframe delay has elapsed since the last message on the network). If two or more nodes listen to the idle network and decide to transmit simultaneously, the messages of these transmitting nodes collide, and the messages are corrupted. While transmitting, a node must also listen to detect a message collision. On detecting a collision between two or more messages, a transmitting node transmits 32 jam bits and waits a random length of time to retry its transmission. This random time is determined by the standard binary exponential backoff algorithm: The retransmission time is randomly chosen between 0 and  $(2^i)$  slot times, where  $i$  denotes the  $i$ th collision event detected by the node, and one slot time is the minimum time needed for a round-trip transmission. However, after 10 collisions have been reached, the interval is fixed at a maximum of 1023 slots. After 16 collisions, the node stops attempting to transmit and reports failure back to the node microprocessor. Further recovery may be attempted in higher layers [92].

The Ethernet data payload size is between 46 and 1500 bytes. There is a nonzero minimum data size requirement because the standard states that valid frames must be at least 64 bytes long (which includes 18 bytes of overhead). If the data portion of a frame is less than 46 bytes, the pad field is used to fill out the frame to the minimum size.

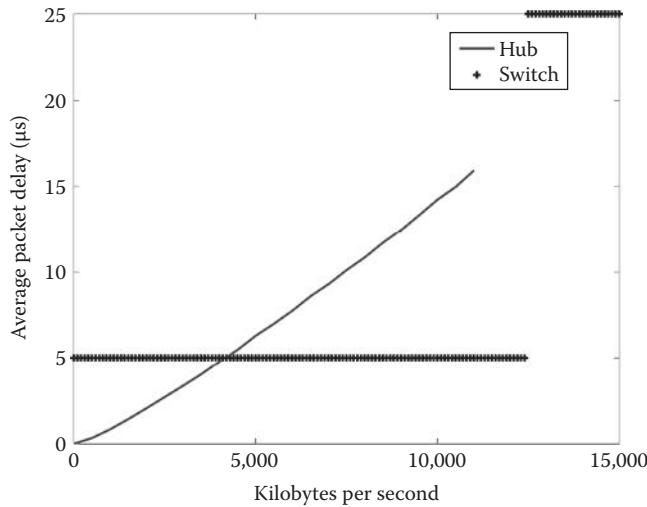

Several solutions were proposed for using this form of Ethernet in control applications [19]; however, to a large extent, these solutions have been rendered moot with the proliferation of switched Ethernet as described below. On the other hand, many of the same issues reappear with the migration to wireless Ethernet for control.

#### 2.3.4.2 Switched Ethernet (CSMA/CA)

Switched Ethernet utilizes switches to subdivide the network architecture, thereby avoiding collisions, increasing network efficiency, and improving determinism. It is widely used in manufacturing applications. The main difference between switch- and hub-based Ethernet networks is the intelligence of forwarding packets. Hubs simply pass on incoming traffic from any port to all other ports, whereas switches learn the topology of the network and forward packets to the destination port only. In a starlike network layout, every node is connected with a single cable to the switch as a full-duplex point-to-point link. Thus, collisions can no longer occur on any network cable. Switched Ethernet relies on this star cluster layout to achieve this collision-free property.

Switches employ the cut-through or store-and-forward technique to forward packets from one port to another, using per-port buffers for packets waiting to be sent on that port. Switches with cut-through first read the MAC address and then forward the packet to the destination port according to the MAC address of the destination and the forwarding table on the switch. On the other hand, switches with store-and-forward examine the complete packet first. Using the CRC code, the switch will first verify that the frame has been correctly transmitted before forwarding the packet to the destination port. If there is an error, the frame will be discarded. Store-and-forward switches are slower, but will not forward any corrupted packets.

Although there are no message collisions on the networks, congestion may occur inside the switch when one port suddenly receives a large number of packets from the other ports. If the buffers inside the switch overflow, messages will be lost [25]. Three main queuing principles are implemented inside the switch in this case. They are first-in-first-out (FIFO) queue, priority queue, and per-flow queue. The FIFO queue is a traditional method that is fair and simple. However, if the network traffic is heavy, the network QoS for timely and fair delivery cannot be guaranteed. In the priority queuing scheme, the network manager reads some of the data frames to distinguish which queues will be more important. Hence, the packets can be classified into different levels of queues. Queues with high priority will be processed first followed by queues with low priority until the buffer is empty. With the per-flow queuing operation, queues are assigned different levels of priority (or weights). All queues are then processed one by one according to priority; thus, the queues with higher priority will generally have higher performance and could potentially block queues with lower priority [19].

**FIGURE 2.7** Packet delay as a function of node traffic for a hub and a switch [61]. Simulation results with base-lines (delay magnitudes) computed from experiments.

Thus, although switched Ethernet can avoid the extra delays due to collisions and retransmissions, it can introduce delays associated with buffering and forwarding. This trade-off can be seen in Figure 2.7, which shows the average packet delay as a function of node traffic. The switch delay is small but constant until the buffer saturates and packets must be resent; the hub delay increases more gradually. Examples of timing analysis and performance evaluation of switched Ethernet can be found in [43,61,72,98].

#### 2.3.4.3 Industrial Ethernet

In an effort to package Ethernet to be more suitable for industrial applications, a number of *industrial Ethernet* protocols have emerged. These include EtherNet/IP, Modbus/TCP, and PROFINET. While these protocol specifications vary to some extent at all levels of the OSI model, they all fundamentally utilize or recommend switched Ethernet technology as defined in the previous subsection. Thus, the differences in performance between industrial Ethernet technologies lie more with the devices than the protocols. For example, in an effort to understand the trade-offs between industrial Ethernet technologies, two common industrial Ethernet protocols, EtherNet/IP and PROFINET, were compared in the areas of architecture principles, technologies incorporated, performance, ease of use, diagnostics capabilities, and network management capabilities\* [56]. As part of this effort, parallel multilayer switched Ethernet testbeds were developed utilizing each of these technologies, where the network layout was representative of the structure being utilized at a leading automotive manufacturer.

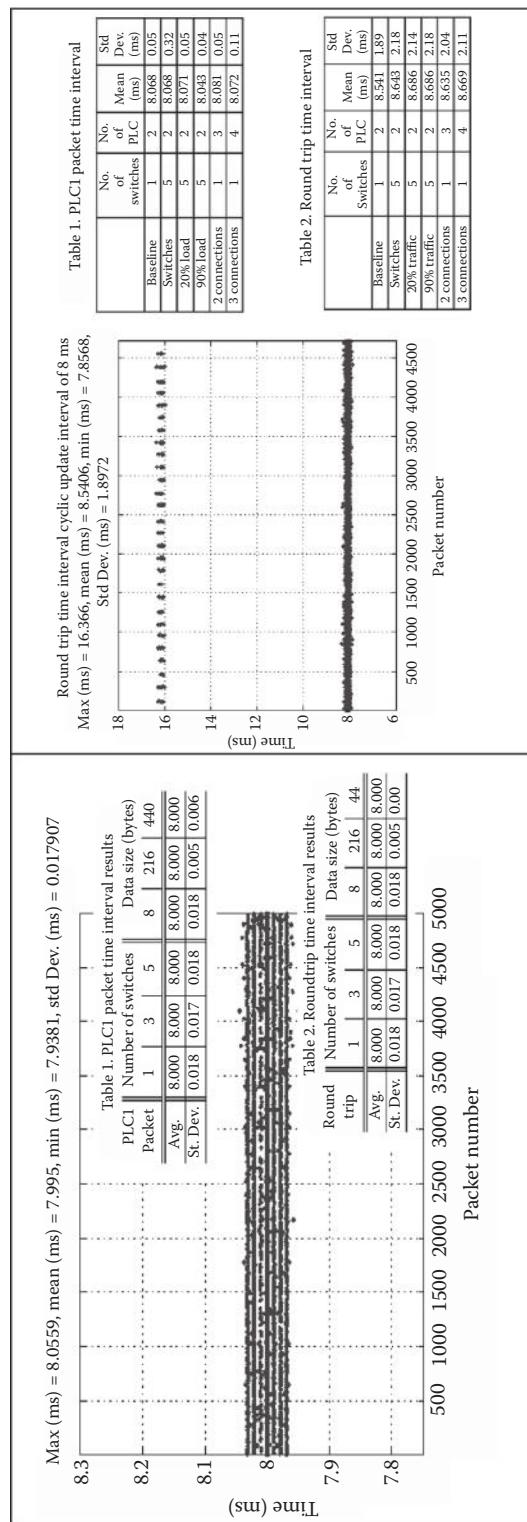

The results indicate that both protocols and protocol devices are fairly similar and are adequate to the task of providing industrial networking capabilities at the PLC level and higher [56]. However, distinct differences were observed, such as those illustrated in Figure 2.8, that indicate additional improvements in device performance may be needed if the solution is to be deployed down to the I/O level.

#### 2.3.4.4 Ethernet for High-Speed and Time-Critical Applications

In the context of NCSs, communication networks that can guarantee the delivery of a transmitted message before a preset operational deadline or within a time interval are called real-time networks. As NCSs are

---

\* Many industrial Ethernet protocols are available, with Modbus/TCP the most widely utilized [32,53]; however, in this instance, the manufacturer was interested in comparing these two industrial Ethernet protocols.

**FIGURE 2.8** Sample plots of round-trip timing measurements for PROFINET (5a) and EtherNet/IP (5b). Here, the round-trip times for packets between two PLCs are plotted for a large number of packets to obtain a time distribution. The embedded tables represent the consolidation of a number of these graphs, where the testing environment is modified in terms of switches between sender and receiver, data size transmitted, and network loading (the plots shown represent the *baseline* case).

being used for faster and more time-critical applications, there is growing need to continually reduce the time interval between messages and to specify operational deadlines with greater precision.

Ethernet networks, while growing in popularity for NCSs, are conventionally best-effort networks without real-time guarantees. Network parameters such as bandwidth, latency, and jitter significantly degrade the real-time performance of an NCS. RTE is a collective term applied to all variants of the core Ethernet technology designed to meet varying degrees of real-time requirements.

The IEC 61784-2 specification [36] includes a categorization of existing RTE technologies into 16 *communication profile families* (CPFs) based on their real-time capabilities. According to the specification, real-time capabilities are graded based on nine performance indicators:

1. Average message latency
2. Number of networked nodes
3. Basic network topology
4. Number of switches between end nodes
5. Throughput (for real-time traffic)
6. Throughput (for coexisting non-real-time traffic)
7. Clock synchronization accuracy
8. Jitter or variation in the period of cyclic messages
9. Redundancy or recovery time

As an example, the automotive manufacturing industry currently defines a high-speed automation network as being able to support a 10 ms poll interval with less than 5 ms latency with about 50 connected nodes [77]. Using the IEC 61784-2 specification, the automotive manufacturing requirements call for an RTE in CPF-2. Networked control systems for motion control (e.g., of servo motors or drives) or for the control of highly dynamic chemical processes (e.g., chemical processes used in the manufacture of semiconductor microchips) may require much shorter time intervals with more precise real-time guarantees.

#### **2.3.4.4.1 Real-Time Ethernet**

Most RTE protocols attempt to first address the nondeterminism in communication delay introduced by the CSMA-CD network arbitration algorithm. A common approach used to eliminate the need for collision arbitration is to specify a single management node or master for the network and to impose an MS, poll-response schedule on all connected nodes (e.g., EtherNet/IP and PROFINET RT). Many real-time protocols additionally mandate the use of specialized network switches to minimize packet collisions. Modern managed switches are able to significantly improve network determinism and speed by prioritizing Ethernet packets if they are generated by a real-time software application, part of high-priority communication session, or containing time-sensitive data. Switches that are able to analyze each packet across multiple layers of the OSI model and adapt accordingly are colloquially called *Smart Switches*. In order to further ensure that the network delay is deterministic and uniform for all the nodes in the network, some RTE protocols use isochronous communication that have either a passed token or a preset communication time table, for example, EtherCAT, SERCOS, Ethernet Powerlink, TCnet, and CIP motion. EtherCAT, for example, uses isochronous transmissions to provide very high speed (60  $\mu$ s round-trip time for a network with 1000 nodes) and very low jitter (1  $\mu$ s variation) between messages [24]. Like many other high-speed automation protocols, EtherCAT requires precise clock synchronization between all connected nodes. Precisely synchronized clocks allow the protocol to more efficiently utilize available bandwidth by reducing the overhead and idle time associated with carrier synchronization. Clock synchronization is so critical to the operation of RTE protocols that many of them include a clock synchronization algorithm. CIP motion, for example, includes a clock synchronization algorithm called CIP Sync [18].

#### 2.3.4.4.2 Precise Clock Synchronization

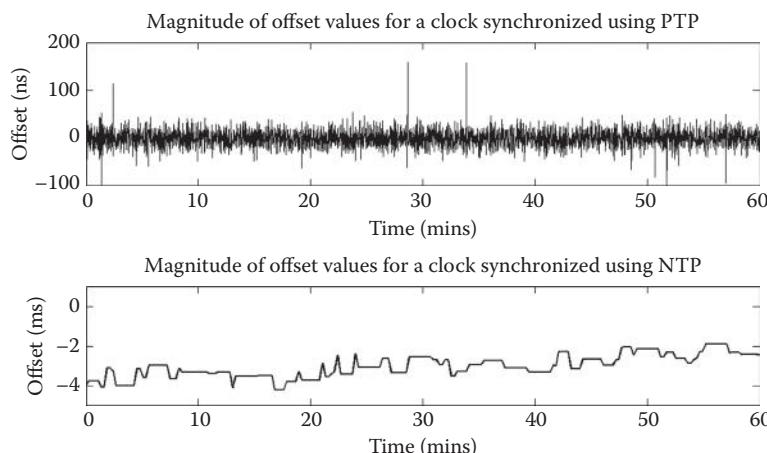

The need for precise clock synchronization across a network extends beyond the requirements of RTEs. Modern manufacturing processes are increasingly data driven. Precisely, time-stamped measurements from machines enable improved diagnosis, control, and optimization.

NCSs in current manufacturing plants generally operate at periodic intervals of 10 ms or larger [6]. In order to ensure the fidelity of sampled events, the authors in [85] suggest that clock synchronization between networked nodes be accurate within 1 ms. Clock synchronization accuracy required for a system is defined by either the maximum sampling rate within the system or the minimum time difference between monitored events. NCS sampling intervals are continually shrinking with tighter process control requirements. For example, the authors in [71,87] identify fault conditions such as electric arcing in the semiconductor fabrication process that occur over a time frame of 1–100  $\mu$ s and state that these fast events may also have to be accurately reported and addressed by an NCS in the future [44]. In order to accurately record and respond to events occurring in the order of microseconds, clocks must presumably be synchronized to within a microsecond of accuracy.

For most applications including personal computing and transactions over the Internet, Network Time Protocol (NTP) [50] is used to synchronize clocks. NTP is an application layer Ethernet protocol designed to synchronize clocks over a variable latency network. When used in a local area network, the NTP algorithm has been shown to achieve submillisecond synchronization accuracy [63] between a time-server and several slaves.

The current state-of-the-art Ethernet clock synchronization algorithm is the IEEE 1588 Version 2 Precision Time Protocol (PTP) [23,37]. It provides submicrosecond clock synchronization of nodes across a local area Ethernet network [2]. The several orders of magnitude improvement in the accuracy of PTP over NTP is gained by using specialized network interface hardware to time stamp and decode PTP packets. The need for specialized network interfaces and switches constrains PTP to be used only in industrial local area networks where submicrosecond-level synchronization is required. Typically, these are applications where diagnostic data must be time-stamped with microsecond accuracy or where the sampled data must be reported at the rate of several kiloHertz mandate the use of PTP. Some RTEs such as SERCOS and EtherCAT adopt PTP as their default clock synchronization algorithm [24,83].

Figure 2.9 shows the result of an experiment where PTP and NTP were used to synchronize several slave clocks to a single time-server over a local Ethernet network subject to background network traffic

**FIGURE 2.9** A comparison of clock offsets derived from the PTP and NTP protocols (note the different time scales on the y-axis).

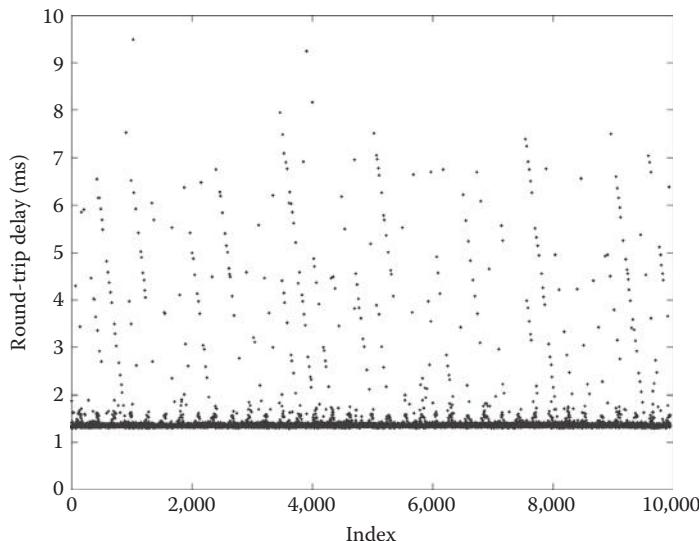

consistent with an automation environment (<50% bandwidth utilization). The figure shows that PTP accuracy is close to five orders of magnitude better for the same network conditions.

### 2.3.5 Impact of Ethernet Application Layer Protocols: OPC

OPC is an open communication standard that is often used in industry to connect SCADA systems and human-machine interfaces (HMIs) to control systems and fieldbus networks [34,51,86].\* It is based on the Microsoft DCOM standard [68] and is the dominant factory-floor application layer protocol utilized for diagnostics and is beginning to be used for sequential control [67]. The main benefit of OPC is that it allows any products that support the standard to share data. Although OPC actually consists of many different communication specifications, its most commonly used form is called data access, which supports both client-server and publisher-subscriber communication models. The server maintains a table of data values, and the client can read or write updates. The overhead associated with OPC (and DCOM in general) is significant, as shown in Figure 2.10. Most of this delay is due to the software implementation of the OPC protocol; OPC was never intended for a real-time environment. However, it is very useful to push data up from the low-level controls to the higher-level supervisors or diagnostic systems. It can also be used to send commands down from the HMIs to the control systems. Its high level of interoperability enables the connection of multiple control systems from different vendors in a unified manner. However, when OPC is used to send control data, the additional delay caused by the higher-level application layer protocol must be considered.

### 2.3.6 Wireless Networks

The move to wireless has resulted in yet another explosion of protocol technologies due to the fact that the change in the media from a wire to air has resulted in the need for higher level of consideration of many external issues (e.g., noise, coexistence, and security) as well as the opportunity for the development of more elaborate protocols to address these issues (e.g., frequency hopping, dynamic transmission power algorithms, and new CA and backoff-style algorithms) [4,13,17]. Table 2.2 provides a high-level

**FIGURE 2.10** Illustration of overhead delay associated with OPC over a 100 Mb/s switched Ethernet network. Mean = 1.5 ms with standard deviation = 0.03 ms; for comparison purposes, the mean UDP round-trip time over the same network is 0.33 ms.

\* While OPC originally stood for *OLE for Process Control*, the official stance of the OPC Foundation is that OPC is no longer an acronym, and the technology is simply known as OPC.

**TABLE 2.2** High-Level Description of Common Wireless Technologies Illustrating Trade-Offs

Characteristic	802.11	Bluetooth	ZigBee
Range	High	Medium, depends on class	Low
Power consumption	High	Medium	Low
Data rate	Very high	High	Low
Optimal data size	High	Medium	Low
Redundancy	Low	Low	High

comparison of three technologies that are utilized in manufacturing that offer somewhat complementary capabilities. From the table, it is clear that, at least at this time, one size does not fit all when it comes to matching a wireless protocol to application requirements. In the remainder of this section, 802.11 and Bluetooth are explored in detail. For additional discussion of ZigBee, see Refs. [13,103].

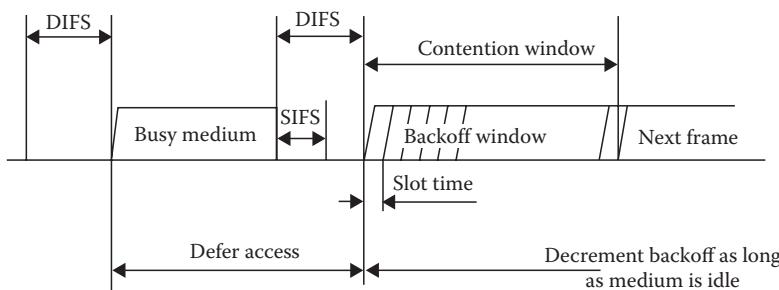

### 2.3.6.1 Wireless Ethernet (CSMA/CA)

Wireless Ethernet, based on the IEEE 802.11 standard, can replace wired Ethernet in a transparent way as it implements the two lowest layers of the ISO-OSI model [3,101]. Besides the physical layer, the biggest difference between 802.11 and 802.3 is in the medium access control. Unlike wired Ethernet nodes, wireless stations cannot *hear* a collision. A CA mechanism is used but cannot entirely prevent collisions. Thus, after a packet has been successfully received by its destination node, the receiver sends a short ACK packet back to the original sender. If the sender does not receive an ACK packet, it assumes that the transmission was unsuccessful and retransmits.

The CA mechanism in 802.11 works as follows. If a network node wants to send while the network is busy, it sets its backoff counter to a randomly chosen value. Once the network is idle, the node waits first for an interframe space and then for the backoff time before attempting to send (see Figure 2.11). If another node accesses the network during that time, it must wait again for another idle interval. In this way, the node with the lowest backoff time sends first. Certain messages (e.g., ACK) may start transmitting after a shorter interframe space; thus, they have a higher priority. Collisions may still occur because of the random nature of the backoff time; it is possible for two nodes to have the same backoff time.

Several refinements to the protocol also exist. Nodes may reserve the network either by sending a request to send message or by breaking a large message into many smaller messages (fragmentation); each successive message can be sent after the smallest interframe time. If there is a single master node on the network, the master can poll all the nodes and effectively create a TDM contention-free network.

In addition to time delays, the difference between the theoretical data rate and the practical throughput of a control network should be considered. For example, raw data rates for 802.11 wireless networks range from 11 to 54 Mbits/s. The actual throughput of the network, however, is lower due to both the overhead associated with the interframe spaces, ACK, and other protocol support transmissions, and

**FIGURE 2.11** Timing diagram for wireless Ethernet (IEEE 802.11).

**TABLE 2.3** Maximum Throughputs for Different 802.11 Wireless Ethernet Networks

Network Type	802.11a	802.11g	802.11b
Nominal data rate	54	54	11
Theoretical throughput	26.46	17.28	6.49
Measured throughput	23.2	13.6	3.6

Note: All data rates and throughputs are in Mb/s.

**TABLE 2.4** Computed Frame Times and Experimentally Measured Delays on Wireless Networks

Network Type	802.11a	802.11g	802.11b
Frame time (UDP), computed	0.011	0.011	0.055
Median delay (UDP), measured	0.346	0.452	1.733
Frame time (OPC), computed	0.080	0.080	0.391
Median delay (OPC), measured	2.335	2.425	3.692

Note: All times in ms.

the actual implementation of the network adapter. Although 802.11a and 802.11g have the same raw data rate, the throughput is lower for 802.11g because its backward compatibility with 802.11b requires that the interframe spaces be as long as they would be on the 802.11b network. Computed and measured throughputs are shown in Table 2.3. The experiments were conducted by continually sending more traffic on the network until a further setpoint increase in traffic resulted in no additional throughput.

Experiments conducted to measure the time delays on wireless networks are summarized in Table 2.4 and Figure 2.12. Data packets were sent from the client to the server and back again, with varying amounts of cross-traffic on the network. The send and receive times on both machines were time-stamped. The packet left the client at time  $t_a$  and arrived at the server at time  $t_b$ ; then left the server at time  $t_c$  and arrived at the client at time  $t_d$ . The sum of the pre- and postprocessing times and the transmission time on the network for both messages can be computed as (assuming that the two nodes are identical)

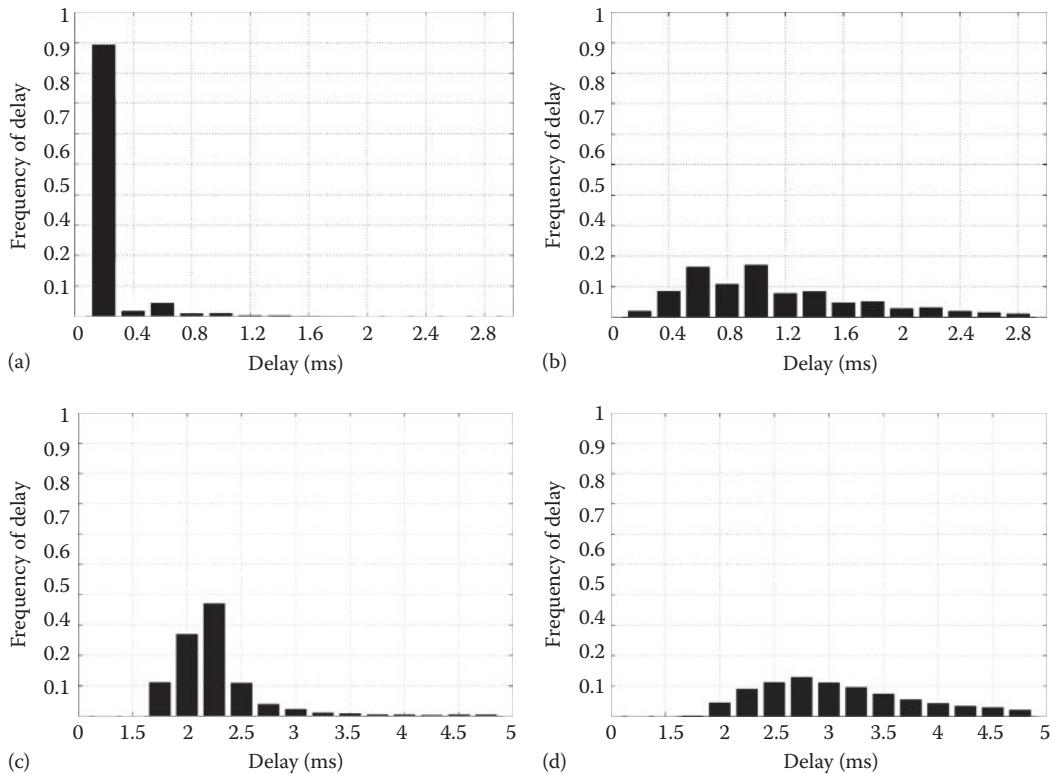

$$2 * T_{\text{delay}} = 2 * (T_{\text{Pre}} + T_{\text{wait}} + T_{\text{tx}} + T_{\text{post}}) = t_d - t_a - (t_c - t_b)$$

Note that this measurement does not require that the clocks on the client and the server be synchronized. As the delays at the two nodes can be different, it is this sum of the two delays that is plotted in Figure 2.12 and tabulated in Table 2.4.

Two different types of data packets were considered: user datagram protocol (UDP) and OPC. UDP packets carry only a data load of 50 bytes. OPC requires extra overhead to support an application layer; consequently, the OPC packets contain 512 data bytes (in addition to the overhead). For comparison purposes, the frame times (including the overheads) are computed for different packets.

### 2.3.6.2 Bluetooth

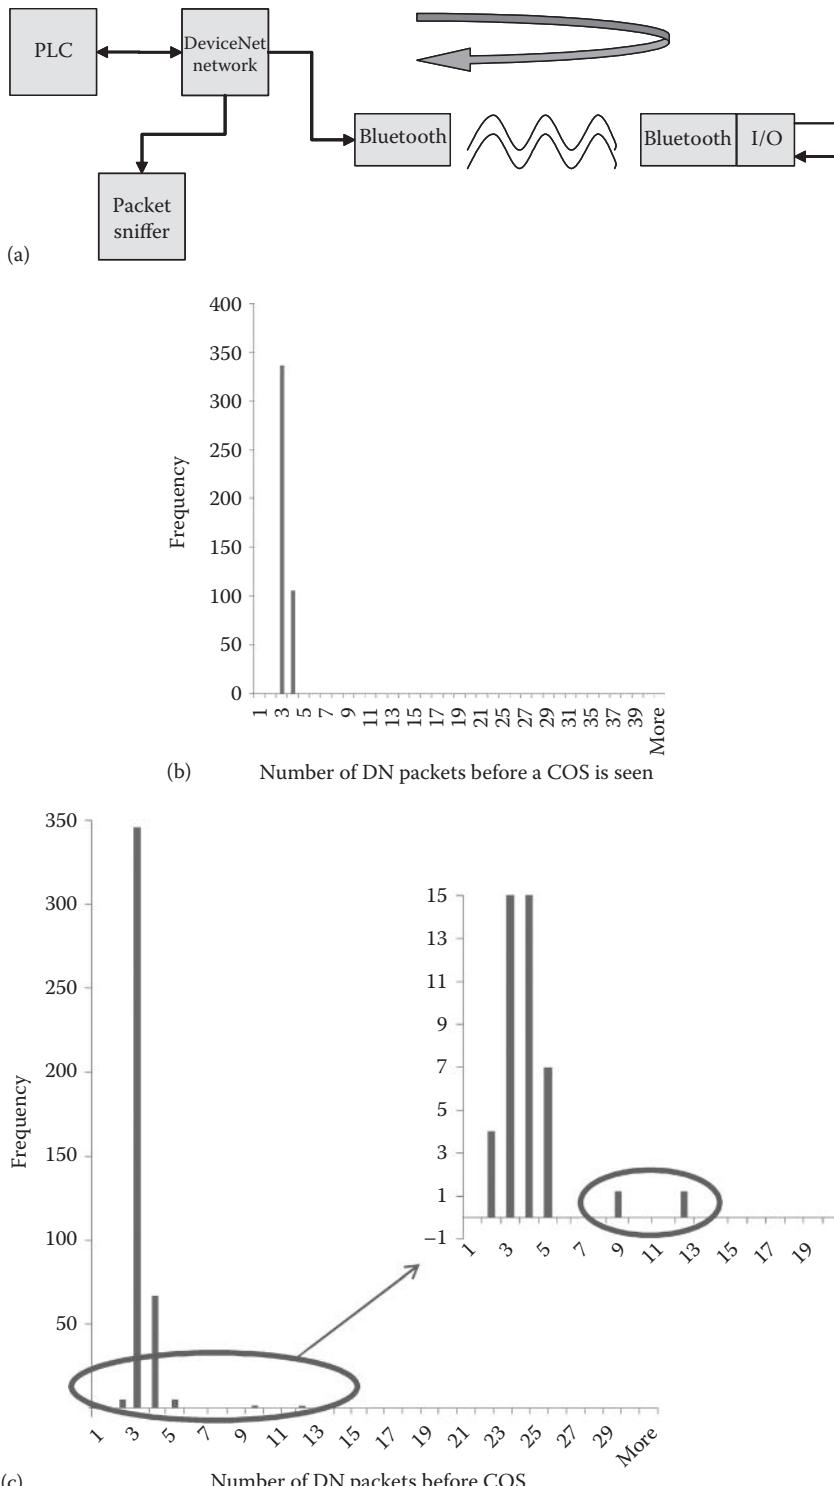

Bluetooth was originally designed as a wireless replacement for cellular phone headsets; however, its mid-range wireless capabilities in terms of distance and power consumption, combined with its frequency hopping capability for improved noise immunity, have led to its consideration as a wireless solution for lower-level connectivity on the manufacturing floor. Bluetooth operates in the same 2.4 GHz frequency band as 802.11b and g and defines a full OSI communications stack, with the lower levels published as IEEE standard 802.15.1 [11]. Advantages of Bluetooth, which make it ideal for manufacturing, include dynamic connection establishment without need for human interaction, utilization of forward error

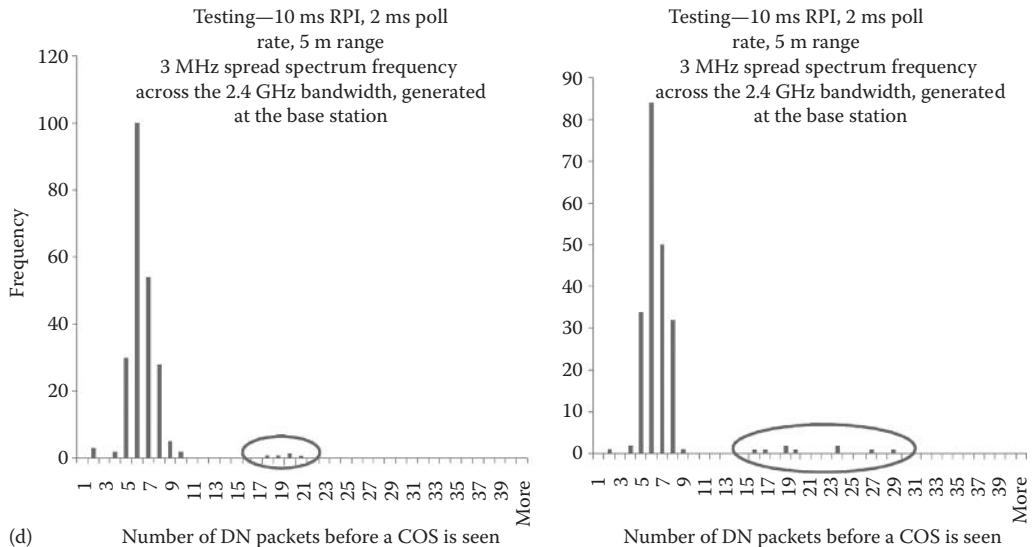

**FIGURE 2.12** Distributions of packet delays for different values of cross-traffic throughput on an 802.11a network. (a) UDP delays, 3 Mb/s cross-traffic; (b) UDP delays, 22 Mb/s cross-traffic; (c) OPC delays, 3 Mb/s cross-traffic; and (d) OPC delays, 22 Mb/s cross-traffic.

correction (FEC) for delivering the messages without error and without requiring retransmission, and a frequency hopping capability for improved noise immunity and coexistence that includes a capability to *learn* of and avoid areas in the spectrum that are crowded with other transmissions. Drawbacks include loss of efficiency from the FEC capability (a 1 Mbps communications channel can deliver only 721 Kbps) and disruption of 802.11 transmissions (coexistence issue) due to the fact that the technology frequency hops at a faster rate than specified for 802.11b/g [11,13].

Bluetooth applications have also been shown to exhibit nondeterministic response time behavior in the face of ambient interference. While this behavior is not limited to Bluetooth wireless systems, it provides a good example of an issue that must be addressed before common wireless technologies can be utilized effectively in NCSs. As an example, Figure 2.13 shows the results of an experiment to better understand the determinism of a Bluetooth NCS. As shown in Figure 2.13a, the test setup includes two Bluetooth nodes, namely, a controller and an I/O block, and a DeviceNet network hardwired system with a *Packet Sniffer* node capability providing for real-time monitoring and time-stamping of information for performance evaluation. The experiment consists of DeviceNet requests sent out over the Bluetooth network to change the value (i.e., *flip*) of a bit on the I/O block. When a packet is returned indicating that the bit value has been changed (i.e., a *change of state* is observed), a request is then placed to flip it back, etc. The packet interval of DeviceNet transmissions and poll rate of the system are set to be representative of typical DeviceNet operations and to ensure that the packet interval is significantly shorter than the response time of the Bluetooth system. Thus, a practical performance metric of the “number of DeviceNet packets between observed COS occurrences” can be used. Figure 2.13b shows a baseline result with minimal noise interference and ideal distance between the two Bluetooth nodes;

**FIGURE 2.13** Experimental characterization of determinism in a Bluetooth system. (a) Bluetooth determinism performance experimental setup, (b) baseline result with minimal channel noise and near ideal distance between nodes, (c) distance test (10 m) is inset expanded view of nondeterminism.

**FIGURE 2.13 (continued)** Experimental characterization of determinism in a Bluetooth system. (d) interference test, with nondeterminism highlighted.

note the tight and bounded distribution around these packets indicating relatively high determinism. Figure 2.13c shows the same system, but with the distance increased to 10 m and the antennae of the two nodes oriented to be perpendicular to each other. The inset reveals that while average performance does not degrade significantly, there is a significant loss of determinism due to the expanded tail of the distribution. Figure 2.13d illustrates that the same problem can occur when noise interference is introduced (note that the noise levels were purposely set to be below the threshold where the Bluetooth system would invoke frequency hopping to avoid noisy areas of the spectrum).

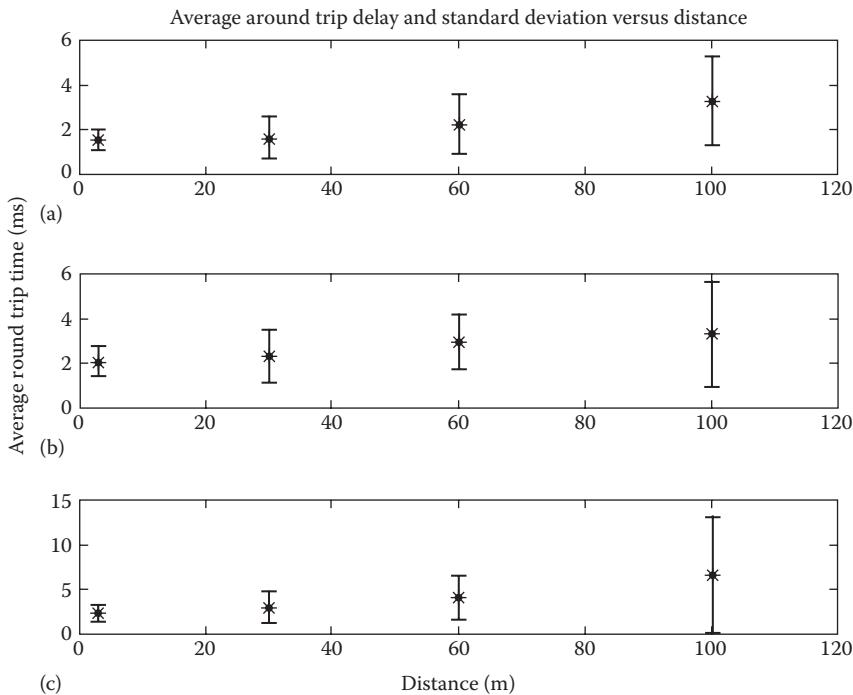

The results summarized in Figure 2.13 do not represent an exhaustive evaluation of Bluetooth, nor do they illustrate performance issues that are exclusive to Bluetooth. Rather the results illustrate one of the general problems with wireless that must be addressed if wireless is to be utilized in time-critical networked control and safety systems, namely, lack of determinism of the protocol in the face of external factors and the lack of focus on determinism in the design of the protocol as well as products and systems utilizing the protocol. The need for determinism in NCSs is explored further in Section 2.5.

### 2.3.6.3 Experimental Evaluation of Wireless Performance

To a much greater extent than in wired communication, the physical medium must be considered when characterizing the performance of wireless systems. When operating in license-free wireless bands, the quality of the physical communication channel cannot be guaranteed. Cohabitation with transmitters serving multiple applications must not only be tolerated, but also expected. Further, there are effects resulting from the propagation of radio signals in the conditions inside industrial environments, such as reflections and signal attenuation, which must be tolerated [76]. The four major categories of properties affecting wireless performance are radio propagation path loss, active radio interference, passive channel errors, and channel access errors and constraints. These are discussed in the following subsections.

#### 2.3.6.3.1 Radio Propagation Path Loss

The strength of a received signal is a fundamental property affecting wireless network performance. Most wireless devices have a minimum signal-to-noise ratio (SNR) required to operate. It is therefore important to consider energy lost in the transmission medium when characterizing wireless network performance.

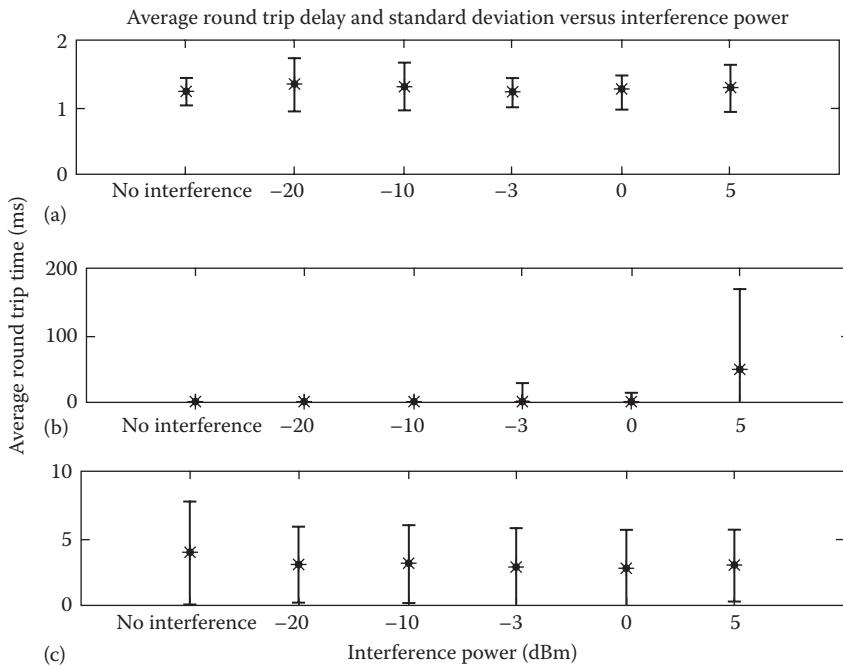

**FIGURE 2.14** A comparison of the round-trip delays between an access point and client node placed at increasing distances when using 802.11a (a), 802.11b, (b) and 802.11g (c) respectively.

In a wireless system, increasing the distance between the nodes increases not only the cumulative path loss but also the effects due to reflections and scattering. The result is sporadic deep fades (sudden drops in received signal strength) in the SNR that cause bit transmission errors, which in turn require retransmissions at various levels and consequently greater communication delay.

The distance between two 802.11 devices was varied to study the impact on the round-trip communication delay. Attenuation from walls and floors was not explicitly controlled, but the environment was selected to closely resemble the plant floor of an automotive manufacturing industry. Figure 2.14 shows the results of the experiment for 802.11a, b, and g protocols respectively [4].

#### 2.3.6.3.2 Active Radio Interference

802.11 and Bluetooth ordinarily occupy license-free ISM radio bands, which are shared with microwave ovens, RF identification devices, motion sensors, wireless security cameras, narrowband wireless telephones, and other short-range communication devices. In industrial environments, other sources of radio interference include high energy arc welders, motor drives, and frequency controllers. A significant source of radiation in the 2.45–2.485 GHz frequency range is the commercial microwave oven. Radiation power in a microwave can reach a maximum of 16–33 dBm. An analysis of the impact of microwave oven leakage on 802.11-based WLAN is presented in [102]. A band occupancy study of the 2.4 GHz band [10] shows that while the microwave oven does affect WLAN performance, the most significant source of interference in terms of power and duty cycle is a coexisting WiFi access point. Studies on the spectral footprint of welders and motor controllers conclude that the energy from these devices is limited to frequencies below 1 GHz and pose no significant threat to the communication protocols discussed here [73]. Further, the industrial environment is characterized by sudden and large variations in propagation conditions. The presence of uncoordinated interference sources close to network components induces deep fades and signal distortion that leads to clustered bit errors.

**FIGURE 2.15** A comparison of the round-trip delays between an access point and client node subject to increasing interference when using 802.11a (a), 802.11b, (b) and 802.11g (c) respectively.

Figure 2.15 shows the results of an experiment to illustrate the impact of an interfering radio source at close proximity. The interference source was equipped with a band filter and modulation scheme to mimic a rogue 802.11b or 802.11a transmitter (chosen depending on the operating band of interest). The interference power was therefore limited to 20 dBm, and the frequency bandwidth of the signal was also limited to 25 MHz [4].

#### 2.3.6.3.3 Passive Channel Errors

Even in conditions where signal strength is above the critical limit and there are no active sources of interference, wireless transmissions are subject to scattering, diffraction, and reflections. In an industrial setting, due to the large size of the plant area and the presence of scattering surfaces, several reflected radio paths with different relative lengths may exist between the transmitter and the receiver. As a result, multiple instances of the same transmitted signal arrive at the receiver dispersed in time. These reflected signals interfere with the original transmission, occasionally causing destructive interference. This leads to a sudden drop in received signal strength called a deep fade. The channel properties on the plant floor are dynamic, and this deep fade condition may rapidly appear and disappear, causing bursts of bit errors and retries during the period of the deep fade.

In an industrial setting, the RMS multipath delay spread can be upwards of 200 ns [73]. In the case of an 802.11b transmission at 11 Mbits/s using single-carrier quadrature phase shift keying, the symbol rate is 11 Msymbols/s. The symbol period is therefore about 91 ns. With a delay spread of 200 ns, it is likely that waveforms corresponding to adjacent symbols will frequently overlap at the receiver, causing intersymbol interference (ISI). Failure to decode the symbols will result in intermittent bit errors.

ISI is less pronounced in Bluetooth transmissions since the symbol rate is much lower (1 Msymbols/s). The use of several subcarriers in the OFDM modulation scheme and the presence of a long guard interval in the 802.11g standards completely eliminate ISI.

### 2.3.6.3.4 Channel Access Errors and Constraints

Wireless transceivers are half-duplex devices capable of either transmitting or receiving at a particular time. This gives rise to several issues specific to wireless CSMA systems. The *hidden terminal problem* [95] is one where a particular node inaccurately estimates a channel as available when another node is transmitting out of range. The first node transmits over an occupied channel causing interference. Another form of channel access error occurs when spurious radio transmissions interfering with the system will cause all nodes in range to wait indefinitely for the medium to become available, essentially hanging the network.

## 2.4 NCS Characterization

---

Determination of an optimal NCS (which includes solutions for control, diagnostics, and/or safety applications) design for a particular manufacturing application requires knowing not only the theory and trade-offs of the NCS protocols being considered (i.e., a theoretical perspective) but also experimental data to augment the theoretical understanding of the NCS capabilities (i.e., experimental perspective) and an analytical study that allows for gauging the relative importance of performance metrics (e.g., end-to-end speed and jitter) to the specific application environment (i.e., analytical perspective). In this section, we explore these three perspectives in detail and show how they can be utilized collectively to provide a methodology for NCS design decision making [55].

### 2.4.1 Theoretical Perspective

The theoretical information perspective involves a general overview of network operation and the metrics that should be evaluated when assessing the best NCS solution for a particular system. The comparative evaluation of network technologies and implementations is primarily a study of trade-offs. Indeed, the move from point-to-point to networked systems itself is a study of trade-offs. One important aspect of the trade-off study is illustrated with the Lian curve, discussed in Section 2.2.4. This curve illustrates the impact of network congestion on NCS performance in a digital control environment. Finding and maintaining NCS operation in the sweet spot for optimized performance is a study of trade-offs, which is a topic of ongoing research. It is important to note that the term *network* can be used very loosely in this analysis. For example, oftentimes the network congestion is actually observed in the devices themselves as they parse and encode data for end-to-end application communication [47]. The Lian curve phenomena can still be observed in these environments with the network definition extended to include the node processing.

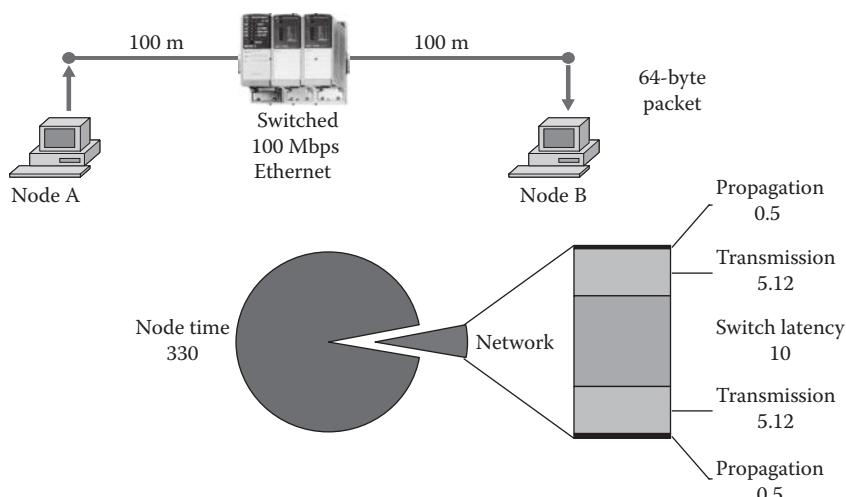

A theoretical understanding of the network choices is a clear prerequisite to an NCS deployment decision. The understanding should extend beyond the network protocol performance to the entire system performance, and an important component of that understanding is the clear definition of performance metrics that are important to the particular application environment. An example of metrics that may be important in automotive manufacturing environment can be found in Ref. [1], which is the output of an industrial network performance workshop; in this case, the top five metrics were *node performance, ease of use and diagnostics tools, cost of security/technology, capability for prioritization, and time synchronization*. The exercise of this workshop revealed a few important aspects of the metric selection process, which are important to the analytical application of these metrics in NCS decision making. The first is that many of the metrics such as ease of use or cost of complexity may be difficult to quantify, but these metrics must be incorporated into the quantified decision-making process (i.e., these metrics should not be avoided). Oftentimes, a qualitative metric can be broken down into quantitative submetrics (e.g., ease of use into average time between system crashes plus average time to diagnose a problem) so that it can be compared with other factors; the challenge is understanding the appropriate weighting for these quantifications. The second important aspect is that metrics can often overlap significantly. Care should be taken to break these metrics down into subcomponents so that a nonoverlapping set of subcomponents can be determined. This will avoid any *double counting* in the decision-making process.

## 2.4.2 Experimental Perspective

Usually, the theoretical knowledge that can be applied to NCS analysis must be augmented with experimental knowledge to complete the performance information base. This need for an experimental perspective is especially true when assessing the contribution of end node performance to the system performance analysis. Node performance should be evaluated in all systems because, as noted in Section 2.2, node performance has been shown to dominate over network performance in many manufacturing system environments. This is especially true in higher-level switched Ethernet systems, where the emphasis is on providing services such as security and self-typing on top of the data delivery mechanism [56,72]. These services provide overhead that contributes to network congestion; in smaller networks, where the node count does not number in the thousands, the degradation in individual node performance due to overhead factors such as these dominates. For example, Figure 2.16 illustrates that, in a particular two-node Ethernet network, node delay accounted for over 90% of the entire end-to-end delay [72]. Figure 2.5 (Section 2.2.3) gives an example of the impact of protocol overhead, in this case VPN to support security.

With respect to both network and node performance, specific network overhead factors that should be considered experimentally include self-typing or higher-level protocols for enabling control systems such as OPC (discussed in Section 2.3.5) and XML,\* protocols for security such as VPN, and choices of Ethernet transport layer protocols such as TCP/IP vs. UDP. The impact of these factors is explored in detail in [72].

The wireless NCS application environment demands an additional level of experimental data to provide detailed information about the impact of the medium on NCS performance. In wired systems, the *wire* is generally considered to be a medium that can guarantee end-to-end delivery, provided that the protocol on top of it handles issues of congestion and performance (which is true for most industrial network protocols). There are a number of factors in the various wireless manufacturing environments that can severely compromise wireless NCS performance. For example, a mobile phone or a wire mesh used to strengthen a cement wall can lead to intermittent and difficult-to-diagnose NCS performance issues. Knowing the impact of these issues in advance helps optimize decisions as well as reduce discovery times for NCS performance problems detected during operation [4].

**FIGURE 2.16** Illustration of node delay contribution to total delay in a typical two-node Ethernet network (pictured in the image). Time given in microseconds.

\* eXtensible Markup Language (XML) is a self-typing language often used to support communications among dissimilar components on an industrial Ethernet network.

### 2.4.3 Analytical Perspective

While the theoretical and experimental analysis provides an excellent foundation for NCS evaluation, it does not provide a capability to combine the results for differential analysis with respect to the specifics of the application environment. A final analytical step is thus needed where the factors can be weighed and combined to yield a single answer with respect to the best decision. The weighted analysis can be achieved through a simple normalized weighting of factors of concern that are determined through either theoretical or experimental means [54]. The weighting equation takes the form of

$$WCost_{\text{total}} = \frac{W_H}{(W_H + W_E + W_P)} Cost_H + \frac{W_E}{(W_H + W_E + W_P)} Cost_E + \frac{W_P}{(W_H + W_E + W_P)} Cost_P \quad (2.3)$$

where

$Cost_H$ ,  $Cost_E$ , and  $Cost_P$  are the costs associated with hardware, engineering, and maintenance and performance

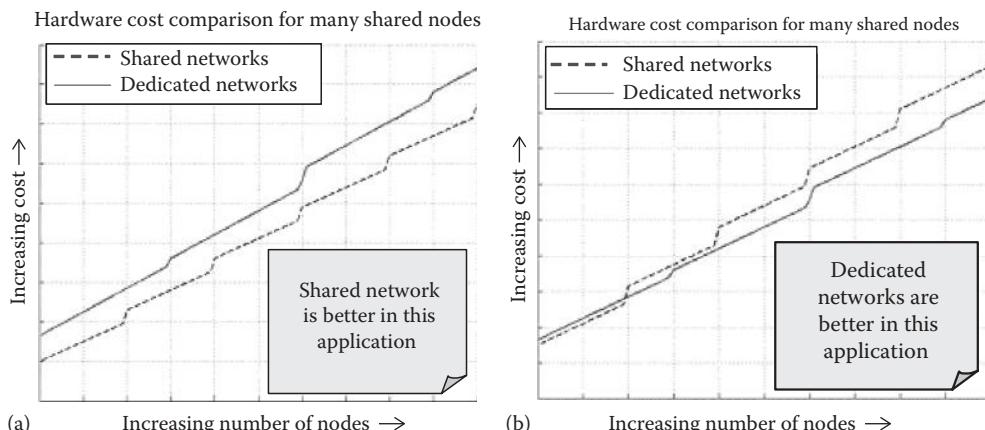

$W_H$ ,  $W_E$ , and  $W_P$  are the weights assigned, respectively, to these costs

Each cost factor is made up of a number of contributors, which are themselves weighted in a normalized manner as in

$$Cost_H = \frac{W_1}{\sum_{i=1}^n W_i} \cdot Cost_{H1} + \frac{W_2}{\sum_{i=1}^n W_i} \cdot Cost_{H2} + \dots + \frac{W_n}{\sum_{i=1}^n W_i} \cdot Cost_{Hn} \quad (2.4)$$

The weights should be chosen to reflect the particular NCS application environment. Equation 2.3 is normalized so that factors can be incrementally added to the formulation as these factors are quantified during the course of understanding the NCS environment. Note that Equations 2.3 and 2.4 assume that the factors are independent; thus, as noted earlier, care should be taken to ensure that factors do not overlap.

Figure 2.17 illustrates this analysis applied to the decision of utilizing (separate) dedicated vs. shared networks to support control and safety NCS functionality. Depending on the prioritization of factors, the best solution can vary.

**FIGURE 2.17** Illustration of the application of the weighted analytical perspective resulting in decisions of (a) shared or (b) dedicated networks for supporting control and safety functionality, respectively, depending on weights chosen.

It is important to note that manufacturers tend to consistently overemphasize upfront costs such as installation and underemphasize recurring maintenance and performance costs when making network decisions. Utilizing the more formalized approach presented here, this *forgetting* of the recurring costs can be avoided [54].

## 2.5 Applications for Industrial Networks

---

In this section, we briefly describe current trends in the use of networks for distributed multilevel control, diagnostics, and safety. There is an enormous amount of data produced in a typical manufacturing system, as thousands of sensors record position, velocity, flow, temperature, and other variables hundreds of times every minute. In addition to this physical information, there are the specifications for the parts that must be produced, the orders for how many parts of each type are needed, and the maintenance schedules for each machine. Generally, the information content can be thought of as supporting a control, diagnostics, or safety function, or some combination of these. To support the aggregate of these functions in a manufacturing environment, separate networks or network partitions are sometimes employed, where each network or partition is dedicated to one or more function types, such as control and diagnostics, with the network protocol chosen that best fits (i.e., balances) the QoS requirements of the function type(s) [90]. In this section, networks for these function types are explored, focusing on the QoS requirements that often govern the network protocol choice.

### 2.5.1 Networks for Control

Control signals can be divided into two categories: real time and event based. For real-time control, signals must be received within a specified amount of time for correct operation of the system. Examples of real-time signals include continuous feedback values (e.g., position, velocity, and acceleration) for servo systems, temperature and flow in a process system, and limit switches and optical sensors in material flow applications (e.g., conveyors). To support real-time control, networks often must have a high level of determinism; that is, they must be able to guarantee end-to-end communication of a signal within a specified amount of time. Further, QoS of NCSs can be very dependent upon the amount of jitter in the network; thus, for example, fixed determinism is usually preferred over bounded determinism.

Event-based control signals are used by the controller to make decisions, but do not have a time deadline. The system will wait until the signal is received (or a timeout is reached), and then the decision is made. An example of an event-based signal is the completion of a machining operating in a CNC; the part can stay in the machine without any harm to the system until a command is sent to the material handler to retrieve it.

In addition to dividing control signals by their time requirements, the data size that must be transmitted is important. Some control signals are a single bit (e.g., a limit switch) whereas others are very large (e.g., machine vision). Generally speaking, however, and especially with real-time control, data sizes on control networks tend to be relatively small, and high levels of determinism are preferred.

Control networks in a factory are typically divided into multiple levels to correspond to the factory control distributed in a multilayer hierarchical fashion. At the lowest level of networked control are device networks, which are usually characterized by smaller numbers of nodes (e.g., less than 64), communicating small data packets at high sample frequencies and with a higher level of determinism. An example of networked control at this level is servo control; here network delay and jitter requirements are very strict. Deterministic networks that support small data packet transmissions, such as CAN-based networks, are very common at this level. Although seemingly nonoptimal for this level of control (large packet sizes), switched Ethernet is becoming common, due to the desire to push Ethernet into all levels in the factory to support web services and greater transparency between control layers. Regardless of the network type, determinism and jitter capabilities for lower-level networked control are enhanced oftentimes by utilizing techniques that minimize the potential for jitter through network contention, such as MS operation, polling techniques, and deadbanding [69].

An intermediate level of network is the cell or subsystem, which includes SCADA. At this level, multiple controllers are connected to the network (instead of devices directly connected to the network). The controllers exchange both information and control signals, but as the cells or subsystems are typically physically decoupled, the timing requirements are not as strict as they are at the lowest levels, or nonexistent if event-driven control is enforced [62]. These networks are also used to download new part programs and updates to the lower-level controllers. TP and Ethernet-based networks are commonly used at this level, with the ability to communicate larger amounts of data and support for network services generally taking precedence over determinism.

Networks at the factory or enterprise level coordinate multiple cells and link the factory-floor control infrastructure to the enterprise-level systems (e.g., part ordering and supply chain integration). Large amounts of data travel over these networks, but the real-time requirements are usually minimal to nonexistent. Ethernet is the most popular choice here primarily because Internet support at this level is usually critical (e.g., cloud services), and Ethernet also brings attractive features to this environment such as support for high data volumes, network services, availability of tools, capability for wide area distribution, and low cost.

Currently, wireless networks are not commonly utilized for control. When they are utilized, it is often because a wired system is impossible or impractical (e.g., a stationary host controller for an autonomous guided vehicle [AGV]). Wireless systems are more applicable to discrete control; issues with the determinism of wireless communications in the face of interference (as explored in Section 2.3.6) usually result in the requirement that wireless time-critical control systems go through extensive and often costly verification prior to deployment.

### 2.5.2 Networks for Diagnostics

Diagnostic information that is sent over the network often consists of large amounts of data sent infrequently. For example, a tool-monitoring system may capture spindle current at 1 kHz. The entire current trace would be sent to the diagnostic system after each part is cut (if the spindle current is used for real-time control, it could be sent over the network every 1 ms, but this would then be considered control data). The diagnostic system uses this information for higher-level control, such as to schedule a tool change or shut down a tool that is underperforming.

Diagnostics networks are thus usually set up to support large amounts of data with the emphasis on speed over determinism. Ethernet is the dominant network protocol in system diagnostics networks. As with control, diagnostics is often set up in a multitier hierarchical fashion, with different physical layer technology (e.g., wireless, broadband, and fiber-optic) utilized at different levels to support the data volume requirements. Also, a variety of data compression techniques, such as COS reporting and store and forwarding of diagnostic information on a process *run-by-run* basis, are often used in communicating diagnostic information up the layers of the network hierarchy [38,84]. Wireless is an ideal medium for diagnostics because determinism and high levels of data integrity are usually not required, and diagnostics systems can often take advantage of the flexibility afforded by the wireless media. As an example, a personal digital assistant handheld system can be designed to collect diagnostics data wirelessly from a nearby machine and perform system health checks. Maintenance engineers thus could utilize a single portable unit as a diagnostics tool for all machines in a factory.

As noted in Section 2.1, diagnostics networks enable diagnostics of the networked system rather than the network itself (with the latter referred to as network diagnostics). Both types of diagnostics are commonly used in manufacturing systems. Many network protocols have built-in network diagnostics. For example, nodes that are configured to send data only when there is a COS may also send *heartbeat* messages every so often to indicate that they are still on the network.

### 2.5.3 Networks for Safety

Traditionally, safety interlocks around manufacturing cells have been hardwired using ultrareliable safety relays to ensure that the robots and machines in the cell cannot run if the cell door is open or

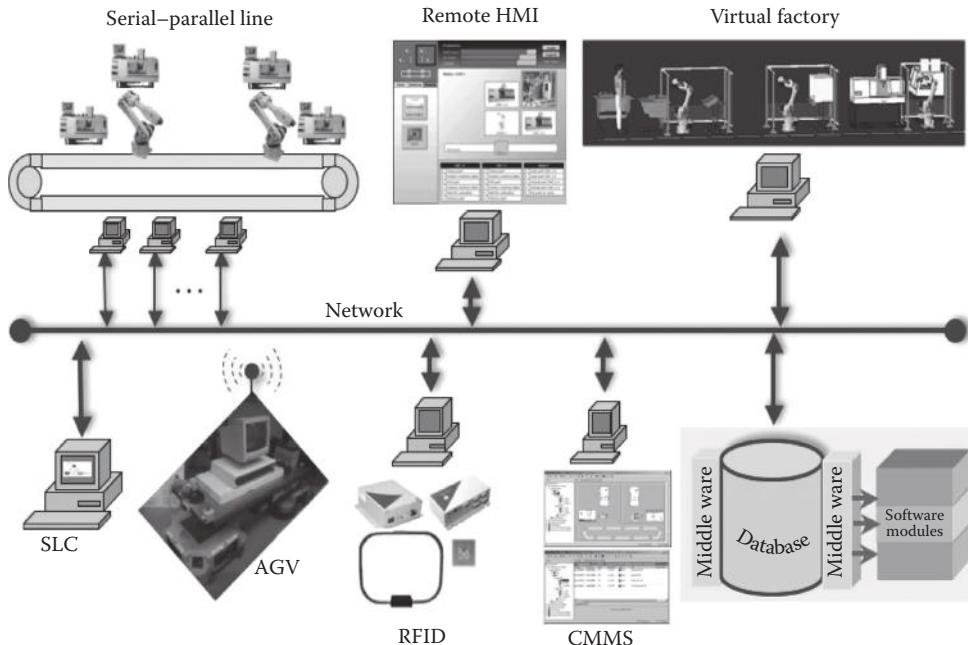

there is an operator inside the cell. This hardwiring is not easy to reconfigure and can be extremely difficult to troubleshoot if something goes wrong (e.g., a loose connection). Safety networks allow the safety systems to be reconfigurable and significantly improve the ability to troubleshoot. They also allow safety functions to be more easily coordinated across multiple components, for example, shutting down all machines in a cell at the same time and also coordinating *soft shutdown* where appropriate (safe algorithms for gradual shutdown of systems without damage to systems and/or scrapping of product). Further, safety network systems often provide better protection against operators bypassing the safety interlocks and thus making the overall system safer.

Safety networks have the strongest determinism and jitter requirements of all network function types. Safety functions must be guaranteed within a defined time; thus, the network must provide that level of determinism. Further, the network must have a deterministic heartbeat-like capability; if network connectivity fails for any reason, the system must revert to a safe state within the guaranteed defined time; this is often referred to as *fail-to-safe*. CAN-based and switched Ethernet-based networks are popular candidates for networked safety because of their high levels of determinism, the network self-diagnostic mechanisms they can utilize to determine the node and network health, and the ability of the latter to support capabilities such as web services as well as its general dominance in control and diagnostics domains. However, it is important to note that most network protocols, in and of themselves, are adequate to the task of supporting safety networking. This is because safety systems must support a fail-to-safe capability if a communication is not received within a predetermined amount of time. In other words, safety systems must be robust to the possibility of network failure of any network. This is often accomplished by adding functionality at higher levels (e.g., application) of the communication stack to guarantee proper safety functionality [75]. Thus, even wireless safety systems are possible. The key is understanding if the benefit of a more flexible or commonplace network technology, such as wireless, is outweighed by the reduced guaranteed response time of the safety system in the increased occurrence of fail-to-safe events due to network delays.

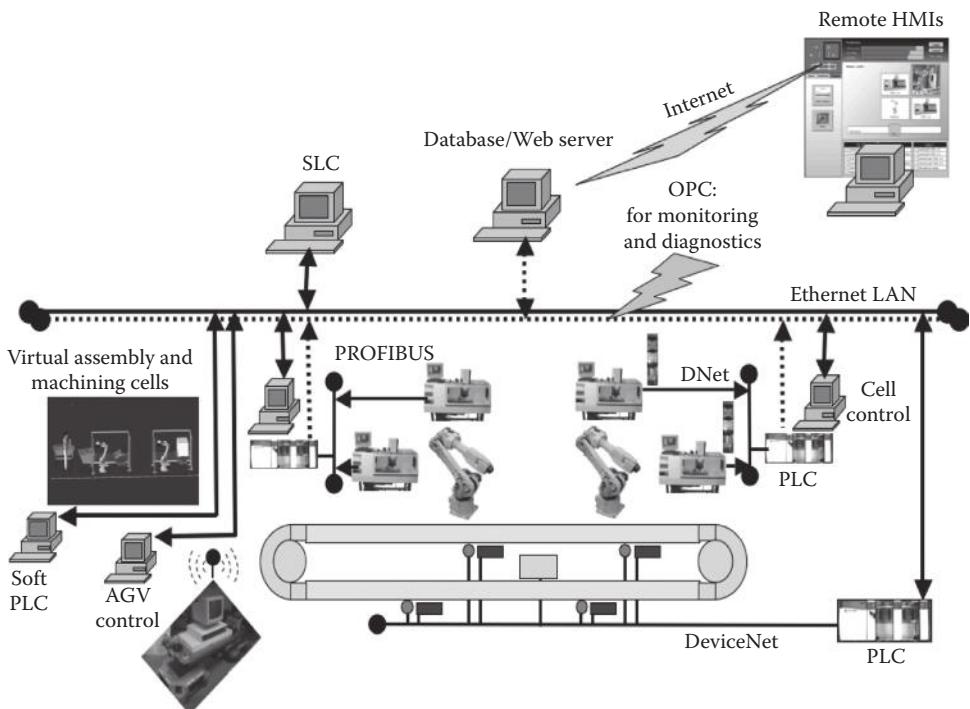

#### 2.5.4 Multilevel Factory Networking Example: Reconfigurable Factory Testbed

The reconfigurable factory testbed (RFT) at the University of Michigan is a comprehensive platform that enables research, development, education, validation, and transfer of reconfigurable manufacturing system concepts [58]. It consists of both real and virtual machines controlled over a communication network and coordinated through a unified software architecture. The RFT is conceived to be extensible to allow the modular incorporation and integration of additional components (hardware and/or software, real and/or virtual). The hardware components of the RFT include a serial-parallel manufacturing line consisting of two machining cells connected by a conveyor, a suite of communication and control networks, an AGV, and an RFID system. The software components of the RFT include a virtual factory simulation, an open software integration platform and data warehouse, an infrastructure of Web-based HMIs, and a computerized maintenance management system. A schematic of the RFT is shown in Figure 2.18.

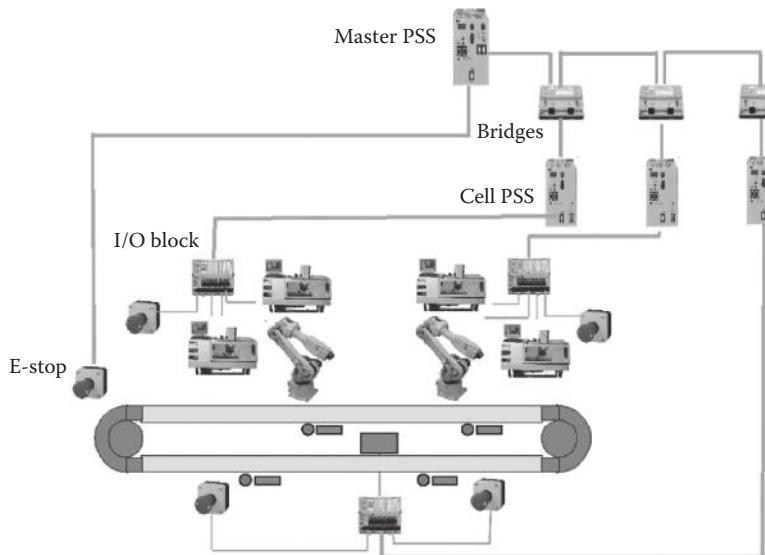

The network shown in Figure 2.18 represents a multitier-networked control, diagnostic, and safety network infrastructure that exists on the RFT. The serial-parallel line component of the RFT is the primary component currently being utilized to explore manufacturing networks. With respect to control networks, cell 1 has a DeviceNet network to connect the machines and robot controllers (including the robot gripper and the clamps in the machines); cell 2 uses PROFIBUS for the same purpose. The conveyor system (pallet stops, pallet sensors, motor, and controller) was originally outfitted to communicate via a second DeviceNet network; this was converted to an 802.11 wireless-networked system. The cell-level controllers (including the conveyor controller) communicate with the system level controller (SLC) over Ethernet via OPC and support an event-based control paradigm. The SLC has a wireless network connection with the AGV. All of these control networks are shown in Figure 2.19.

**FIGURE 2.18** Reconfigurable factory testbed.

**FIGURE 2.19** Networks on the RFT: control networks are indicated by solid lines, and diagnostics networks are indicated by dashed lines.

**FIGURE 2.20** Safety network implementation on the RFT.

The network infrastructure for collecting the diagnostic data on the RFT uses OPC. For example, for every part that is machined, the spindle current on the machine is sampled at 1 kHz. These time-dense data are directly sampled using LabVIEW\* and then stored in the database. Compressed diagnostics data focused on identifying specific features of the current trace are passed to higher levels in the diagnostics network.

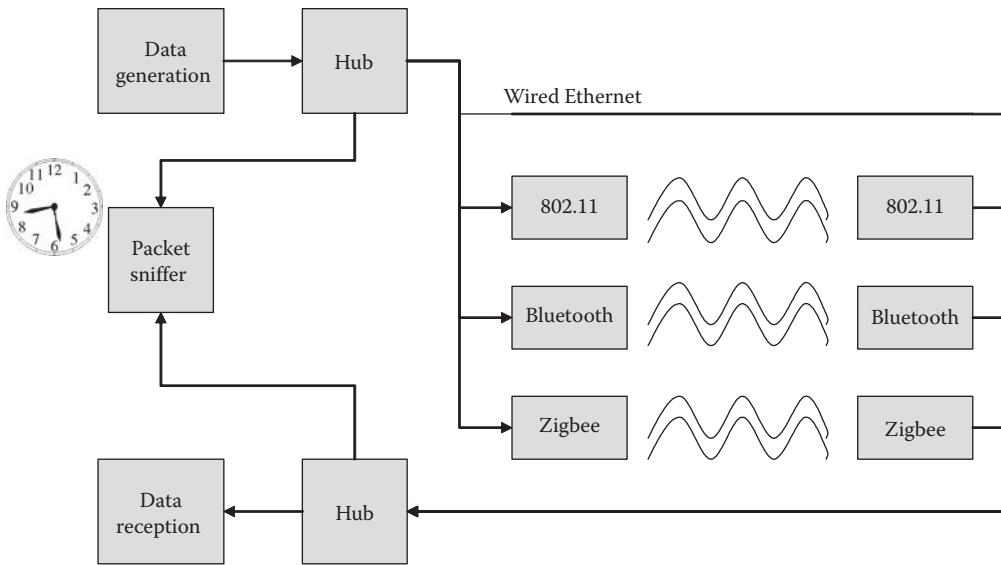

Networks for safety are implemented in the serial-parallel line utilizing the SafetyBUS p protocol, as shown in Figure 2.20. As with the control and diagnostics system, the implementation is multilayer, corresponding to levels of safety control. Specifically, safety networks are implemented for each of the two cells as well as the conveyor. The safety network interlocks the emergency stops, robot cages, and machine enclosures with the controllers. These three cell-level networks are coordinated through a hierarchy to a high-level master safety network. This implementation not only allows for safety at each cell to be controlled individually but also provides a capability for system-wide safe shutdown. Further, this implementation allows for multilayer logic to be utilized for the implementation of safety algorithms.

As manufacturing networks research and development has increasingly shifted toward industrial Ethernet and wireless communications, so too has the focus in RFT networking deployment and analysis. For example, in providing an experimental capability to support NCS design evaluation (see Section 2.4), the wireless performance testbed shown in Figure 2.21 was developed in collaboration with USCAR, a collaboration of automotive manufacturers [97]. Here, a simple parallel point-to-point wireless environment is provided for three common industrial wireless protocols: IEEE 802.11, Bluetooth, and ZigBee. An Ethernet real-time packet sniffer is utilized to monitor traffic, thereby determining the performance of the wireless connection. The testbed is set up so that various wireless configurations and interference environments can be evaluated in a laboratory setting. The testbed can thus be utilized as both a design/evaluation and a troubleshooting tool. With respect to the latter, wireless signal generation and analysis equipment are utilized with the testbed to effectively record wireless patterns in the field and then play back these patterns in the experimental environment for analysis and troubleshooting.

The RFT implementation of multilayered networks for control, diagnostics, and safety provides a rich research environment for exploration into industrial control networks. Specifically, topics that can be

---

\* National Instruments, Austin, TX.

**FIGURE 2.21** Experimental setup for determining and investigating the wireless NCS performance.

addressed include (1) coordination of control, diagnostics, and/or safety operation over one, two, or three separate networks; (2) distributed control design and operation over a network; (3) distribution of control and diagnostics in a hierarchical networked system; (4) compression techniques for hierarchical diagnostics systems; (5) remote control safe operation; (6) hierarchical networked safety operation and soft shutdown; (7) heuristics for optimizing control/diagnostics/safety network operation; (8) network standards for manufacturing; (9) best practices for network systems design and operation; as well as (10) seamlessly integrating simulations with physical systems over the network [33,45,46,58,70].

## 2.6 Future Trends

As the rapid move toward networks in industrial automation continues, the process has now matured to the point that a large portion of the migration is not just toward networks, but from one network technology to another (e.g., the move to switched Ethernet everywhere as a consolidation effort or the move to wireless). The immediate advantages of reduced wiring and improved reliability have been accepted as a fact in industry and are often significant enough by themselves (e.g., return-on-investment—ROI) to justify the move to networked solutions. Further, with the advent of more detailed ROI calculators such as that discussed in Section 2.4, other networking advantages can be quantified. It is expected that diagnostics network adoption will continue to lead the way in the overall network proliferation trend, followed by control and then safety networks, but the ordering is driven by the stricter QoS balancing requirements of the latter, not by any belief of higher ROI of the former. In fact, in gauging the criticality of control and safety with respect to diagnostics, it is conceivable that significantly higher ROI may be achievable in the migration to control and especially safety networking. However, even with diagnostics networks, the possibilities and benefits of e-Diagnostics and (with control) e-Manufacturing are only beginning to be explored.

Looking to the future, the most notable trends appearing in industry are (1) the move to wireless networks at all levels, (2) the domination of switched Ethernet, and (3) the design of systems to include network attributes and thus leverage network advantages and mitigate disadvantages [5,101]. The dominance of Ethernet-based technologies will continue for the most part due to the explosion of web services available. With respect to wireless growth, it is not expected that wireless will replace wired in all applications, but rather the traditional barriers to wireless implementation (e.g., technology, security,

and reliability) will continue be lowered, and the trend of incorporating network attributes into systems will better allow for the mitigation of these barriers. This will allow the significant benefits of wireless to be realized, such as further reduction of the volume of wiring needed (although often power is still required), enabling the placement of sensors in difficult locations, and enabling the placement of sensors on moving parts such as on tool tips that rotate at several thousand RPM. Issues with the migration to wireless include interference between multiple wireless networks, security, and reliability and determinism of data transmission as explored in Section 2.3.6.3. The anticipated benefit in a number of domains (including many outside of manufacturing) is driving innovation that should be able to be leveraged to address many of these issues in the manufacturing domain. However, the determinism issue will be difficult to overcome because manufacturing is not a market driver in the typical application domains of most wireless network technologies.

The trend of integration of traditionally separate industrial systems, such as diagnostics and safety, will continue [80,81,90]. For example, a diagnostics system can raise safety alarms when a process variable is outside the expected range of safe operations. Advancements in network partitioning allow the networked safety system operation to leverage networked diagnostics information into improved safety decision making, without the degradation of overall safety network performance. This capability opens the door to a number of opportunities for improving safety, control, and diagnostics in manufacturing systems.

In summary, as the industry moves forward in networked communications, many among the dozens of protocols that have been developed for industrial networks over the last few decades will fall out of favor, but will not die overnight due to the large existing installed base and the long lifetime of manufacturing systems. In addition, new protocols may continue to emerge to address niches, where a unique QoS balance is needed. However, it is expected that Ethernet and wireless will continue to grab larger and larger shares of the industrial network's installed base, driven largely by lower cost through volume, the Internet, higher availability of solutions and tools for these network types (e.g., web-enabled tools), and the unmatched flexibility of wireless. Indeed, it is not unreasonable to expect that, in the next decade, the next major milestone in industrial networking, namely, the *wireless factory*, will be within reach, where diagnostics, control, and safety functions at multiple levels throughout the factory are enabled utilizing wireless technology.

## Acknowledgments

The authors would like to acknowledge support from the NSF ERC for reconfigurable manufacturing systems (ERC-RMS) grant EEC95-92125. We would also like to thank the many students of the ERC-RMS who did much of the work on which much of this chapter is based and Feng-Li Lian for his extensive research on NCSs.

## 3.1 Introduction

---

The advent of embedded microcontrollers and the possibility of equipping microcontrollers with small, fast, and low-cost network interfaces has allowed for the creation of smart distributed systems consisting of a set of networked embedded devices. The main reasons for building a system in a distributed manner are the possibilities of having redundancy and exploiting parallelism. In the context of embedded networks, a distributed system also supports the following applications:

- *Distributed sensing* with smart transducers. A smart transducer is the combination of sensor/actuator, processing element, and network interface. Smart transducers perform local preprocessing of the analog sensor signal and transmit the measurement digitally via the network.
- Systems that integrate *legacy systems*, which cannot be extended or changed due to legal or closed system issues. The unchanged legacy system is thus integrated as a subsystem into a network, establishing a larger overall system.
- *Complexity management* by dividing the overall applications into several subsystems with separate hardware and software. A distributed network of embedded devices also comes with increased complexity for typical configuration and management tasks such as system setup (no hyphen/space), diagnosis, repair, monitoring, calibration, and change. In order to handle this complexity, computer-automated mechanisms can perform tasks such as registering new devices, auto-configuring data flow, and detecting configuration mismatches.

In this chapter, we examine state-of-the art mechanisms for handling these tasks. A considerable number of mature solutions for configuration and management exist in the context of fieldbus systems and service-oriented architectures (SOAs). A fieldbus system is a network for industrial manufacturing plants. The fieldbus system conducts fieldbus nodes comprising sensors, actuators, valves, console lights, switches, and contactors. Challenges for fieldbus systems are interoperability, real-time communication, robustness, support for management, and configuration. Thus, fieldbus systems have evolved a set of interesting concepts for supporting setup, configuration, monitoring, and maintenance of embedded devices connected to a fieldbus. Twenty years ago, a typical process automation plant consisted of various field devices from a half-dozen vendors. Each device had its own setup program with different syntax for the same semantics. The data from the devices often differed in format and in routine to interface each device [1]. Since that time, many fieldbus configuration and management methods have been devised.

The following sections are organized as follows: Section 3.2 gives definitions for the concepts and terms in the context of configuration and management of networked embedded systems. Section 3.3 investigates requirements for configuration and management tasks. Section 3.4 analyzes the necessary interfaces of an intelligent device and proposes meaningful distinctions between interface types. Section 3.5 discusses profiles and other representation mechanisms of system properties for embedded devices. Section 3.6 gives an overview of application development methods and their implications for configuration and management of distributed embedded systems. Section 3.7 examines the initial setup of a system in terms of hardware and software configuration. Section 3.8 deals with approaches for system management, such as application download, diagnosis, and calibration of devices. Section 3.9 presents maintenance methods for reconfiguration, repair, and reintegration of networked devices. Section 3.10 concludes this overview.

## 3.2 Concepts and Terms

---

The purpose of this section is to introduce and define some important concepts and terms that are used throughout this chapter.

### 3.2.1 Configuration versus Management

The term *configuration* is used for a wide range of actions. Part of configuration deals with setting up the hardware infrastructure of a network and its nodes, that is, physically connecting nodes (cabling) and configuring nodes in a network (e.g., by using switches and jumpers). Configuration also involves setting up the network on the logical (i.e., software) level. Therefore, a particular configuration mechanism often depends on the network issues such as topology or underlying communication paradigm. For example, the TTP-Tools [2] are designed for the time-triggered architecture [3]. TTP-Tools provide various design and configuration mechanisms for engineering dependable real-time systems, but it is assumed that the system is based on a time-triggered paradigm [3].

In contrast to configuration, *management* deals with handling of an established system and includes maintenance, diagnosis, monitoring, and debugging. As with configuration, different systems can differ greatly in their support and capabilities in these areas.

Configuration and management are often difficult to separate because procedures such as plug and play (see Section 3.2.3) involve both configuration and management tasks.

### 3.2.2 Smart Devices

The term *smart* or *intelligent* device was first used in this context by Ko and Fung in [4], meaning “a sensor or actuator device that is equipped with a network interface in order to support an easy integration into a distributed control application.”

In the context of networked embedded systems, an *intelligent* device supports its configuration and management by providing its data via a well-defined network interface [5] and/or offering a self-description of its features. The description usually comes in a machine-readable form (e.g., as an XML description) that resides either locally at the embedded device (e.g., IEEE1451.2 [6]) or at a higher network level, referenced by a series number (e.g., Object Management Group [OMG] Smart Transducer Interface [7]).

### 3.2.3 Plug and Play versus Plug and Participate

*Plug and play* describes a feature for automatic integration of a newly connected device into a system without user intervention. Although this feature works well for personal computers within an office environment, it is quite difficult to achieve this behavior for automation systems because without user intervention, the system would not be able to ascertain which sensor data should be used and which actuator should be instrumented by a given device. Therefore, in the automation domain, the more correct term *plug and participate* should be used, which describes the initial automatable configuration and integration of a new device. For example, after connecting a new sensor to a network, the sensor could be automatically detected, given a local name, and assigned to a communication slot. The task of a human system integrator is then reduced to deciding on further processing and usage of the sensor data.

### 3.2.4 State

Zadeh states that “The notion of state of a system at any given time is the information needed to determine the behavior of the system from that time on” [8, p. 3]. In real-time computer systems, we distinguish between the *initialization state* (i-state) and the *history state* (h-state) [9].

The i-state encompasses the static data structure of the computer system, that is, data that are usually located in the static (read-only) memory of the system. The i-state does not change during the execution of a given application, for example, calibration data of a fieldbus node. The h-state is the “dynamic data structure [...] that undergoes change as the computation progresses” [9, p. 91]. Examples of an h-state are the cached results of a sequence of measurements that are used to calculate the current state of a process variable.

The size of the h-state at a given level of abstraction may vary during execution. A good system design will aim at having a *ground state*, that is, when the size of the h-state becomes zero. In a distributed system, this usually requires all tasks to be inactive and no messages to be in transit.

### 3.3 Requirements for Configuration and Management

---

The requirements for a configuration and management framework are driven by several factors. We have identified the following points:

- *(Semi)automatic configuration:* The requirement for a plug-and-play-like configuration can be justified by three arguments: Firstly, automatic or semiautomatic configuration saves time and therefore leads to better maintainability and lower costs. Secondly, the necessary qualification of the person who sets up the system may be less if the overall system is easier to configure. Thirdly, the number of configuration faults will decrease because monotonous and error-prone tasks such as looking up configuration parameters in manuals are done by the computer. In most cases, a fully automatic configuration will be possible only if the functionality of the system is reduced to a manageable subset. For more complex applications, consulting a human mind is unavoidable. We thus distinguish two use cases: (1) the automatic setup of simple subsystems and the (2) computer-supported configuration of large distributed systems. The first case mainly concerns systems that require an *automatic* and *autonomous* (i.e., without human intervention) reconfiguration of network and communication participants in order to adapt to different operating environments. Usually, such systems either use very sophisticated (and often costly) negotiation protocols or work only on closely bounded and well-known application domains. The second case is the usual application.
- *Comprehensible interfaces:* In order to minimize errors, all interfaces will be made as comprehensible as possible. This includes the uniform representation of data provided by the interfaces and the capability for selectively restricting an interface to the data required by the interface's user. The comprehensibility of an interface can be expressed by the *mental load* that it puts on the user. Different users need different specialized interfaces, each with minimal mental load. For example, an application developer mostly has a service-centered view of the system. Physical network details and other properties not relevant for the application should be hidden from the developer [10].
- *Uniform data structures:* Configuration and management of distributed embedded systems requires representations of system properties that are usable by software tools. In order to avoid a situation in which each application deals with the required information in its own way, these representations should be generic, highly structured, and exactly specified.
- *Low overhead on embedded system:* Typical embedded hardware is restricted by requirements for cost, size, power consumption, and mechanical robustness. Thus, embedded hardware usually provides far less memory and processing power than average desktop systems. Currently, typical microcontrollers provide about several hundred bytes of RAM and less than 128 kB of Flash ROM. Clocked by an internal oscillator, these microcontrollers provide only a few MIPS of processing power. The local application will consume most of the available resources, and consequently, the designers of configuration and management mechanisms must ensure that there is no excessive overhead on the embedded system nodes. This requirement drives design decisions where configuration data are compressed or even stored on a separate repository outside the embedded network.
- *Use of standard software/hardware:* Computers running standard Windows or Linux operating systems do not provide guaranteed response times for programs, and most hardware interfaces are controlled by the operating system. Lack of a guaranteed response time might violate the special timing requirements of an embedded real-time protocol, and thus, it is often not possible to directly connect a configuration host computer to the fieldbus network without a gateway. Instead, a configuration tool must use some other means of communication, such as standard communication protocols or interfaces such as TCP/IP, RS232, USB, or standard middleware like Common

Object Request Broker Architecture (CORBA). Often, the system uses a dedicated gateway node that routes the configuration and management access to the sensor/actuator nodes; thus, the timing of the embedded network is not disturbed by configuration traffic, and the embedded nodes do not need to implement a USB or CORBA interface and can be kept slim. In order to reduce the complexity of the involved conversion and transformation steps, the interface to and from the embedded node must be comprehensible, structurally simple, and easy to access.

## 3.4 Interface Separation

---

If different user groups access a system for different purposes, users should only be provided with an interface that presents information relevant for their respective purposes [11].

Interfaces for different purposes may differ in accessible information and temporal behavior of the access across the interface.

Kopetz, Holzmann, and Elmenreich have identified three interfaces to a transducer node [5]:

The configuration and planning (CP) interface allows the integration and setup of newly connected nodes. The CP interface is used to generate the *glue* in the network that enables network components to interact in the intended manner. The CP interface is not usually time critical.

The diagnostic and management (DM) interface is used for parameterization and calibration of devices and for collecting diagnostic information to support maintenance activities. For example, a remote maintenance console can request diagnostic information from a certain sensor. The DM interface is not usually time critical.

The real-time service (RS) interface is used to communicate the application data, for example, sensor measurements or set values for an actuator. This interface usually has to fulfill timing constraints such as a bounded latency and a small communication jitter. The RS interface has to be configured by the use of the CP (e.g., communication schedules) or DM interface (e.g., calibration data or level monitors).

The TTP/A fieldbus system in [12] uses time-triggered scheduling to provide a deterministic communication scheme for the RS interface. A specified part of the bandwidth is reserved for arbitrary CP and DM activities. Therefore, it is possible to perform CP tasks while the system is in operation without a probe effect on the RS [13].

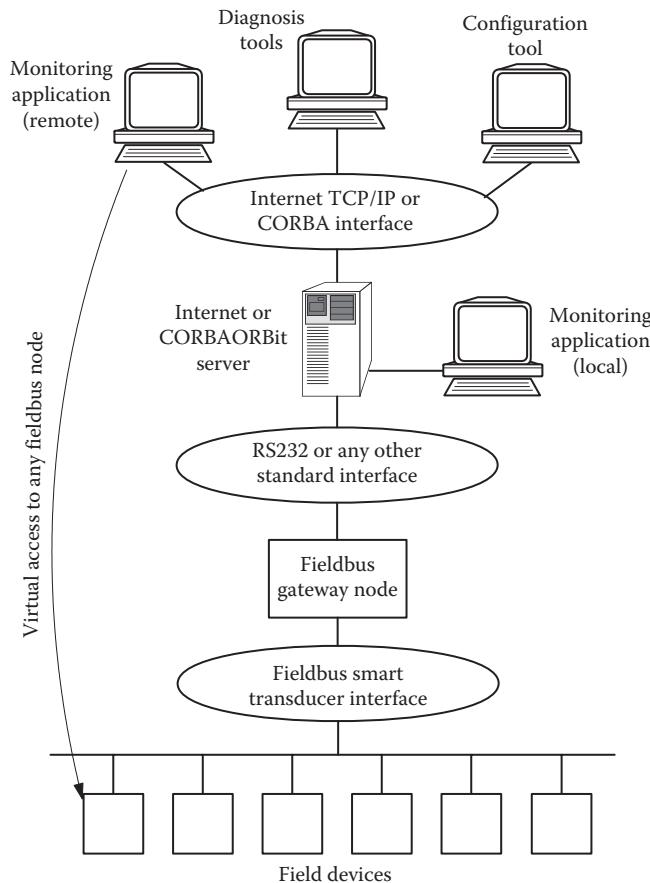

### 3.4.1 Interface File System Approach

The concept of an Interface File System (IFS) was introduced in [5]. The IFS provides a unique addressing scheme to all relevant data belonging to nodes in a distributed system. Thus, the IFS maps real-time data, many kinds of configuration data, self-describing information, and internal state reports for diagnostic purposes.

The IFS is organized hierarchically as follows: The *cluster name* addresses a particular fieldbus network. Within the cluster, a specific node is addressed by the *node name*. The IFS of a node is structured into *files* and *records*. Each record is a unit of 4 bytes of data.

The IFS is a generic approach that has been implemented with the TTP/A protocol as a case study for the OMG Smart Transducer Interface. The IFS approach supports the integration and management of heterogeneous fieldbus networks well. The IFS provides the following benefits:

- The IFS establishes a well-defined interface between network communication and local application. The local application uses application programming interface functions to read and write data from/into the IFS. The communication interface accesses the IFS to exchange data across the network.
- The IFS provides transparency on network communication because a task does not have to discriminate between data that are locally provided and data that are communicated via the network.

**FIGURE 3.1** Architecture for remote configuration and monitoring.

- Because the configuration and management data are mapped into the IFS, the IFS supports access from configuration and management tools from outside the network well. Figure 3.1 depicts an architecture with configuration and management tools that access the IFS of a fieldbus network from the Internet.

The IFS maps different data domains such as RS data, configuration data, and management data using a consistent addressing scheme. In fact, the management interface can be used to define the RS data set dynamically (e.g., to select between a smoothed measurement and a measurement with better dynamics as the output from a sensor). Although real-time guarantees for communication of real-time data are necessary, access to configuration and management data is not time critical. This enables the employment of web-based tools for remote maintenance.

Tools that operate on the IFS have been implemented using CORBA as middleware. CORBA is an object model managed by the OMG that provides transparent communication among remote objects. Objects can be implemented in different programming languages and can run on different platforms. The standardized CORBA protocol IIOP (Internet Inter-ORB Protocol) can be routed over TCP/IP, thus supporting worldwide access to and communication between CORBA objects across the Internet.

Alternatively, it is possible to use web services as management interface for embedded devices. A case study that implements web services on top of the IFS is described in [14].

### 3.4.2 Service-Oriented Device Architectures

In a network of smart transducers, finding a model that can suit each sensor is necessary for accessing data in the same way and for enabling cheaper development and maintenance of the network.

SOA concerns the organization of self-contained and distributed computing components in services so that complex applications can be developed as compositions of loosely coupled components.

The SOA approach is independent of any technology because architectures specify a common language for the definition of services. The Web Service Description Language (WSDL) provides a means for the specification of functionalities offered by a web service so that the implementation of the service can be separated from the component's interface. Services are described in terms of actions, I/O interface, and constraints on data, as well as communication protocols. In order to interact with other web services, a central service registry may be deployed. The Universal Description, Discovery, and Integration registry is a platform-independent registry that enables components to discover each other. Provider components can publish their WSDL descriptions on the registry, enabling client components to reach the provider components using Simple Object Access Protocol (SOAP) messages. SOAP relies on XML to provide an abstract and structured representation for messages.

Because complex services can be assembled from individual services, interaction in the process needs to be coordinated. Synchronization can be controlled by a central orchestrator or directly managed by the distributed entities according to their roles (service choreography). Such coordination may be hard-coded into the procedures used to access the service. However, this is difficult to apply in networks of numerous distributed services and multiple interleaved business processes. Approaches dealing with this issue are the Business Process Execution Language for Web Services, the Web Services Choreography Interface, and the Web Services Choreography Description Language.

### 3.4.3 Resource-Oriented Architectures

An interesting characteristic of communication between components concerns the information used for requesting a service. A typical distinction is between remote procedure call (RPC) and the Representation State Transfer (REST) model. Remote procedure call is an interprocess communication mechanism that allows processes to call procedures (which are turned into methods on object-oriented platforms such as Java RMI) on different address spaces. SOAP-based services implement this approach. A module called *stub* manages this mechanism. *Stub* takes care of data serialization (i.e., marshaling) and hides network mechanisms from developers. The main difference between RPC and REST is that in RPC, the sender sends part of its state to the receiver to perform the request and delegates the receiver to carry out the procedure. In contrast, in the REST model, the sender considers the receiver a collection of resources identified by URIs, and only representations of those resources are sent back to the requester. Therefore, REST web services are manipulations of resources (addressable by URI) rather than procedure or method calls to components. REST is an architectural style defining the behavior of web services in terms of client-server interactions. Accordingly, a client requests a resource to a server. The server processes the request and returns a representation of the resource, consisting of a document describing the state of the resource. This requires resources to be identified with a global identifier (e.g., URI) and means that network components use a standard interface and protocol to exchange such representations (e.g., HTTP). Consequently, the user can progress through a web application by navigating links, which represent state transitions where a different state of the application is returned to the user, who is unaware of the actual network infrastructure (e.g., topology). Therefore, REST does not provide any mechanism for device discovery, as users are supposed to start their navigation at an index page and receive a meaningful list of resources available on the site (server), as well as connections to other sites. Due to its resource-centered approach, REST is usually considered a resource-oriented architecture. This approach was first described in Fielding's PhD thesis [15] and during the definition of the HTTP protocol, although a RESTful approach can also be implemented in other application-level protocols (e.g., SOAP). To enable service interoperability, a typical solution adopted by REST designs is

to describe the payload of HTTP messages in the XML or JSON (Javascript object notation) format. This means that REST can directly take advantage of HTTP, using a uniform interface to access resources (i.e., GET, POST, PUT, and DELETE operations). On the contrary, SOAP-oriented designs use HTTP only as a means for complex XML messages, describing both the protocol and the data to be exchanged when interacting with the service. Moritz et al. [16] examine possible solutions for IP-based smart cooperating objects. In particular, the author provides a comparison of RESTful architectures with the DPWS and underlines necessary requirements when using REST architectures. Moreover, he claims that DPWS can be easily used to model a RESTful application, but a RESTful design can model only a restricted subset of the DPWS design.

What is missing in RESTful architectures is support for asynchronous messaging and eventing, as well as dynamic discovery of resources and semantics.

The interface of REST web services can be described by means of the Web Application Description Language (WADL), a machine-readable and XML-based description of HTTP-based web applications. Therefore, WADL is the parallel of WSDL for RESTful web services, as WADL focuses only on describing the interface without any support for semantics. Kamilaris et al. [17] propose a service discovery mechanism using WADL to advertise REST web services when joining the network. The approach is then evaluated in a smart home scenario, consisting of a network of smart meters. In WSDL definitions, semantic annotations can be added using the Semantic Annotation for WSDL. Another solution is the OWL-S description language, which uses an RDF ontology to assign a semantic to the web service functionality, although OWL-S does not provide any means to express its relationships to other services [18]. However, as the original RDF specification does not include quantifiers, Verborgh et al. [18] aim at providing a semantic method to express RESTful web services. In particular, because RESTful services strongly depend on their URIs, a descriptive semantic explanation of the relationship between a resource and its URI should be provided. To enable automated agents to consume REST web service, it is necessary to describe the meaning of services and their relationships with other services. RESTdesc is proposed as a valid solution for describing the semantics of RESTful web services according to the functionalities they implement, rather than their input-output interface. RESTdesc allows the semantic description of web services as implications in the Notation 3[n3]\* format, which means that services are defined by the pre- and post-conditions needed to execute a request. This gives a reasoner (e.g., EYE {eye}†) the possibility of performing inferences by dynamically evaluating preconditions and applying given axioms, thus providing a flexible solution to handle complex situations. Indeed, the authors suggest that RESTdesc descriptions can be used for automatic context-aware discovery of services, as well as service composition and execution. An example use case illustrating the power of these semantic descriptions is presented in [19]. The authors show that a service composition is a logic entailment binding initial and goal configuration. Accordingly, each service is seen as implication, and service composition is a chain of implications corresponding to a dependency relationship between services. Beyond the formal demonstration, the authors also show how the plan can be implemented by an executor component. Certain rules involve physical data, and thus, these rules are context dependent and are considered only during plan execution.

### 3.5 Profiles, Datasheets, and Descriptions

---

In order to support computer-aided configuration, dedicated computer-readable representations of network and node properties are required. This information plays a similar role to that of manuals and datasheets for a computer-based support framework during configuration and management of a system. These computer-readable representations allow the establishment of common rule sets for developing and configuring applications and for accessing devices and system properties (for configuration as well as management functions). In the following section, we will discuss the profile approach as well as several mechanisms following an electronic datasheet approach: Electronic Device Description

---

\* <http://www.w3.org/TeamSubmission/n3/>

† <http://eulersharp.sourceforge.net>

Language (EDDL), Field Device Tool/Device Type Manager (FDT/DTM), transducer electronic data-sheets (TEDS), smart transducer descriptions (STD) of the IFS, Devices Profile for Web Services (DPWS), and constrained application protocol (CoAP).\*

### 3.5.1 Profiles

Profiles are a widely used mechanism to create interoperability in distributed embedded systems. We distinguish between several types of profiles, namely, application, functional, or device profiles. Heery and Patel propose a very general and short profile definition that we adopt for our discussion. In short, "... profiles are schemata, which consist of data elements drawn from one or more namespaces,<sup>1</sup> combined together by implementers, and optimized for a particular local application" [20].

In many cases, a profile is the result of the joint effort of a group of device vendors in a particular area of application. Usually, a task group is founded that tries to identify reoccurring functions, usage patterns, and properties in the device vendors' domain and then creates strictly formalized specifications according to these identified parts, resulting in the so-called profiles.

More specifically, for each device type, a profile defines exactly what kind of communication objects, variables, and parameters have to be implemented so that a device will conform to the profile. Profiles usually consist of several types of variables and parameters (e.g., process parameters, maintenance parameters, and user-defined parameters) and provide a hierarchical conformance model that allows for the definition of user-defined extensions of a profile. A device profile need not necessarily correspond to a particular physical device, for example, a physical node could consist of multiple *virtual* devices (e.g., multipurpose I/O controller), or a virtual device could be distributed over several physical devices.

Protocols supporting device, functional, and application profiles are CANopen [21], Profibus, and LON [22] (LonMark functional profiles). Figure 3.2 depicts, as an example, the visual specification of a LonMark<sup>2</sup> functional profile for an analog input object. The profile defines a set of network variables (in this example, only mandatory variables are shown) and local configuration parameters (none in this example). The arrow specifies that this profile outputs a digital representation of an analog value, whereas the structure of this output is defined with the standardized (in LON) network variable type SNVT\_lev\_percent (−163.84% to 163.84% of full scale). In addition, a profile also specifies other important properties, such as timing information, valid range, update rate, power-up state, error condition, and behavior (usually as a state diagram).

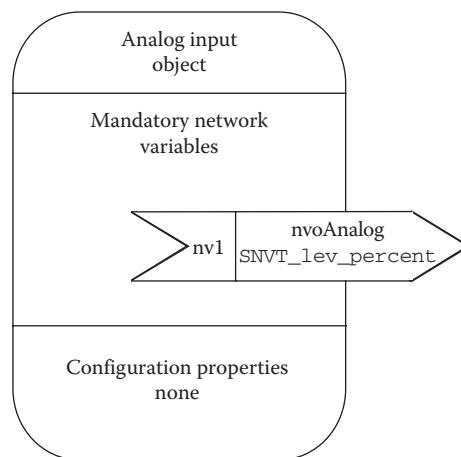

FIGURE 3.2 Functional profile for an analog input.

\* <http://tools.ietf.org/html/draft-ietf-core-coap-18>

Although the approach for creating profiles is comparable in different protocols, the profiles are not always interchangeable between the various fieldbuses, although advancements (at least for process control-related fieldbuses) have been made within the IEC 61158 [23] standard. Block- and class-based concepts such as function blocks, as defined for the Foundation Fieldbus (FF) or the Profibus DP or component classes in IEEE 1451.1 [24] can be considered implementations of the functional profile concept.

### 3.5.2 Electronic Device Description Language

The EDDL was first used with the HART communication protocol in 1992 [25]. In 2004, EDDL was extended by combining the device description languages of HART, PROFIBUS, and Fieldbus Foundation, resulting in an approved international standard IEC 61804-2 [26]. An additional standard IEC 61804-3 extends EDDL by an enhanced user interface, graphical representations, and persistent data storage [27]. In 2004, the OPC Foundation joined the EDDL Cooperation Team. Subsequently, EDDL is used in the open OPC Unified Architecture.

In EDDL, each fieldbus component is represented by an electronic device descriptor (EDD). An EDD is represented in a text file and is operating system independent. Within the basic control and database server, an EDDL interpreter reads the EDD files corresponding to the devices present at the fieldbus system.

Although EDD files are tested against various fieldbus protocols by the vendors, there is no standardized test process for assuring that an EDD works with every available EDDL interpreter. Another weak point of EDDL is that the functionality that can be described with EDDL is limited by the basic functions required by the IEC 61804-2 standard. Thus, device functionality that cannot be described by these functions is often modeled via additional proprietary plug-ins outside the standard. With fieldbus devices becoming increasingly sophisticated, it will become difficult to adequately describe devices with the current EDDL standard.

### 3.5.3 Field Device Tool/Device Type Manager

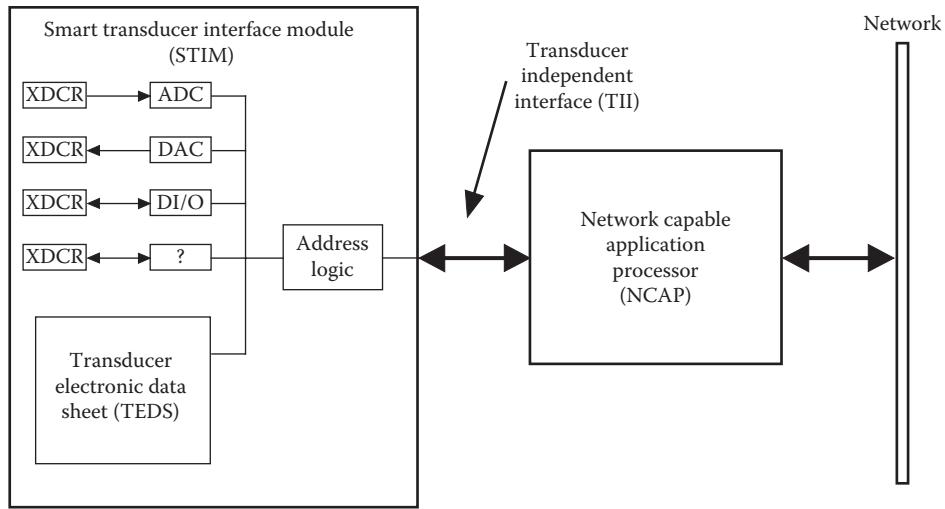

The FDT/DTM is a manufacturer-spanning configuration concept for fieldbus devices [28]. FDT is supported by the FDT group, which currently consists of over 50 members (vendors and users). The FTD group is responsible for the certification of DTM.

A DTM is an executable software that acts as a device driver. An FDT/DTM configuration system consists of the following parts: an FDT frame application for each distributed control system, a communication DTM (comm-DTM) for each fieldbus system, and a device DTM for each field device type. Device functionality is fully encapsulated into the DTM so FDT/DTM comes with no limits regarding the functionality of more complex future devices. In contrast to EDDL, FDT/DTM comes with higher costs for the device manufacturers because manufacturers have to provide the DTM device drivers. On the other hand, EDDL puts greater strain on system manufacturers.

The FDT software has to be executed on a server separate from the basic control and database server. Currently, DTM can run only on Microsoft Windows, which is a drawback due to Microsoft's upgrading and licensing policies (Windows versions evolve rather fast in comparison to the lifetime of an automation plant, and it is not possible to obtain support and extra licenses for outdated Windows versions).

### 3.5.4 Transducer Electronic Datasheet

The TEDS was developed to establish a generic electronic datasheet format as part of the smart transducer-related IEEE 1451 standards family. The IEEE 1451.2 [6] standard specifies the TEDS including the digital interface to access datasheets, read sensors, or set actuators.

**FIGURE 3.3** Smart transducer interface module connected to NCAP.

Figure 3.3 depicts the TEDS in context with the system architecture as defined in the IEEE 1451 standard:

- *Smart transducer interface module (STIM)*: A STIM contains between 1 and 255 transducers of various predefined types together with their descriptions in the form of the corresponding TEDS.
- *Network capable application processor (NCAP)*: The NCAP is the interface to the overall network. By providing an appropriate NCAP, the transducer interface is independent of the physical fieldbus protocol.
- *Transducer independent interface (TII)*: The TII is the interface between the STIM and the NCAP. The TII is specified as an abstract model of a transducer instrumented over 10 digital communication lines.

TEDS describe node-specific properties, such as the structure and temporal properties of devices and transducer data. IEEE 1451 defines self-contained nodes with the TEDS stored in a memory directly located at the node. This causes an overhead on the nodes, so the representation of the configuration information for such a system must be compact. IEEE 1451 achieves this goal by providing a large set of predefined transducer types and modes based on enumerated information, in which identifiers are associated with more detailed prespecified descriptions (similar to error codes). Although the standard defines some possibilities for parameterization of transducer descriptions, this approach restricts the device functionality expressiveness in a similar way as in EDDL.

### 3.5.5 Interface File System/Smart Transducer Descriptions

STDs as defined in [29] are a method for formally describing properties of devices that follow the CORBA Smart Transducer Interface standard (the descriptions themselves are currently not part of the standard).

The STD uses XML [30] as the primary representation mechanism for all relevant system aspects. Together with related standards, such as XML Schema or XSLT, XML provides advanced structuring, description, representation, and transformation capabilities. XML is becoming the de facto standard for data representation and has extensive support throughout the industry. Some examples where XML has already been used for applications in the fieldbus domain can be found in [31–33].

As the name implies, STDs describe the properties of nodes in the smart transducer network. The STD format is used for both describing *static* properties of a device family (comparable to classic datasheets) and devices that are configured as part of a particular application (e.g., if the local STD also contains the local node address). The properties described in STDs cover microcontroller information (e.g., controller vendor, clock frequency, and clock drift), node information (e.g., vendor name, device name/version, and node identifiers), protocol information, and node service information specifying the behavior and the capabilities of a node. In the current approach, a service plays a similar role as a functional profile (see Section 3.5.1) or function block. The functional units align to the interface model of the CORBA STI standard [34].

It is not always possible to store all relevant information outside the node, but by focusing on reducing the amount of required information on the node to the minimum, extensive external meta-information can be used without size constraints. The reference to this external information is the unique combination of series and serial number of the node. The series number is identical for all nodes of the same type. The serial number identifies the instance of a node among all nodes of a series.

The advantages of this approach are twofold:

- Firstly, the overhead at the node is very low. Current low-cost microcontrollers provide internal RAM and EEPROM memory of around 256 bytes. This is not sufficient for storing more than the most basic parts of datasheets according to standards such as the IEEE 1451.2 standard without extra hardware such as external memory. With the proposed description approach, only 8 bytes of memory are required for storing the series and serial numbers.
- Secondly, instead of implicitly representing the node information with many predefined data structures mapped to a compact format, it is possible to have an explicit representation of the information in a well-structured and easy-to-understand way. A typical host computer running the configuration and management tools can easily deal with very extensive generic XML descriptions. Furthermore, XML formats are inherently easy to extend, so the format is open for future extensions of transducer or service types.

### 3.5.6 Devices Profile for Web Services

The Universal Plug and Play (UPnP) standard is a first step toward the implementation of service-oriented device architectures, and UPnP is already diffused in common consumer electronic devices such as network-attached storage systems and media servers. Other frameworks are commonly used in distributed and service-oriented settings, such as OSGi, Jini, and CORBA. However, these frameworks are usually not applicable to very resource-constrained devices.

The DPWS is a collection of standards that allow embedded devices to support secure web services. DPWS does not rely on a global service registry to store and retrieve service descriptions because DPWS uses dynamic service discovery mechanisms to allow devices to advertise themselves and discover their peers. Moreover, due to metadata description of devices, provided services can be accessed alike. Communication among devices is granted by an event-based mechanism. This provides a way to notify state changes according to a publish/subscribe policy.

To meet constraints of deeply embedded devices, Moritz et al. [35] developed uDPWS, a lightweight version that can be run by 8-bit microcontrollers. In this variant, the authors use a table-driven implementation (consisting in a simple string comparison) to avoid parsing the whole incoming message as XML file.

Since SOAP representations rely on XML, data management introduces a certain overhead. A solution to overcome the heavyweight XML representation is to use a binary format. A potential candidate is the Efficient XML interchange (EXI), recommended by W3C since 2011. EXI provides an alternative compact representation of structured data that can be easily integrated into existing XML-based services by means of special converters. A comparison between different formats is addressed by Sakr [36].

EXI is shown to provide the greatest compression and compactness compared to other representations. Therefore, EXI enhances deeply constrained embedded devices with an efficient way of processing XML information, enabling devices to be integrated in SOAs. An implementation of EXI that can be run by deeply embedded systems is proposed by Kyusakov [37].

### 3.5.7 Constrained Application Protocol

Using HTTP is the straightforward solution to implement a REST approach. However, as HTTP provides functionalities that can be considered unnecessary in constrained environments, the IETF constrained RESTful environments working group (CoRE) has proposed the CoAP{coap} as an alternative that can be run by deeply embedded systems (e.g., 8-bit microcontrollers). To maintain an easy mapping with HTTP, CoAP uses the same methods (i.e., GET, POST, PUT, and DELETE). However, instead of using TCP, CoAP uses UDP along with a simple retransmission mechanism in which each GET request is associated with a unique identifier. Moreover, CoAP provides an eventing mechanism to the architecture.

In HTTP, data are transferred from a server to a client after a synchronous request. However, in networks of resource-constrained devices, such as sensor nodes, this means that a node should perform polling on another peer in order to monitor the peer's state, thus increasing the network usage and power consumption. To overcome this limitation, CoAP allows a node to subscribe to updates of a certain resource. Therefore, CoAP provides an asynchronous eventing mechanism, in which nodes can become observers of a certain resource and receive notification of status changes. Another characteristic of REST is that REST does not provide any mechanism for device and resource discovery. In HTTP and the web, discovery of resources takes place by accessing an index page listing links to resources on the same or different servers. Therefore, links define relationships between web resources. This means that giving a meaning to links enables machines to automatically calculate how to use resources on a server. For this purpose, a CoRE link format (RFC6690) has been proposed as the format to be used in M2M applications within the CoAP protocol. Accordingly, links are defined by a list of attributes. A resource-type attribute, *rt*, defines the semantic type of a resource, which may be expressed by a URI referencing a specific concept in an ontology.

The interface description attribute, *if*, can be used to describe the service interface, for instance, by URI referencing a machine-readable document such as a WADL definition. Finally, a maximum size attribute, *sz*, can be used to return an indication of the maximum expected size of the resource representation.

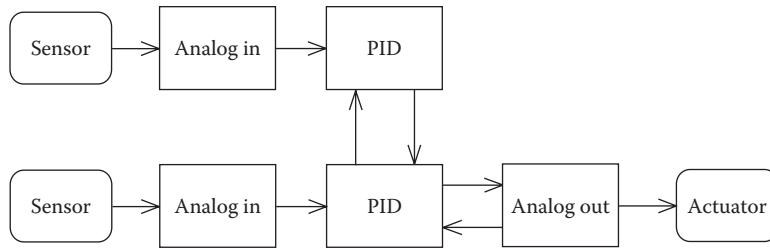

According to this approach, a client can contact the server using a GET to a predefined location (i.e., */well-known/core*), which returns the list of resources exposed by the server and their media type. To provide a basic filtering mechanism, the query can be associated to certain standardized attributes. In particular, *href* filters resources according to their path and type, allowing retrieval of certain Multipurpose Internet Mail Extensions types. Similarly, the attributes *rt* and *if* can be used to select resources according to their application-specific meaning and permitted operations. In addition, it is possible to deploy a resource directory listing links to resources stored on other services. In order to be visible to clients, resource providers can POST their resources to the */well-known/core* position of the chosen directory node.

## 3.6 Application Development

---

In the following section, we examine several application development approaches and how they influence system configuration.

Model-based development is a widely used approach in distributed systems. The basic idea is to create a model of the application that consists of components that are connected via links that represent the communication flow between the components. Different approaches usually differ in what constitutes

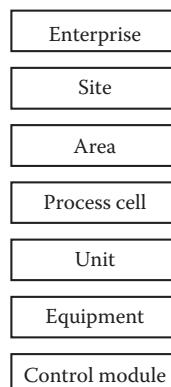

**FIGURE 3.4** Example of an application model.

a component (e.g., function blocks, subsystems, services, functional profiles, and physical devices) and the detailed semantics of a link. Many approaches support the recursive definition of components, which allows grouping multiple lower-level components into one higher-level component. Figure 3.4 depicts a model of a typical small control application consisting of two analog inputs receiving values from two sensors, two PIDs, and one analog output controlling an actuator.

The model-based approach is not the only application design approach. Another approach used by multiple fieldbus configuration tools is the ANSI/ISA-88.01-1995 procedural control model [38]. This modeling approach enforces a strictly modular hierarchical organization of the application (see Figure 3.5). There should be little or no interaction between multiple process cells. Interaction between components in a process cell is allowed. To make best use of this approach, the structure of the network site and the application should closely correspond to the hierarchy specified by this model.

The modeling approach conceptually follows the typical hierarchy of process control applications, with multiple locally centralized Programmable Logic Controllers that drive several associated control devices. This eases transition from predecessor systems and improves overall robustness because this approach provides fault containment at the process cell level, the downside being that the coupling between the physical properties of the system and the application is rather tight. An example of a fieldbus protocol that supports this modeling approach is the Profibus PA protocol, which supports this model by providing a universal function block parameter for batch identification [39].

Another design approach is the *two-level design approach* [40], which originated in the domain of safety critical systems. In this approach, the communication between components must be configured before configuring the devices. Although this requires many design decisions to be taken very early in the design process, this approach greatly improves overall composability of the components in the system.

**FIGURE 3.5** ANSI/ISA-88.01-1995 hierarchical model.

Abstract application models provide several advantages for application development:

- The modular design of applications helps to deal with complexity by applying a *divide-and-conquer* strategy. Furthermore, modular design supports reuse of application components and physical separation.
- The separation of application logic from physical dependencies allows hardware-independent design that enables application development before hardware is available, as well as easing migration and possibly allowing the reuse (of parts) of applications.

For configuring a physical fieldbus system from such an application model, we must examine (1) how this application model maps to the physical nodes in the network and (2) how information flow is maintained in the network.

In order to map the application model to actual devices, fieldbuses often provide a model for specifying physical devices, for example, in Profibus DP, the physical mapping between function blocks and the physical device is implemented as follows (see Figure 3.6): A physical device can be subdivided in several modules that take the role as *virtual devices*. Each device can have from one (in case of simple functionality) to many slots, which provide the mapping from physical devices to function blocks. A function block is mapped to a slot, whereas slots may have associated physical and transducer blocks. Physical and transducer blocks represent physical properties of a fieldbus device. Parameters of a function block are indexed, and the slot number and parameter index cooperatively define the mapping to data in the device memory.

In contrast, the FF follows an object-oriented design philosophy. Thus, all information items related to configuring a device and the application (control strategy) are represented with objects. This includes function blocks, parameters, as well as subelements of parameters. These objects are collected in an object dictionary (OD), whereas each object is assigned an index. This OD defines the mapping to the physical memory on the respective device. In order to understand the methods for controlling the communication flow between the application components, we first examine some recurring important communication properties in fieldbus applications:

- Use of state communication as primary communication mechanism for operating a fieldbus [41]. State communication usually involves cyclically updating the associated application data.
- Support for asynchronous/sporadic communication (event communication) in order to perform management functions and deal with parts of the application that cannot be performed with state communication.

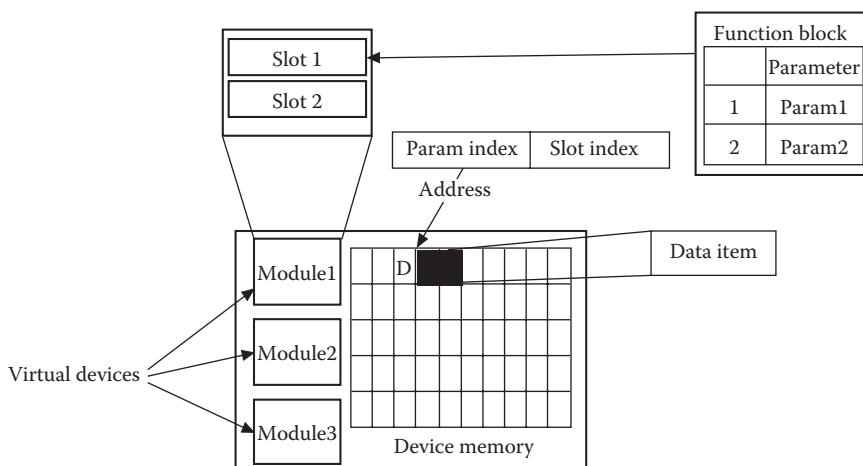

FIGURE 3.6 Mapping of function blocks to physical device in Profibus DP.

A common method to achieve these properties is by scheduling. There are many scheduling approaches with vastly different effects on configuration. The following are some commonly adopted approaches in fieldbus systems:

*Multicycle polling:* In this approach, communication is controlled by a dedicated node that authorizes other nodes to transmit their data [42]. This dedicated node, typically called the *master node*, polls the other nodes in a time division multiplexing scheme. Thus, the cyclic polling also takes care of bus arbitration. This approach is taken, for example, in WorldFIP, FF, and ControlNet. For configuring the devices in such a network, the master nodes require at least a list of nodes to be polled, that is, in a configuration with a single master, only one node need be configured with time information to control the whole cluster.

*Time-triggered:* In a time-triggered communication model, the communication schedule is derived from the progression of physical time. This approach requires a predefined collision-free schedule that defines a priori when a device is allowed to broadcast its data and an agreement on a global time, which requires synchronization of the local clocks of all participating devices [3]. Examples of protocols that support time-triggered communication are TTP/A [12], TTP/C [43], and the synchronous part of the Flexray protocol [44]. In order to configure the communication in these systems, the schedules must be downloaded to all nodes in the network.

*Event-triggered:* Event-triggered communication implements a push model in which the sender decides when to send a message, for example, when a particular value has changed more than a given *delta*. Collisions on the bus are solved by collision detection/retransmission or collision avoidance, that is, bitwise arbitration protocols such as CAN [45]. Event-triggered communication does not depend on scheduling because communication conflicts are either resolved by the protocol at the data link layer (e.g., bit-wise arbitration) or must be resolved by the application.

Scheduling information is usually stored in dedicated data structures that are downloaded to the nodes in the network to be available for use by the network management system functions of the node.

The TTP/A protocol integrates configuration information for application data flow and the communication schedule. Thus, the local communication schedules (named *round descriptor lists*) as well as the interfaces of application services [34] are mapped into the same interfacing mechanism, the *IFS* (see Section 3.4.1).

For representation of the overall system, cluster configuration description (CCD) format was developed, which acts as a central uniform data structure that stores all the information pertinent to the fieldbus system. This information includes the following:

- *Cluster description meta-information:* This description block holds information on the cluster description itself, such as the maintainer, name of the description file, or the version of the CCD format itself.
- *Communication configuration information:* This information includes round sequence lists as well as round descriptor lists, which represent the detailed specification of the communication behavior of the cluster. Additionally, this part of the CCD also includes (partially physical) properties important for communication, such as the UART specification, line driver, and minimum/maximum signal run times.
- *Cluster node information:* This block contains information on the nodes in a cluster, whereas nodes are represented with the STD format.

## 3.7 Configuration Interfaces

---

In the previous section, we focused on the relationship between application and configuration. In this section, we examine parts of system configuration that are mostly independent of the application. We briefly look at the physical configuration of networked embedded systems, how nodes are recognized by the configuration system, and how application code is downloaded to nodes.

### 3.7.1 Hardware Configuration

The hardware configuration encompasses the setup of the plugs and cables of the network. For instance, several fieldbus systems implement means to avoid mistakes, such as connecting a power cable to a sensor input, which would cause permanent damage to the system or even harm people. Moreover, hardware configuration interfaces such as plugs and clamps are often subject to failure in harsh environments, for example, on a machine that induces a lot of vibration.

For hardware configuration, the following approaches can be identified:

- Usage of special jacks and cables that support a tight mechanical connection and avoid mistakes in orientation and polarity by their geometries, for example, the actuator–sensor interface<sup>3</sup> (AS-i) specifies a mechanically coded flat cable that allows the connection of slaves on any position on the cable by using piercing connectors. AS-i uses cables with two wires transporting data and energy via the same line. The piercing connectors support simple connection, safe contacting, and protection up to class IP67.
- Baptizing devices in order to obtain an identifier that allows addressing the newly connected device. This could be done by explicitly assigning an identifier to the device, for example, by setting dip switches or entering a number over a local interface, or implicitly by the cabling topology, for example, devices could be daisy-chained and obtain their name subsequently according to the chain.
- Alternatively, it is possible to assign unique identifiers to nodes in advance. This approach is taken, for example, with Ethernet devices for which the MAC address is a worldwide unique identifier, or in the TTP/A protocol that also uses unique node IDs. However, such a worldwide unique identifier will require many digits making it unpractical to have the number printed somewhere on the device. To overcome this problem, machine-readable identifiers in the form of barcodes or RF tags are used during hardware configuration.
- Simple configuration procedures, which can be carried out and verified by nonexpert personnel.

### 3.7.2 Plug and Participate

Hardware configuration is intended to be simple, and consequently a networked system should behave intelligently in order to relieve human personnel of error-prone tasks.

In the case of plug and participate, the system runs an integration task that identifies new nodes, obtains information about these nodes, and changes the network configuration in order to include the new nodes in the communication.

Identification of new nodes can be supported with manual baptizing as described in the previous section. Alternatively, it is also possible to automatically search for new nodes and identify them as described in [46].

If there can be different classes of nodes, it is necessary to obtain information on the type of the newly connected nodes. This information will usually be available in the form of an electronic datasheet that can be obtained from the node or from an adequate repository.

The necessary changes of the network configuration for including the new node greatly depend on the employed communication paradigm. In the case of a polling paradigm, only the list of nodes to be polled has to be extended. In the case of a time-triggered paradigm, the schedule has to be changed and updated in all participating nodes. In the case of an event-triggered paradigm, only the new node has to be authorized to send data; however, it is very difficult to predict how a new sender will affect the timing behavior of an event-triggered system. In all three cases, critical timing might be affected due to a change in response time, that is, when the cycle time has to be changed. Thus, in time-critical systems, extensibility must be taken into account during system design, for example, by reserving at first unused bandwidth or including spare communication slots.

### 3.7.3 Service Discovery Mechanisms

Service discovery defines how network entities can represent and advertise services, so that they can be detected and used by other members. This is a naming problem: assigning each entity a persistent identifier that can be used for retrieving resources. A simple naming system may use broadcasting or multicasting to advertise or retrieve resources (according to push or pull semantics). For instance, this is what happens in the address resolution protocol. Another solution is to use centralized name servers (registries), which can be static nodes or dynamically elected by the community. This approach presents single points of failure that can be improved by organizing nodes in a hierarchy of registries (e.g., domain name service).

Large-scale distributed systems usually use logical overlays, and as such, topologies are set up depending on certain criteria, such as physical distance between nodes. We refer to [47] for a complete overview of resource naming.

Dargie [48] classifies naming systems in three generations: name services (e.g., DNS), directory services (e.g., CORBA and LDAP), and service discovery systems. Although name service offers just mapping between identifiers and resources, directory services enable attribute-based queries because each entry is defined by a set of attributes. However, the author suggests that the first two generations may not be enough in dynamically changing environments such as mobile networks, where entities join and leave the network, thus continuously modifying the network topology. According to Dargie [48], service discovery systems can provide self-configuration and self-healing properties to networks of mobile embedded devices. These systems are indeed able to update the network configuration by discovering new services and detecting failures and disconnected entities (e.g., using leasing on services). Dargie [48] reports on state of the art of service discovery systems. Network size affects bandwidth, so he divides systems into small and large systems. Small systems (e.g., Jini, UPnP, SLP, and Bluetooth) can be implemented as directory based or using multicast. On the other hand, service discovery for large systems (e.g., Ninja SDS, Twine, Jxta, and Ariadne) has to take into account scalability issues. Consequently, systems can be implemented as registries organized in multiple hierarchies or using logical overlays connecting nodes in a peer-to-peer manner.

### 3.7.4 Application Configuration and Upload

Some frequently recurring applications, such as standard feedback control loops, alert monitoring, and simple control algorithms can often be put in place like building bricks because these applications are generically available (e.g., PID controllers).

For more complex or unorthodox applications, however, it is necessary to implement user-defined applications. These cases require code to be uploaded onto target devices.

About 15 years ago, the most common method of reprogramming a device was to have an EPROM memory chip in a socket that was physically removed from the device, erased under UV radiation, and programmed using a dedicated development system, that is, a PC with a hardware programming device, and then put back into the system.

Today, most memory devices and microcontrollers provide an interface for in-system serial programming of Flash and EEPROM memory. The hardware interface for in-system serial programming usually consists of a connector with four to six pins attached either to an external programming device or directly to the development PC. These programming interfaces are often proprietary to particular processor families, but there also exist some standard interfaces that support a larger variety of devices. For example, the JTAG debugging interface (IEEE Standard 1149.1) also supports the upload of application code.

While the in-system serial programming approach is much more convenient than the socketed EPROM method, both approaches are conceptually reasonably similar because it is still necessary to establish a separate hardware connection to the target system. A more advanced approach for uploading applications is in-programming. In this approach, it is possible to program and configure a device without taking the device out of the distributed target system and without using extra cables and hardware interfaces.

In-system configuration is supported by state-of-the-art flash devices, which can reprogram themselves in part by using a bootloader program. Typically, whenever a new application has to be set up, the programming system sends the node a signal causing it to enter a dedicated upload mode. During the upload phase, the node's service is usually inactive. Failures that lead to misconfiguration must be corrected by locally connecting a programming tool.

Alternatively, application code could be downloaded via the network into the RAM memory at startup. In this case, only the bootloader resides in the persistent memory of the device, and the user-defined application code has to be downloaded at startup. This approach has the advantage of being stateless, so that errors in the system are removed at the next startup, thus engineers could handle many faults by a simple restart of the system. On the other hand, this approach depends on the configuration instance at startup—the system cannot be started if the configuration instance is down. Moreover, the restart time of a system may be considerably longer.

## 3.8 Management Interfaces

---

The possibility of performing remote management operations on distributed devices is one of the most important advantages of these systems. Wollschläger states that “in automation systems, engineering functions for administration and optimization of devices are gaining importance in comparison with control functions” [49, p. 89].

Typical management operations are monitoring, diagnosis, or node calibration. Unlike primary fieldbus applications, which often require cyclical, multidrop communication, these management operations usually use a one-to-one (client–server) communication style. For this reason, most fieldbus systems support both communication styles.

A central question is whether and how this management traffic influences the primary application, a problem known as probe effect [13]. System management operations that influence the timing behavior of network communication are critical for typical fieldbus applications (e.g., process control loops) that require exact real-time behavior.

The probe effect can be avoided by reserving a fixed amount of the bandwidth for management operations. For example, in the FF and WorldFIP protocols, the application cycle (macro cycle) is chosen to be longer than strictly required by the application, and the remaining bandwidth is free for management traffic.

In order to avoid collisions within this management traffic window, adequate mechanisms for avoiding or resolving such conflicts must be used (e.g., token-passing between nodes that want to transmit management information and priority-based arbitration).

In TTP/A, management communication is implemented by interleaving real-time data broadcasts (implemented by multipartner rounds) with the so-called master–slave rounds that open a communication channel to individual devices.

If management traffic is directly mingled with application data, such as in CAN, LonWorks, or Profibus PA, care must be taken that this management traffic does not influence the primary control application. This is typically achieved by analyzing network traffic and leaving enough bandwidth headroom. For complex systems and safety-critical systems that require certain guarantees on system behavior, this analysis can become very difficult.

### 3.8.1 Monitoring and Diagnosis

In order to perform passive monitoring of the communication of the application, it usually suffices to listen on the network. However, the monitoring device must have knowledge of the communication scheme used in the network in order to be able to understand and decode the data traffic. If this scheme is controlled by the physical time, as is the case in time-triggered networks, the monitoring node must also synchronize itself to the network.

Advanced networked embedded devices often have built-in self-diagnostic capabilities and can disclose their own status to the management system. It depends on the capabilities of the system how such information reaches the management framework. Typically, a diagnosis tool or the diagnosis part of the management framework will regularly check the information in the nodes. This method is called *status polling*. In some fieldbus protocols (e.g., FF), devices can also transmit status messages by themselves (*alert reporting*).

In general, restrictions from the implementation of the management interface of a fieldbus protocol also apply to monitoring because in most fieldbus systems, the monitoring traffic is transmitted using the management interface.

For systems that do not provide this separation of management from application information at the protocol level, other means must be taken to ensure that monitoring does not interfere with the fieldbus application. Status polling usually is performed periodically, and thus, it should be straightforward to reserve adequate communication resources during system design so that the control application is not disturbed. In case of alert reporting, the central problem without adequate arbitration and scheduling mechanisms is discerning how to avoid overloading the network in case of *alarm showers*, when many devices want to send their messages at once. It can be very difficult to give timeliness guarantees (e.g., the time between an alarm occurring and the alarm being received by its respective target) in such cases. The typical approach for dealing with this problem (e.g., as taken in CAN) is to provide much bandwidth headroom.

For in-depth diagnosis of devices, it is sometimes also desirable to monitor operation and internals of individual field devices. This temporarily involves greater data traffic, which cannot be easily reserved a priori. Therefore, the management interface must provide some flexibility on the diagnosis data in order to dynamically adjust to the proper level of detail using some kind of *pan and zoom* approach [50].

### 3.8.2 Calibration

The *calibration* of transducers is an important management function in many fieldbus applications. There is some ambiguity involved concerning the use of this term. Berge strictly distinguishes between *calibration* and *range setting*:

“Calibration is the correction of sensor reading and physical outputs so they match a standard” [39, p. 363]. According to this definition, calibration cannot be performed remotely because the device must be connected to a standardized reference input.

*Range setting* is used to move the value range of the device so that the resulting value delivers the correctly scaled percentage value. *Range setting* does not require any input and measurement of output, thus *range setting* can be performed remotely. In the HART bus, this operation is called *calibration*, whereas calibration is called *trim*.

Network technology does not influence the way calibration is handled, although information that is required for calibration is stored as part of the properties that describe a device. Such information could be the minimum calibration span limit, this being “the minimum distance between two calibration points within the supported operation range of a device.” Additionally, calibration-related information, that is, individual calibration history can be stored in the devices themselves. This information is then remotely available for management tools in order to check the calibration status of devices. Together with the self-diagnosis capabilities of the field devices, this allows performance of a focused and proactive management strategy.

## 3.9 Maintenance in Fieldbus Systems

---

Maintenance is the activity of keeping the system in good working order. Typical networked embedded systems (e.g., fieldbuses) provide extensive management features, such as diagnosis and monitoring, which help greatly in maintaining systems. There are several different maintenance schemes that

influence the way these steps are executed in detail. Choice of a particular maintenance scheme is usually motivated by the application requirements [39]:

- *Reactive maintenance* is a scheme in which a device is fixed only after it has been found to be broken. Reactive maintenance should be avoided in environments where downtime is costly (such as in factory applications). Thus, designers of such applications will usually choose more active maintenance strategies. Nonetheless, fieldbus systems also provide advantages for this scheme because fieldbus systems support fast detection of faulty devices.
- *Preventive maintenance* is a scheme in which devices are serviced in regular intervals even if devices are working correctly. This strategy prevents unexpected downtime, thus improving availability. Due to the associated costs, this approach will only be taken in safety-related applications such as in aviation, train control, or where unexpected downtime would lead to very high costs.
- *Predictive maintenance* is similar to preventive maintenance, differing in a dynamic service interval that is optimized by using long-time statistics on devices.
- *Proactive maintenance* focuses on devices that are expected to require maintenance.

Maintenance mainly comprises the following steps:

- Recognizing a defective device
- Repairing (replacing) the defective device
- Reintegrating the serviced device

In fieldbus systems, faulty devices will usually be recognized via the network. This is achieved by monitoring the fieldbus nodes and the application or with devices that are capable of sending alerts (also refer to Section 3.8).

After the source of a problem has been found, the responsible node must be serviced. This often means disconnecting the node from the network, thus strategies are required to allow the system to deal with *disconnection* of the node, as well as reconnecting and *reintegrating* the replacement node.

If the whole system has to be powered down for maintenance, the faulty node can simply be replaced, and integration of the replacement node occurs as part of the normal initial startup process. If powering down the whole system is undesirable or even impossible (in the sense of leading to severe consequences, as in the case of safety-critical applications), this process becomes more complicated. In this case, we have several options:

- *Implementation of redundancy*: This approach must be taken for safety- or mission-critical devices, where the respective operations must be continued during replacement after a device becomes defective. A detailed presentation of redundancy and fault-tolerant systems can be found in [51].
- *Shut down part of the application*: In the case of factory communication systems that often are organized as multilevel networks and/or use a modular approach, it might be feasible to shut down a local subnetwork (e.g., a local control loop, or a process cell as defined in the ANSI/ISA-88.01-1995 standard).

The replacement node must be configured with individual node data, such as calibration data (these data usually differ between replaced and replacement nodes), and the *state* of a node. The state information can include the following:

- Information accumulated during run-time (the history state of a system): This information must be transferred from the replaced node to the replacement node.
- Timing information so that the node can synchronize with the network: In networks that use a distributed static schedule (e.g., TTP/A), each node must be configured with its part of the global schedule in order to establish a network-wide consistent communication configuration.

One alternative approach for avoiding this transfer of system state is to design (and create) a stateless system. Bauer proposes a generic approach for creating stateless systems from systems with state in [52]. Another possibility is to provide well-defined reintegration points where this state is minimized. Fieldbus applications typically use a cyclical communication style so the start of a cycle is a *natural* reintegration point.

## 3.10 Conclusion

---

Configuration and management play an important role for distributed embedded systems. The need for configuration and management in the domain of industrial fieldbus systems has led to interesting mechanisms evolving during the last 20 years. Most of these mechanisms can also be applied in the domain of embedded systems.

The configuration phase can be subdivided into a part that requires local interaction such as connection of hardware and setting dip switches, and a part that can be performed remotely via the fieldbus system. A good design requires the local part to be as simple as possible in order to simplify the interactions of local personnel. The other part should be supported by tools that assist the system integrator in tedious and error-prone tasks such as adjusting parameters according to the datasheet of a device. Examples of systems with such a configuration support are, among others, the IEEE 1451, the FDT, and the EDDL, which all employ machine-readable electronic datasheets in order to support configuration tools.

Management encompasses functions such as monitoring, diagnosis, calibration, and support for maintenance. In contrast to the configuration phase, most management functions are used concurrently to the RS during operation. Some management functions, such as monitoring, may require real-time behavior for themselves. In order to avoid a probe effect on the RS, scheduling of the fieldbus system must be designed to integrate management traffic with real-time traffic.

### 4.1 Introduction

---

Sensors are used in many devices and systems to provide information on the parameters being measured or to identify the states of control. They are good candidates for increased built-in intelligence. Microprocessors can make smart sensors or devices a reality. With this added capability, it is possible for a smart sensor to directly communicate measurements to an instrument or a system. In recent years, the concept of computer networking has gradually migrated into the sensor community. Networking of transducers (sensors or actuators) in a system and communicating transducer information via digital means versus analog cabling facilitate easy distributed measurements and control. In other words, intelligence and control, which were traditionally centralized, are gradually migrating to the sensor level. This can provide flexibility, improve system performance, and ease system installation, upgrade, and maintenance. Thus, the trend in industry is moving toward distributed control with intelligent sensing architecture. These enabling technologies can be applied to aerospace, automotive, industrial automation, military and homeland defenses, manufacturing process control, smart buildings and homes, and smart toys and appliances for consumers.

As examples, (1) in order to reduce the number of personnel to run a naval ship from 400 to less than 100 as required by the reduced-manning program, the US Navy needs tens of thousands of networked sensors per vessel to enhance automation and improve maintenance, and (2) airplane manufacturers would like to network hundreds of sensors for monitoring and characterizing airplane performance.

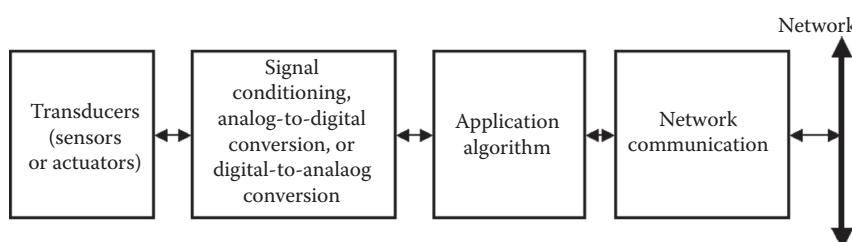

Sensors are used across industries and are going global [1]. The sensor market is extremely diverse, and it is expected to grow to \$252 billion by 2016. The rapid development and emergence of smart sensor and field network technologies have made the networking of smart transducers a very economical and attractive solution for a broad range of measurement and control applications. However, with the existence of a multitude of incompatible networks and protocols, the number of sensor interfaces and amount of hardware and software development efforts required to support this variety of sensor networks are enormous for both sensor producers and users alike. The reason is that a sensor interface customized for a particular network will not necessarily work with another network. It seems that a variety of networks will coexist to serve their specific industries. The sensor manufacturers are uncertain of which network(s) to support and are restrained from full-scale smart sensor product development. Hence, this condition has impeded the widespread adoption of the smart sensor and networking technologies despite a great desire to build and use them. Clearly, either a common sensor network interface standard is needed to help alleviate this problem [2], or many sensor network interfaces have to coexist in a working environment. With the emergence of the Industrial Internet, Internet of Things, Machines to Machines, and Cyber Physical Systems technologies, smart sensors and sensor networks will play a key role in supporting these technologies to achieve their potentials. Standardized smart sensor and sensor network interfaces will help ease the adoption and use of these technologies.

## 4.2 Smart Transducer Model

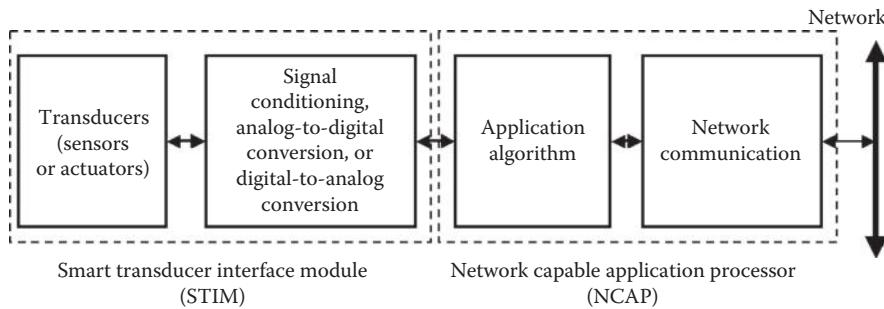

In order to develop a sensor interface standard, a smart transducer model should first be defined. As defined in the IEEE Std 1451.2-1997 [3], a smart transducer is a transducer that provides functions beyond those necessary for generating a correct representation of a sensed or controlled quantity. This functionality typically simplifies the integration of the transducer into applications in a networked environment. Thus, let us consider the functional capability of a smart transducer. A smart transducer should have

- Integrated intelligence closer to the point of measurement and control
- Basic computation capability
- Capability to communicate data and information in a standardized digital format to a network

Based on this premise, a smart transducer model is shown in Figure 4.1. It applies to both sensors and actuators. The output of a sensor is conditioned and scaled, then converted to a digital format through an analog-to-digital (A/D) converter. The digitized sensor signal can then be easily processed by a microprocessor using a digital application control algorithm. On the other hand, the output, after being converted to an analog signal via a digital-to-analog (D/A) converter, can then be used to control

**FIGURE 4.1** A smart transducer model.

**FIGURE 4.2** Functional partitioning.

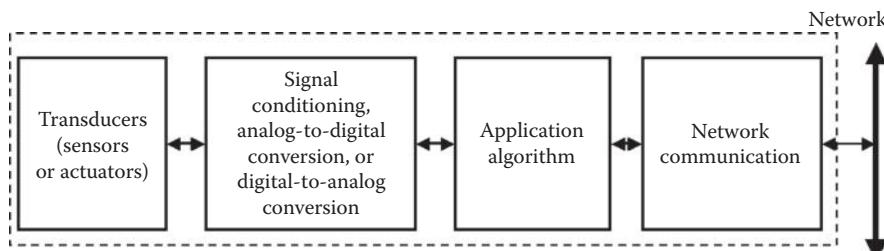

an actuator. Any of the measured or calculated parameters can be passed on to any device or host in a network by means of network communication protocols.

The different modules of the smart transducer model can be grouped into functional units as shown in Figure 4.2. The transducers and signal conditioning and conversion modules can be grouped into a building block called a smart transducer interface module (STIM). Likewise, the application algorithm and network communication modules can be combined into a single entity called a network capable application processor (NCAP). With this functional partitioning, transducer to network interoperability can be achieved in these manners:

1. STIMs from different sensor manufacturers can *plug and play* with NCAPs from a particular sensor network supplier.
2. STIMs from a sensor manufacturer can *plug and play* with NCAPs supplied by different sensor or field network vendors.
3. STIMs from different manufacturers can be interoperable with NCAPs from different field network suppliers.

Using this partitioning approach, a migration path is provided to those sensor manufacturers who want to build STIMs with their sensors, but do not intend to become field network providers. Similarly, it applies to those sensor network builders who do not want to become sensor manufacturers.

As technology becomes more advanced and microcontrollers become smaller relative to the size of the transducer, integrated networked smart transducers that are economically feasible to implement will emerge in the marketplace. In this case, all the modules are incorporated into a single unit as shown in Figure 4.3. Thus, the interface between the STIM and NCAP is not exposed for external access and separation. The only connection to the integrated transducer is through the network connector. The integrated smart transducer approach simplifies the use of transducers by merely plugging the device into a sensor network.

**FIGURE 4.3** An integrated networked smart transducer.

## 4.3 Networking Smart Transducers

---

Not until recently have sensors been connected to instruments or computer systems by means of a point-to-point or multiplexing scheme. These techniques involve a large amount of cabling, which is very bulky and costly to implement and maintain. With the emergence of computer networking technology, transducer manufacturers and users alike are finding ways to apply this networking technology to their transducers for monitoring, measurement, and control applications [4]. Networking smart sensors provides the following features and benefits:

- Enable peer-to-peer communication and distributed sensing and control
- Significantly lower the total system cost by simplified wiring
- Use prefabricated cables instead of custom laying of cables for ease of installation and maintenance
- Facilitate expansion and reconfiguration
- Allow time-stamping of sensor data
- Enable sharing of sensor measurement and control data
- Provide Internet connectivity, meaning *global* or *anywhere*, access of sensor information

## 4.4 Establishment of the IEEE 1451 Standards

---

As discussed earlier, a smart sensor interface standard is needed in industry. In view of this situation, the Technical Committee on Sensor Technology of the Institute of Electrical and Electronics Engineers (IEEE)'s Instrumentation and Measurement Society sponsored a series of projects for establishing a family of IEEE 1451 Standards [5]. These standards specify a set of common interfaces for connecting transducers to instruments, microprocessors, field networks, or the Internet. They cover digital, mixed-mode, distributed multidrop sensor integration with radio frequency identification (RFID), signal treatment, wireless interfaces, network interfaces, and eXtensible Messaging and Presence Protocol (XMPP) to address the needs of different sectors of industry. A key concept in the IEEE 1451 standards is the definition and specification of the Transducer Electronic Data Sheet (TEDS) formats. A TEDS is a standardized method of storing transducer (sensor or actuator) identification and manufacture-related information, such as manufacturer name, sensor types, serial number, and calibration data. The TEDS provides many benefits:

- Enable self-identification of sensors or actuators—a sensor or actuator equipped with the IEEE 1451 TEDS can identify and describe itself to the host or network via the sending of the TEDS.
- Provide long-term self-documentation—the TEDS in the sensor can be updated and stored with information such as location of the sensor, recalibration date, repair record, and many maintenance-related data.
- Reduce human error—automatic transfer of TEDS data to the network or system eliminates the entering of sensor parameters by hands, which could induce errors due to various conditions.
- Ease field installation, upgrade, and maintenance of sensors—this helps to reduce life cycle costs because only lesser skilled persons are needed to perform these tasks by simply doing *plug and play* of sensors.

IEEE 1451, designated as Standard Transducer Interface for Sensors and Actuators, consists of a family of document standards with appropriately named parts, for example, 1451.1 is Common Network Services and 1451.5 is Wireless Communication. This family of standards aims to work with each other to provide a set of seamless interfaces for communicating sensor data/information from devices to networks and the Internet. It works with other application standards like MTConnect for accessing sensor data from machines [6,7] and Open Geospatial Consortium Sensor Web Enablement sensor data for geospatial applications [8,9]. The IEEE 1451 family reference model is shown in Figure 4.4.

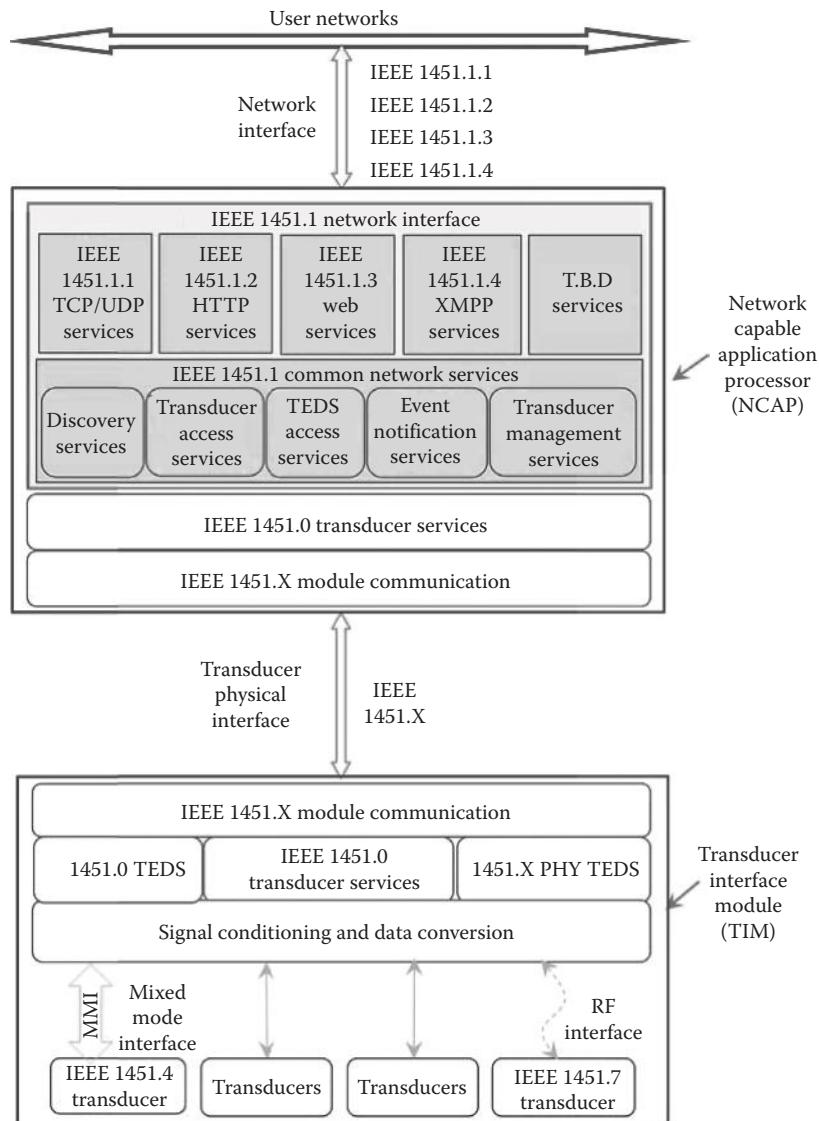

FIGURE 4.4 IEEE 1451 family reference model.

The current status of the family of standards development effort is as follows:

1. IEEE 1451.0-2007, Common Functions, Communication Protocols, and Transducer Electronic Data Sheet (TEDS) Formats—*published standard*
2. IEEE P1451.1,\* Common Network Services [6]—*standard being developed*
3. IEEE 1451.2-1997, Transducer to Microprocessor Communication Protocols and Transducer Electronic Data Sheet (TEDS) Formats [3,10]—*published standard*
4. IEEE P1451.2, Serial Point-to-Point Interface—*standard being developed*. When this standard is completed, it will supersede the IEEE 1451.2-1997

\* P1451.1, the “P” designation means P1451.1 is a draft standard development project. Once the draft document is approved as a standard, “P” will be dropped.

5. IEEE 1451.3-2003, Digital Communication and Transducer Electronic Data Sheet (TEDS) Formats for Distributed Multidrop Systems [11]—published standard
6. IEEE 1451.4-2004, Mixed-mode Communication Protocols and Transducer Electronic Data Sheet (TEDS) Formats [12]—published standard
7. IEEE 1451.5-2005, Wireless Communication and Transducer Electronic Data Sheet (TEDS) Formats [13]—published standard
8. IEEE 1451.7-2010, Transducers to Radio Frequency Identification (RFID) Systems Communication Protocols and Transducer Electronic Data Sheet Formats [14]—published standard
9. IEEE P1451.1.4, Standard for a Smart Transducer Interface for Sensors, Actuators, and Devices—eXtensible Messaging and Presence Protocol (XMPP) for Networked Device Communication—standard being developed
10. IEEE P1451.001, Recommended Practice for Signal Treatment Applied to Smart Transducers—standard is being developed

## 4.5 Goals of IEEE 1451

---

The goals of the IEEE 1451 standards are to

- Develop network-independent and vendor-independent transducer interfaces
- Define TEDS and standardized data formats
- Support general transducer data, control, timing, configuration, and calibration models
- Allow transducers to be installed, upgraded, replaced, and moved with minimum effort by simply *plug and play*
- Eliminate error-prone, manual entering of data and system configuration steps
- Ease the connection of sensors and actuators to networks or Internet by wireline or wireless means

## 4.6 IEEE 1451 Standards

---

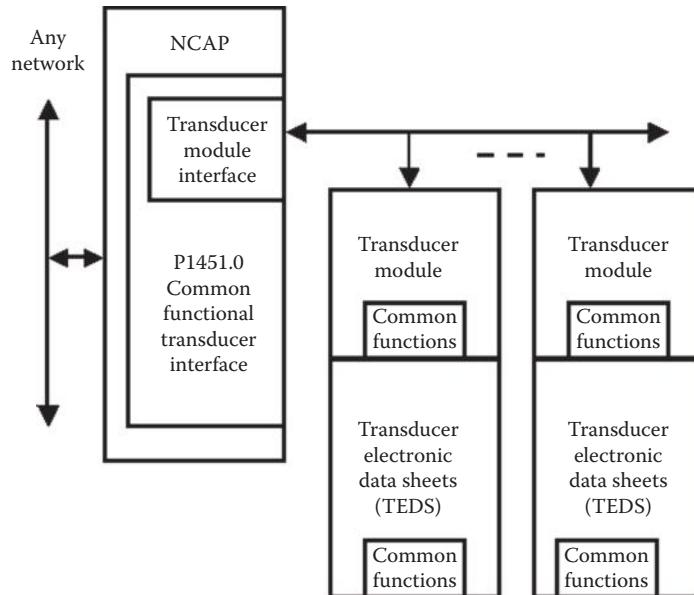

### 4.6.1 IEEE 1451 Smart Transducer Model

The IEEE 1451 smart transducer model parallels the smart transducer model discussed in Figure 4.2. In addition, the IEEE 1451 model includes the TEDS. The model applied to each of the IEEE 1451.X standards is discussed in the following.

### 4.6.2 IEEE 1451.0 Common Functionality and Communication Protocols

Several standards in the IEEE 1451 family share certain characteristics, but there is no common set of functions, communication protocols, and TEDS formats that facilitate interoperability among these standards. The IEEE 1451.0 standard provides that commonality and simplifies the creation of future standards with different physical layers that will facilitate interoperability in the family. This project defines a set of common functionality for the family of IEEE 1451 smart transducer interface standards. This set of functionality is independent of the physical communications media. It includes the basic functions required to control and manage smart transducers, common communications protocols, and media-independent TEDS formats. The block diagram for IEEE 1451.0 is shown in Figure 4.5. The IEEE 1451.0 defines functional characteristics, but it does not define any physical interface.

The IEEE 1451.0 standard defines different types of TEDS, their data format, and the digital interface and communication protocols between the TIM (Transducer Module in Figure 4.5) and the NCAP. The TIM contains the transducer(s) and the TEDS, which is stored in a nonvolatile memory attached to a transducer. The TEDS contains fields that describe the type, attributes, operation, and calibration of the transducer. The mandatory requirement for the TEDS is less than 300 bytes. The rest of the TEDS specification is optional. A transducer integrated with the TEDS provides a very unique feature that makes

**FIGURE 4.5** The block diagram of IEEE 1451.0.

possible the self-describing of transducers to the system or network. Since the manufacture-related data in the TEDS always go with the transducer, and this information is electronically transferred to an NCAP or host, human errors associated with manual entering of sensor parameters into the host are eliminated. Because of this distinctive feature of the TEDS, upgrading transducers with higher accuracy and enhanced capability or replacing transducers for maintenance purpose is simply considered *plug and play*. Many different types of TEDS are defined in the standard, and some of them are mandatory and others are optional. They are listed in Table 4.1.

The TEDS formats are divided into two categories. The first category of TEDS contains data in a machine-readable form, which is intended to be used by the NCAP. The second category of TEDS contains data in a human-readable form. The human-readable TEDS may be represented in multiple languages using different encoding for each language. The Meta TEDS contains the data that describe the TIM. It contains the revision of the standard, the version number of the TEDS, the number of channels in the TIM, and the worst-case timing required to access these channels. This information will allow the NCAP to access the channel information. In addition, the Meta TEDS includes the channel groupings that describe the relationships between channels. Each transducer is represented by a channel. Each channel in the TIM contains a Channel TEDS. The Channel TEDS lists the actual timing parameters for each individual channel. It also lists the type of transducer, the format of the data word being output by the channel, the physical

**TABLE 4.1** IEEE 1451.0 TEDS

TEDS Name	TEDS Type	Mandatory/Optional
Meta TEDS	Machine readable	Mandatory
Channel TEDS	Machine readable	Mandatory
Calibration TEDS	Machine readable	Optional
Generic Extension TEDS	Machine readable	Optional
Meta Identification TEDS	Human readable	Optional
Channel Identification TEDS	Human readable	Mandatory
Calibration Identification TEDS	Human readable	Optional
End-User Application-Specific TEDS	Human readable	Mandatory

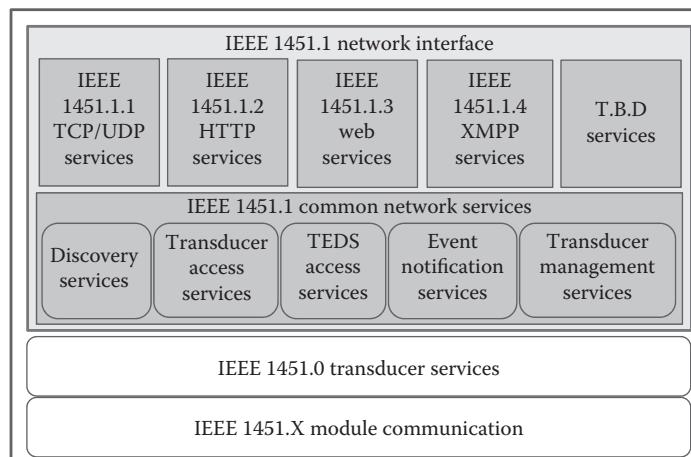

units (temperature in Kelvin and pressure in Pascal, etc.), the upper and lower range limits, the uncertainty or accuracy, whether or not a calibration TEDS is provided, and where the calibration is to be performed. The Calibration TEDS contains all the necessary information for the sensor data to be converted from the A/D converter raw output into the physical units specified in the Channel TEDS. If actuators are included in the TIM, it also contains the parameters that convert data in the physical units into the proper output format to drive the actuators. It also contains the calibration interval and last calibration date and time. This allows the system to determine when a calibration is needed. A general calibration algorithm is specified in the standard. The Generic Extension TEDS is provided to allow industry groups to provide additional TEDS in a machine-readable format. The Meta Identification TEDS is human-readable data that the system can retrieve from the TIM for display purposes. This TEDS contains fields for the manufacturer's name, the model number and serial number of the TIM, and a date code. The Channel Identification TEDS is similar to the Meta Identification TEDS. When transducers from different manufacturers are built into a TIM, this information will be very useful for the identification of channels. The Channel Identification TEDS provides information about each channel, whereas the Meta Identification TEDS provides information for the TIM. The Calibration Identification TEDS provides details of the calibration in the TIM. This information includes who performed the calibration and what standards were used. The End-User Application-Specific TEDS is not defined in detail by the standard. It allows the user to insert information, such as installation location, time it was installed, or any other desired text.

#### 4.6.3 IEEE P1451.1 Common Network Services

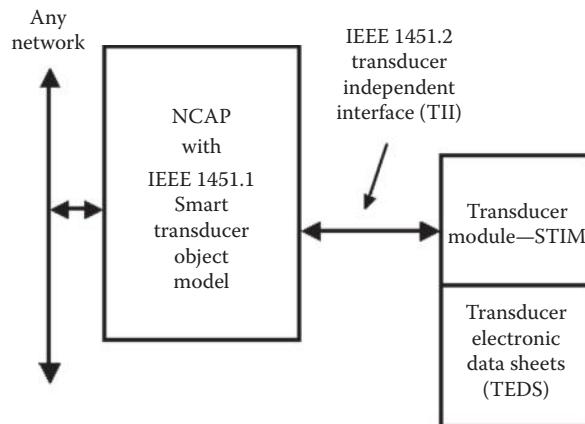

The IEEE P1451.1 defines a set of common network services for smart transducers. These common network services, defined for IEEE 1451 smart transducers, communicate transducer and relevant information through a network via various network communication protocol services providing transducer discovery, transducer and TEDS data access, event notification, and transducer management services. Using this set of common network services, one would be able to access and manage any of the IEEE 1451 sensors and actuators using different popular protocols, such as Hypertext Transfer Protocol and XMPP, as shown in Figure 4.6.

#### 4.6.4 IEEE 1451.2 Transducer Independence Interface

According to the IEEE 1451.2-1999 standard, the STIM (new version of IEEE 1451.2 will use the term TIIM) module can contain a combination of sensors and actuators of up to 255 channels, signal conditioning/processing, A/D converter, D/A converter, and digital logics to support the transducer

**FIGURE 4.6** Network interfaces for smart transducers.

**FIGURE 4.7** Communication between NCAP and STIM via transducer independence interface.

**TABLE 4.2** Transducer Independence Interface Signal Lines

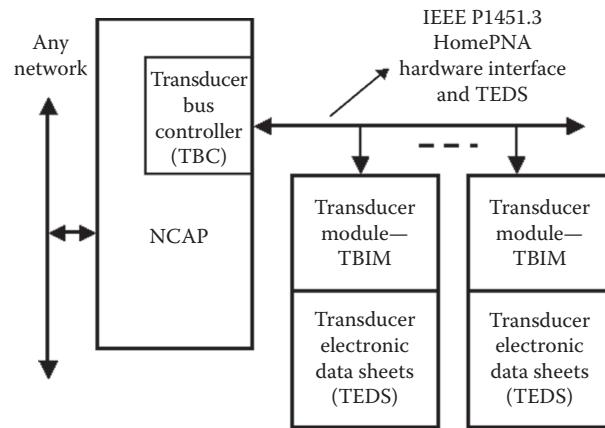

Line	Logic	Driven by	Function
DIN	Positive logic	NCAP	Address and data transport from NCAP to STIM
DOUT	Positive logic	STIM	Data transport from STIM to NCAP
DCLK	Positive edge	NCAP	Positive-going edge latches data on both DIN and DOUT
NIOE	Active low	NCAP	Signals that the data transport is active and delimits data transport framing
NTRIG	Negative edge	NCAP	Performs triggering function
NACK	Negative edge	STIM	Serves two functions: Trigger acknowledge Data transport acknowledge
NINT	Negative edge	STIM	Used by the STIM to request service from the NCAP
NSDET	Active low	STIM	Used by the NCAP to detect the presence of a STIM
POWER	N/A	NCAP	Nominal 5 V power supply
COMMON	N/A	NCAP	Signal common or ground

independent interface (TII). An NCAP can communicate with one or more STIMs via the transducer independent interface (Figure 4.7).

The transducer independence interface defines an enhanced serial peripheral interface by adding a few extra wires for a total of 10 wires in order to be able to provide a high-speed interface for data capture via handshaking lines—NIOE, NTRIG, NACK, and NINT. The NSDET line is added for the NCAP to detect the presence of an STIM, enabling the plug and play of transducers. The signal lines are given in Table 4.2.

#### 4.6.5 IEEE 1451.3 Distributed Multidrop Systems

The IEEE 1451.3 defines a transducer bus for connecting transducer modules to an NCAP in a distributed multidrop fashion. A block diagram is shown in Figure 4.8. The physical interface for the transducer bus is based on Home Phoneline Networking Alliance (HomePNA) specification. Both power and data run on a twisted pair of wires. Multiple transducer modules, called transducer bus interface modules (TBIMs), can be connected to an NCAP via the bus. Each TBIM contains transducers, signal conditioning/processing, A/D, D/A, and digital logics to support the bus and can accommodate large arrays of transducers for synchronized access at up to 128 Mbps with HomePNA 3.0 and up to 240 Mbps with extensions. The TEDS is defined in the eXtensible Markup Language.

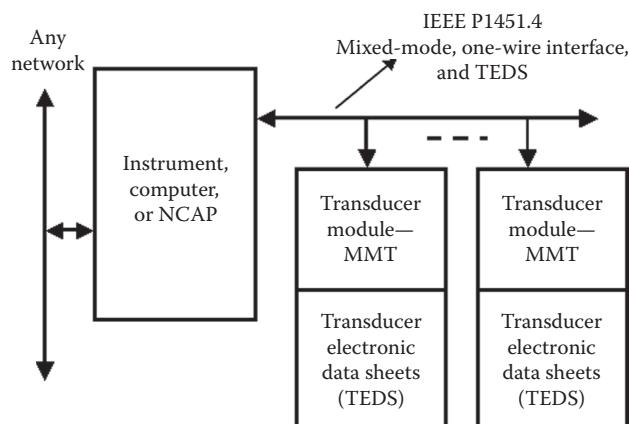

**FIGURE 4.8** Block diagram of IEEE 1451.3.

#### 4.6.6 IEEE 1451.4 Mixed-Mode Interface

The IEEE 1451.4 defines a mixed-mode interface (MMI), which is used for connecting transducer modules, mixed-mode transducers (MMT), to an instrument, a computer, or an NCAP. The block diagram of the system is shown in Figure 4.9. The physical transducer interface not only is based on the Maxim/Dallas Semiconductor's one-wire protocol but also supports up to four wires for bridge-type sensors. It is a simple, low-cost connectivity for analog sensors with a very small TEDS—64 bits mandatory and 256 bits optional. The mixed-mode interface supports a digital interface for reading and writing the TEDS by the instrument or NCAP. After the TEDS transaction is completed, the interface switches into analog mode, where the analog sensor signal is sent straight to the instrument and NCAP, which is equipped with A/D to read the sensor data.

#### 4.6.7 IEEE 1451.5 Wireless Transducer Interface

Wireless communication is emerging, and low-cost wireless technology is on the horizon. Wireless communication links could replace the costly cabling for sensor connectivity. It also could greatly reduce sensor installation cost. Industry would like to apply the wireless technology for sensors; however, the wide use of wireless sensor technologies has been hindered by the interoperability problem

**FIGURE 4.9** Block diagram of IEEE 1451.4.

among wireless sensors, equipment, and data. In response to this need, a wireless sensing workshop was held to involve industry to define IEEE 1451.5, which aims to develop a wireless sensor communication interface standard that will leverage existing wireless communication technologies and protocols [15]. The standard defines wireless communication methods and data format for transducers. The standard adopts existing popular wireless communication protocols, such as WiFi (IEEE 802.11), Bluetooth (IEEE 802.15.1), ZigBee (IEEE 802.15.4), and 6LowPAN (IEEE 802.15.4). The 6LowPAN is an Internet Protocol (IP)-driven protocol (IPv6 compatible) that eases the access of transducers from the Internet. A block diagram of IEEE 1451.5 is shown in Figure 4.10. IEEE 1451.5 defines wireless message formats, a data and control model, security model, and physical TEDS that are scalable to meet the needs of low-cost to sophisticated sensor or device manufacturers. Currently, different sensor networks cited earlier do not interoperate with each other due to the use of different hardware and software protocols. Even though ZigBee and 6LowPAN use the same 802.15.4 wireless communication protocol, they cannot interoperate due to the differences in application-level protocol and data format, etc. The IEEE 1451.5 approach is to help achieve data-level interoperability, that is, the sensor data received at user network is the same, whether it is from a Bluetooth-based sensor network or a ZigBee-based sensor network. This concept is illustrated in Figure 4.10.

#### 4.6.8 IEEE 1451.7 Transducers to RFID Interface

RFID technologies are rapidly emerging as a means of tracking products and assets during manufacturing and distribution. For example, airplane manufacturers track their airplane parts from their suppliers, during the assembly process, and throughout the life cycle and maintenance of the airplanes. RFID standards have been developed to meet these needs. Sensors can provide valuable information about the conditions of products, in particular, the perishable kinds, such as fruits, meats, fishes, and drugs for public safety. There is also a great need to provide sensor data as part of the supply chain reporting; however, there is a lack of openly defined standard interfaces between sensors and RFID tags. The purpose of the IEEE 1451.7 standard is to fill the gap by providing such sensor-to-RFID tag interfaces to meet industry needs. The IEEE 1451.7 standard provides standardized sensor data formats and command/reply set for communicating sensor and RFID tag data to the requesters or clients in the network. It also addresses security protocols to provide secure data. The integration of IEEE 1451.7 transducer (sensor and RFID tag) with the IEEE 1451 family of standard as needed is illustrated in Figure 4.11.

#### 4.6.9 Benefits of IEEE 1451

IEEE 1451 defines a set of common transducer interfaces, which will help to lower the cost of designing smart sensors and actuators because designers would have to design only a single set of standardized digital interfaces. Thus, the overall cost to make networked sensors will decrease. Incorporating the TEDS with the sensors will enable self-description of sensors and actuators, eliminating error-prone, manual configuration.

##### 4.6.9.1 Sensor Manufacturers

Sensor manufacturers can benefit from the standard because they have to design only a single standard physical interface. Standard calibration specification and data format can help to design and develop multilevel products based on TEDS with a minimum effort.

##### 4.6.9.2 Application Software Developers

Applications can benefit from the standard as well because standard transducer models for control and data can support and facilitate distributed measurement and control applications. The standard also provides support for multiple languages—good for international developers.

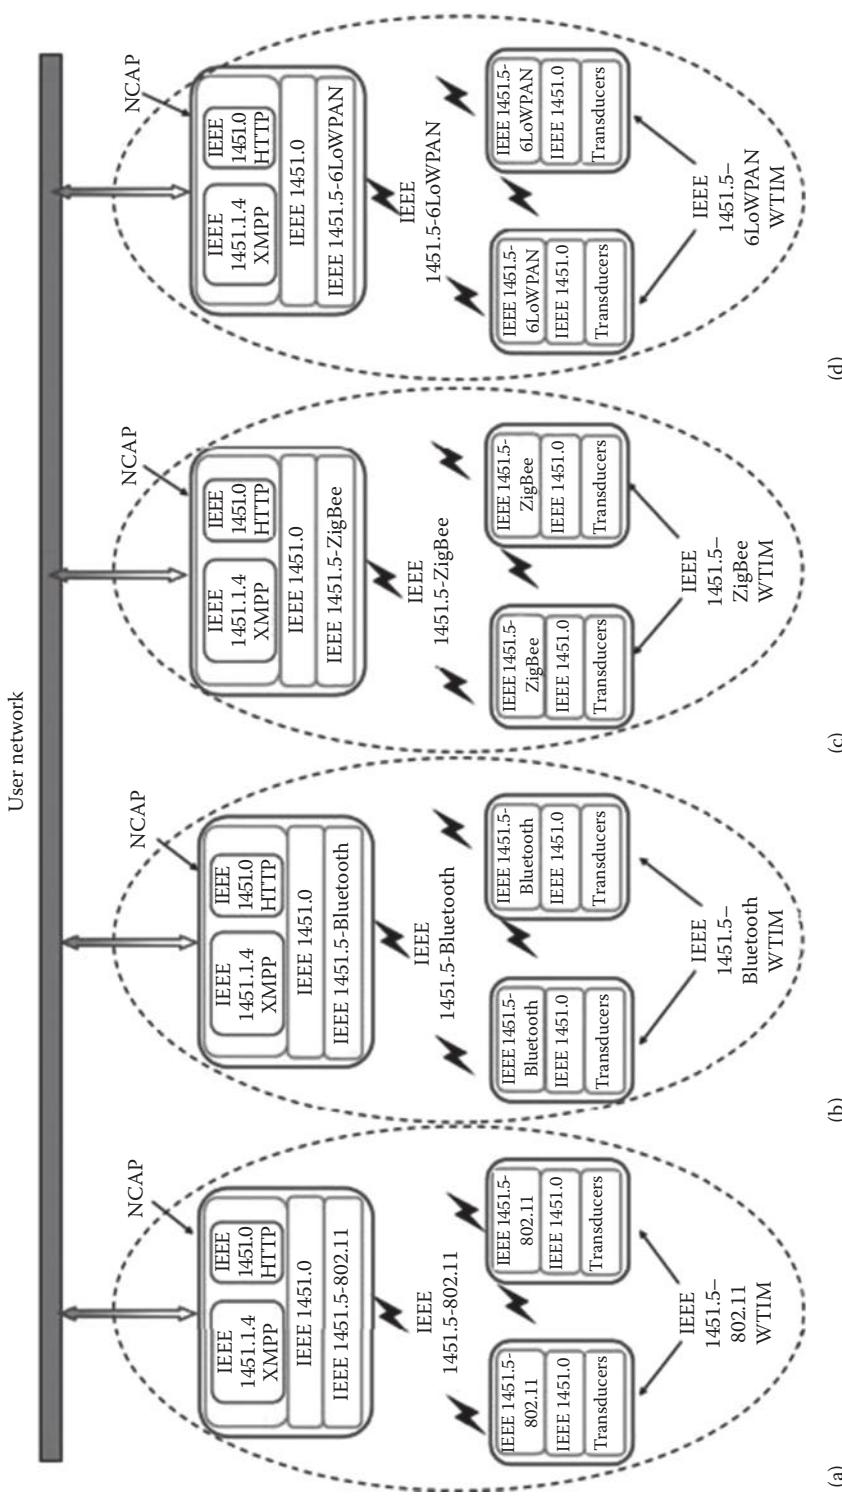

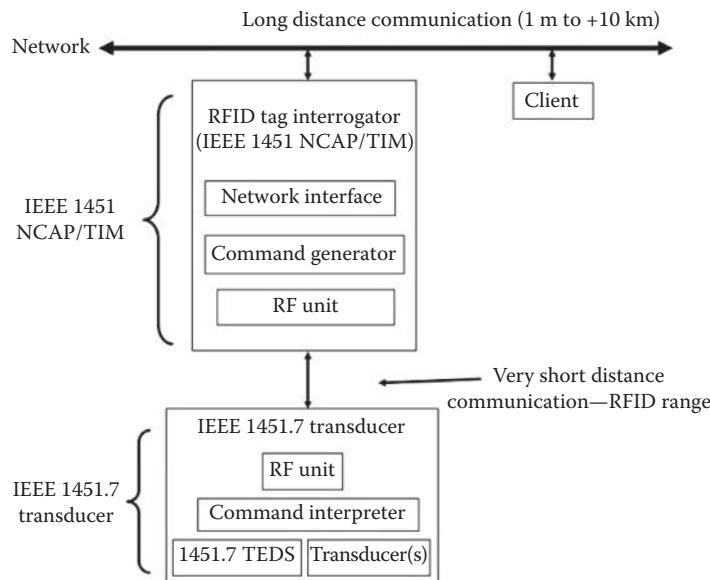

FIGURE 4.10 Interoperable IEEE 1451.5-based wireless sensor networks. (a) IEEE 1451.5-802.11, (b) IEEE 1451.5-Bluetooth WSN, (c) IEEE 1451.5-ZigBee WSN, and (d) IEEE 1451.5-6LoWPAN WSN.

**FIGURE 4.11** Integration of an IEEE 1451 NCAP/TIM module with an IEEE 1451.7 transducer in a network.

#### 4.6.9.3 System Integrators

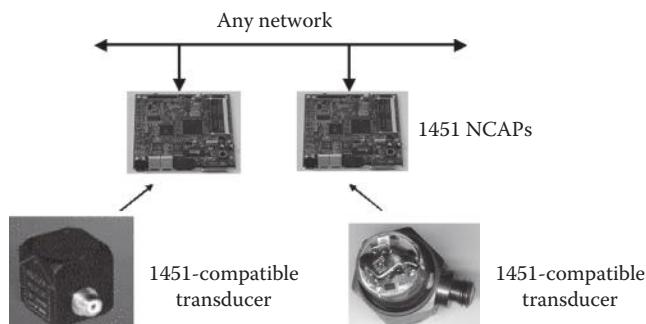

Sensor system integrators can benefit from IEEE 1451 because sensor systems become easier to install, maintain, modify, and upgrade. Quick and efficient transducer replacement results by simply *plug and play*. It can also provide a means to store installation details in the TEDS. Self-documenting of hardware and software is done via the TEDS. Best of all is the ability to choose sensors and networks based on merit.

#### 4.6.9.4 End Users

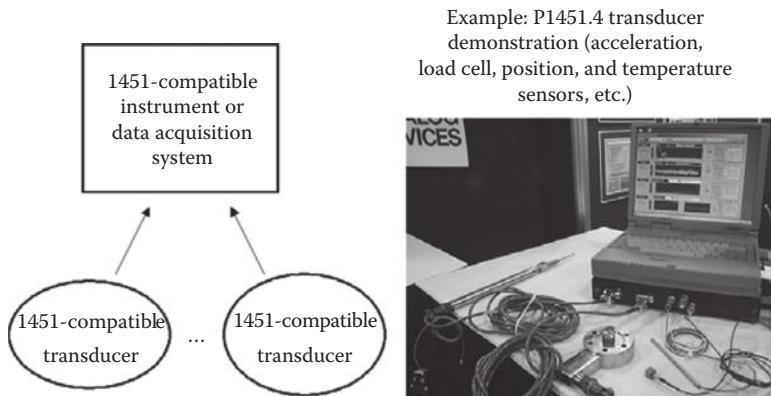

End users can benefit from a standard interface because sensors will be easy to use by simple *plug and play*. Based on the information provided in the TEDS, software can automatically provide the physical units, readings with significant digits as defined in the TEDS, installation details such as instruction, identification, and location of the sensor.

#### 4.6.9.5 Plug and Play of Sensors and Actuators

IEEE 1451 enables *plug and play* of transducers to a network as illustrated in Figure 4.12. In this example, IEEE 1451.4-compatible transducers from different companies are shown to work with a sensor network. IEEE 1451 also enables *plug and play* of transducers to a data acquisition system/instrumentation system

**FIGURE 4.12** IEEE 1451 enables *plug and play* of transducers to a network.

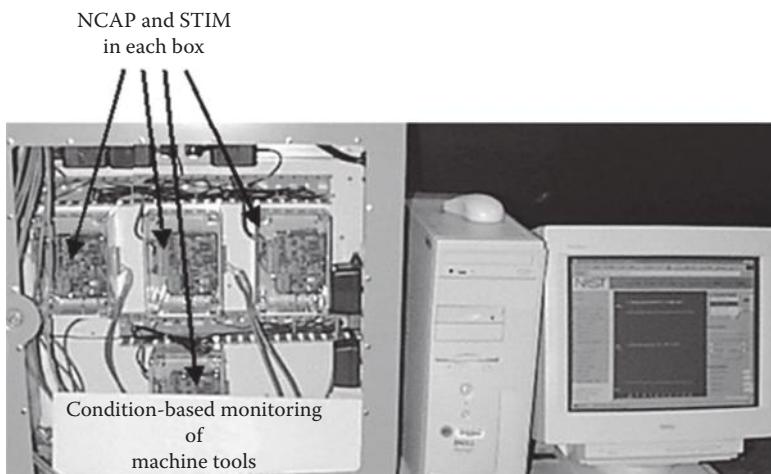

**FIGURE 4.13** IEEE 1451 enables *plug and play* of transducers to data acquisition/instrumentation system.

as shown in Figure 4.13. In this example, various IEEE 1451.4–compatible transducers, such as an accelerometer, a thermistor, a load cell, and a linear variable differential transformer are shown to work with a LabView-based system.\*

## 4.7 Example Application of IEEE 1451.2

IEEE 1451–based sensor network consisting of sensors, STIM, and NCAP is designed and built into a cabinet as shown in Figure 4.14. There were a total of four STIM and NCAP network nodes as pointed to in Figure 4.14. Thermistor sensors were used for temperature measurements. They were calibrated in the laboratory to generate IEEE 1451.2-compliance calibration TEDS for all four STIMs and NCAPs. The thermistors were mounted on the spindle motor housing, bearing, and axis drive motors of a three-axis vertical machining center, which is shown in Figure 4.15. Since each NCAP has a built-in micro web server, a custom web page was constructed using the web tool provided with the NCAP.

**FIGURE 4.14** NCAP-based condition monitoring system.

\* Certain commercial products are identified in this chapter in order to describe the system. Such identification does neither imply recommendation or endorsement by the National Institute of Standards and Technology, nor imply that the products identified are necessarily the best or the only ones available for the purpose.

FIGURE 4.15 Three-axis vertical machining center.

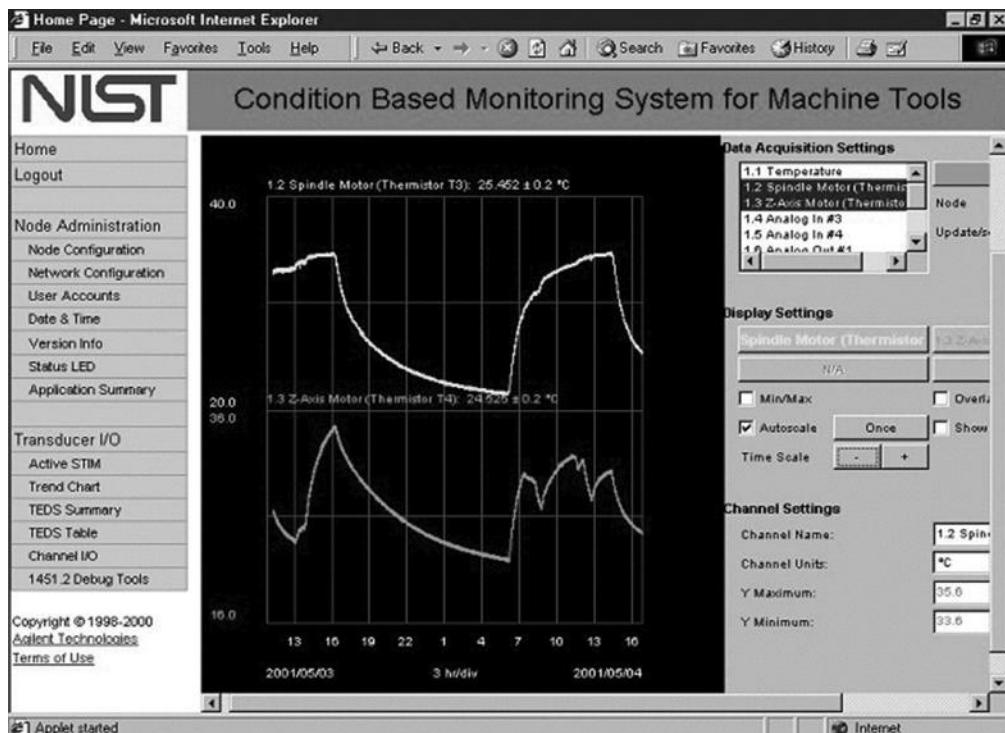

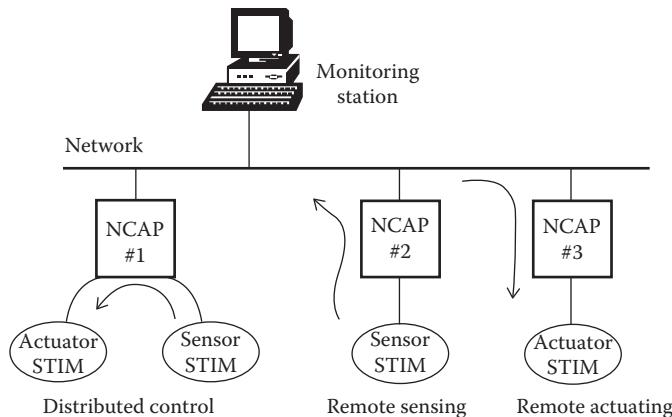

FIGURE 4.16 Temperature trend chart.

Thus, remote monitoring of the machine thermal condition was easily achieved via the Ethernet network and the Internet using a readily available common web browser. The daily trend chart of the temperature of the spindle motor (top trace) and the temperature of the Z-axis drive motor (bottom trace) in the machine is shown in Figure 4.16. The temperature rise tracks the working of the machine during the day, and the temperature fall indicates that the machine shop is closed.

**FIGURE 4.17** Application model of IEEE 1451.

## 4.8 Application of IEEE 1451-Based Sensor Network

A distributed measurement and control system can be easily implemented based on the IEEE 1451 standards [16]. An application model of IEEE 1451 is shown in Figure 4.17. Three NCAP/STIMs are used to illustrate the distributed control, remote sensing or monitoring, and remote actuating. In the first scenario, a sensor and an actuator are connected to the STIM of NCAP #1, and an application software running in the NCAP can perform a locally distributed control function, such as maintaining a constant temperature for a bath. The NCAP reports measurement data, process information, and control status to a remote monitoring station or host. It frees the host from the processor-intensive, closed-loop control operation. In the second scenario, only sensors are connected to NCAP #2, which can perform remote process or condition monitoring functions, such as monitoring the vibration level of a set of bearings in a turbine. In the third scenario, based on the broadcast data received from NCAP #2, NCAP #3 activates an alarm when the vibration level of the bearings exceeds a critical set point. As illustrated in these examples, IEEE 1451-based sensor network can easily facilitate peer-to-peer communications and distributed control functions.

## 4.9 Summary

The IEEE 1451 smart transducer interface standards are defined to allow a transducer manufacturer to build transducers of various performance capabilities that are interoperable within a networking system. The IEEE 1451 family of standards has provided the common interface and enabling technology for the connectivity of transducers to microprocessors, instrumentation systems, and field networks using wired and wireless means. The standardized TEDS allows the self-description of sensors, which turns out to be a very valuable tool for condition-based maintenance. The expanding Internet market has created a good opportunity for sensor and network manufacturers to exploit web-based and smart sensor technologies. As a result, users will greatly benefit from many innovations and new applications.

## Acknowledgments

The author sincerely thanks the IEEE 1451 working groups for the use of the materials in this chapter. Through its program in Smart Machine Tools, the Manufacturing Engineering Laboratory of the National Institute of Standards and Technology has contributed to the development of the IEEE 1451 standards.

### 5.1 Motivation and Objectives for a New Technology

---

The increased use of microcontrollers embedded in low-cost sensors and actuators has provided opportunities for adding diagnosis and configuration data to support increasing application requirements.

The driving force for a new technology called IO-Link<sup>TM\*</sup> has been the need of these low-cost sensors and actuators to exchange the diagnosis and configuration data with a controller (PC or PLC) using a low-cost digital communication technology while maintaining backward compatibility with the current digital input and digital output (DI/DO) signals.

Another driving force is cost reduction and substitution of error-prone analog transmission such as 0–10 V. Using IO-Link avoids digital/analog conversion on the sensor side and analog/digital conversion on the controller side.

In fieldbus concepts, the IO-Link defines a generic interface for connecting sensors and actuators to a Master<sup>†</sup> unit, which may be combined with gateway capabilities to become a fieldbus remote I/O node.

Any IO-Link-compliant Device<sup>‡</sup> can be attached to any available interface port of the Master. Devices perform physical-to-digital conversion in the Device and then communicate the result directly in a standard format using *coded switching* of the 24 V I/O signaling line, thus removing the need for different DI, DO, AI, AO modules, and a variety of cables.

---

\* IO-Link<sup>TM</sup> is a trade name of the “IO-Link Community.” Use of the registered logos for IO-Link<sup>TM</sup> requires permission of the “IO-Link Community.”

† “Master” (with upper case M) means the IO-Link-compliant counterpart to “Device.”

‡ “Device” (with upper case D) means IO-Link-compliant sensor or actuator in this document.

Physical topology is point-to-point from each Device to the Master using three wires over distances up to 20 m. The IO-Link physical interface is backward compatible with the 24 V I/O signaling specified in IEC 61131-2. Transmission rates of 4.8, 38.4, and 230.4 kbit/s are supported.

The Master of the IO-Link interface detects, identifies, and manages Devices plugged into its ports.

Tools allow the association of Devices with their corresponding electronic I/O Device descriptions (IODDs) and their subsequent configuration to match the application requirements.

The IO-Link technology specifies three different levels of diagnostic capabilities: for immediate response by automated needs during the production phase, for medium-term response by operator intervention, or for longer-term commissioning and maintenance via extended diagnosis information.

## 5.2 IO-Link Technology

### 5.2.1 Purpose of Technology

Figure 5.1 shows the basic concept of IO-Link.

The single-drop digital communication interface technology for small sensors and actuators IO-Link (also known as SDCI in IEC 61131-9) defines a migration path from the existing DI/DO interfaces for switching 24 V Devices, as defined in IEC 61131-2, toward a point-to-point communication link. Thus, for example, digital I/O modules in existing fieldbus peripherals can be replaced by IO-Link Master modules providing both classic DI/DO interfaces and IO-Link. Analog transmission technology can be replaced by IO-Link combining its robustness, parameterization, and diagnostic features with the saving of digital/analog and analog/digital conversion efforts.

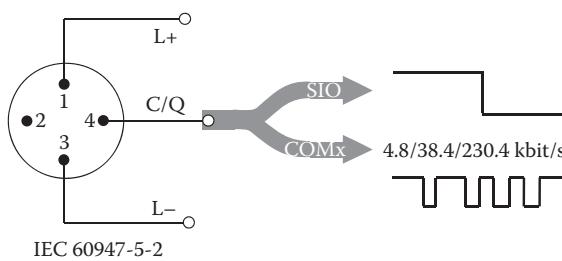

### 5.2.2 Positioning within the Automation Hierarchy

Figure 5.2 shows the domain of the IO-Link technology within the automation hierarchy.

The IO-Link technology defines a generic interface for connecting sensors and actuators to a Master unit, which may be combined with gateway capabilities to become a fieldbus remote I/O node or via an adapter to personal computers or drives.

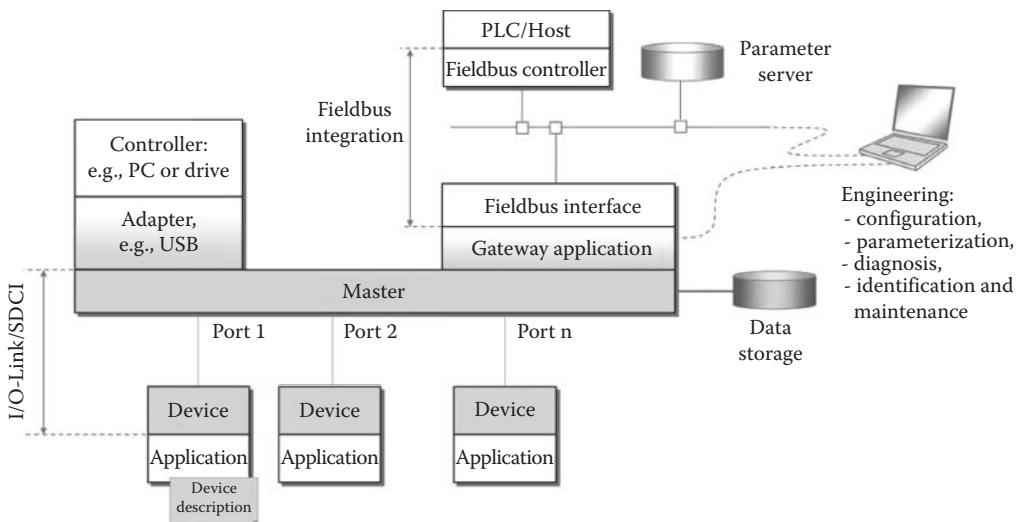

Starting point for the design of IO-Link is the classic 24 V DI defined in IEC 61131-2 and output interface (DO) specified in [1]. Thus, IO-Link offers connectivity of classic 24 V sensors (*switching signals*) as a default operational mode. Additional connectivity is provided for actuators when a port has been configured into single-drop communication mode (*coded switching*).

Many sensors and actuators nowadays are already equipped with microcontrollers offering a universal asynchronous receiver transmitter interface that can be extended by the addition of a few hardware components and protocol software to support IO-Link communication. This second operational mode uses *coded switching* of the 24 V I/O signaling line. Once activated, the IO-Link mode supports parameterization, cyclic data exchange, diagnosis reporting, identification and maintenance information,

Pin	Signal	Definition	Standard
1	L+	24 V	IEC 61131-2
2	I/Q	Not connected, DI, or DO	IEC 61131-2
3	L-	0 V	IEC 61131-2
4	Q	"Switching signal" DI (SIO)	IEC 61131-2
	C	"Coded switching" (COM1, COM2, COM3)	IO-Link (IEC 61131-9)

FIGURE 5.1 IO-Link compatibility with IEC 61131-2.

**FIGURE 5.2** Domain of the IO-Link technology within the automation hierarchy.

and external parameter storage for Device backup and fast reload of replacement devices. To improve start-up performance, these Devices usually provide nonvolatile storage for parameters.

Configuration and parameterization of Devices are supported through an XML-based device description similar to fieldbus electronic device descriptions (see [2]).

### 5.2.3 Wiring, Connectors, and Power

The default connection (port class A) comprises four pins (see Figure 5.1). The default wiring for port class A complies with IEC 60947-5-2 and uses only three wires for 24, 0 V, and a signal line. The fourth wire may be used as an additional signal line complying with IEC 61131-2.

Five-pin connections (port class B\*) are specified for Devices requiring additional power from an independent 24 V power supply.

Maximum length of cables is 20 m, and shielding is not required.

### 5.2.4 Communication Features of IO-Link

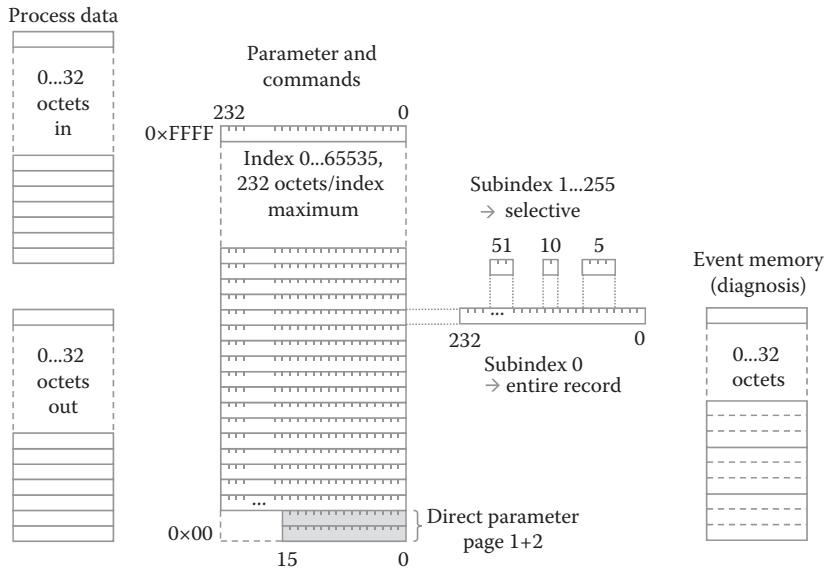

The generic Device model is shown in Figure 5.3 and explained in the following paragraphs.

A Device may receive process data (PD; out) to control a discrete or continuous automation process or send PD (in) representing its current state or measurement values. The Device usually provides parameters enabling the user to configure its functions to satisfy particular needs. To support this case, a large parameter space is defined with access via an index (0–65,535; with a predefined organization) and a subindex (0–255).

The first two index entries 0 and 1 are reserved for the direct parameter pages 1 and 2 with a maximum of 16 octets each. Parameter page 1 is mainly dedicated to Master commands such as Device start-up and fallback, retrieval of Device-specific operational and identification information. Parameter page 2 allows for a maximum of 16 octets of Device-specific parameters.

The other indices (2–65,535) allow access to one record having a maximum size of 232 octets. Subindex 0 specifies transmission of the complete record addressed by the index; other subindices specify transfer of selected data items within the record.

\* A port class A Device using the fourth wire is not compatible with a port class B Master.

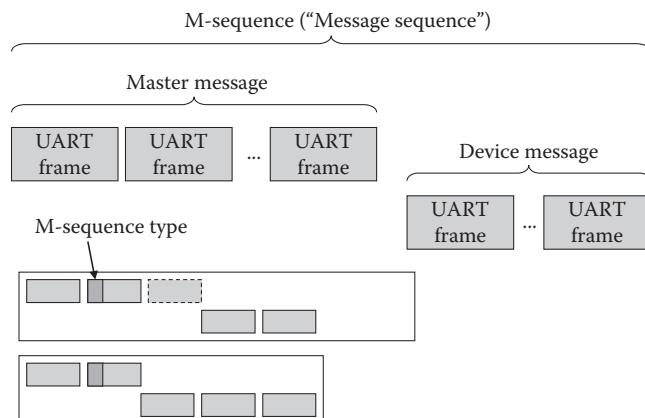

**FIGURE 5.3** Generic Device model for IO-Link (Master's view).

Within a record, individual data items may start on any bit offset, and their length may range from 1 bit to 232 octets, but the total number of data items in the record cannot exceed 255. The organization of data items within a record is specified in the IODD (see [2]).

All changes of Device condition that require reporting or intervention are stored within an event memory before transmission. An event flag is then set in the cyclic data exchange to indicate the existence of an event.

Communication between a Master and a Device is point to point and is based on the principle of the Master first sending a request message and then a Device sending a response message (see Figure 5.4).

Both messages together are called an M-sequence. Several M-sequence types are defined to support user requirements for data transmission (see [1]). The first byte of a Master message controls the data transfer direction (read/write). It is followed by the M-sequence type of communication channel and data integrity checking code, and optional bytes with either *PD* and/or *on-request data* (*OD*).

**FIGURE 5.4** Principle of message sequences between Master and Device.

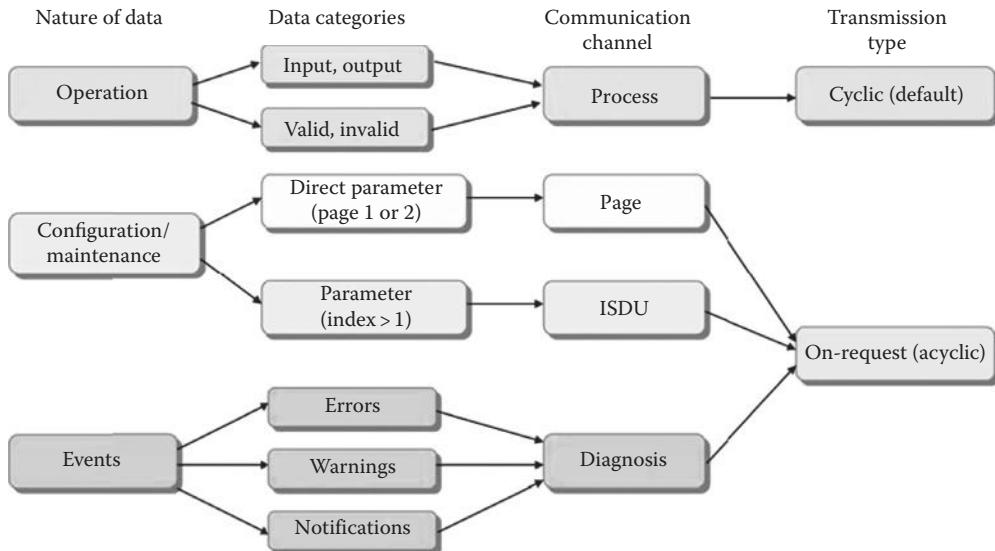

FIGURE 5.5 Relationship between nature of data and transmission types.

Data of various categories are transmitted through separate communication channels within the data link layer (DL), as shown in Figure 5.5.

- Operational data such as Device inputs and outputs are transmitted through a process channel using cyclic transfer. Operational data may also be associated with qualifiers such as valid/invalid.
- Configuration and maintenance parameters are transmitted using acyclic transfers. A page channel is provided for direct access to parameter pages 1 and 2, and an indexed service data unit channel is used for accessing additional parameters and commands via indices.
- Device events are transmitted using acyclic transfers through a diagnostic channel. Device events are reported using three severity levels: error, warning, and notification.

Figure 5.6 shows that each port of a Master has its own DL that interfaces to a common master application layer (AL). Within the AL, the services of the DL are translated into actions on PD objects (input/output), OD objects (read/write), and events. Master applications include a configuration manager, data storage mechanism, diagnosis unit (DU), OD exchange (ODE), and a PD exchange (PDE).

System management checks identification of the connected Devices and adjusts ports and Devices to match the chosen configuration and the properties of the connected Devices. It controls the state machines in the AL and DL, for example, at start-up.

### 5.2.5 Role of a Master

A Master accommodates 1 to  $n$  ports and their associated DLs. During start-up, it changes the ports to the user-selected port modes, which can be INACTIVE, DI, DO, FIXEDMODE, or SCANMODE. If communication is requested, the Master uses a special wake-up current pulse to initiate communication with the Device. The Master then auto-adjusts the transmission rate to COM1, COM2, or COM3 (see [1]) and checks the *personality* of the connected Device, that is, its vendor identification, Device identification, and communication properties.

If there is a mismatch between the Device parameters and the stored parameter set within the Master, the parameters in the Device are overwritten or the stored parameters within the Master are updated depending on configuration.

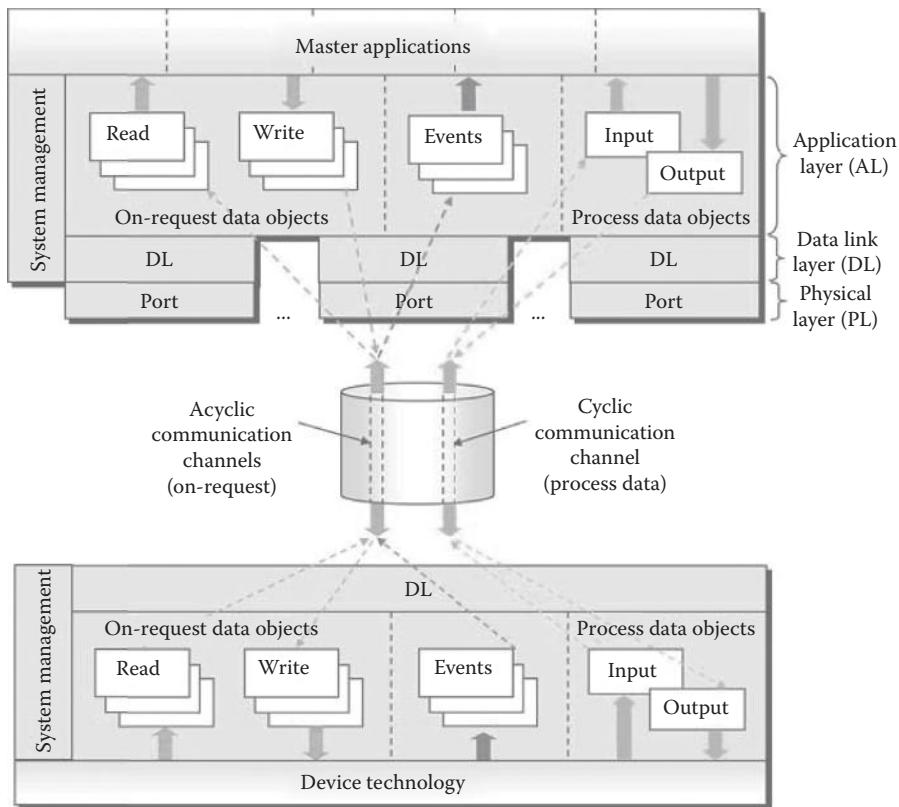

FIGURE 5.6 Object transfer at the application layer (AL) level.

It is also possible to start a device in DI mode, switch to IO-Link communication for configuration and parameterization, and then use a fallback command to switch back to DI mode for normal operation (see Figure 5.7).

Coordination of the ports is also a task of the Master, which the user can configure through the selection of port cycle modes. In *FreeRunning* mode, each port defines its own cycle based on the properties of the connected Device. In *MessageSync* mode, messages sent on the connected ports start at the same time or in a defined staggered manner. In *FixedValue* mode, each port uses a user-defined fixed cycle time (see [1]).

The Master is responsible for the assembling and disassembling of all data from or to the Devices.

The Master provides a data storage area of at least 2048 octets per Device for backup of Device data. The Master may combine these Device data together with all other relevant data for its own operation and make these data available for higher-level applications for Master backup purpose or recipe control.

### 5.2.6 IO-Link Configuration

Engineering support for a Master is usually provided by a Port and Device Configuration Tool (PDCT) connected directly or indirectly via fieldbus to the Master. The PDCT configures both port properties and Device properties (see parameters shown in Figure 5.3). It combines both an interpreter of the IODD and a configurator (see Figure 5.2). The IODD provides all the necessary properties to establish communication and the necessary parameters and their boundaries to establish the desired function of a sensor or actuator. The PDCT also supports the compilation of the PD for propagation on the fieldbus and vice versa.

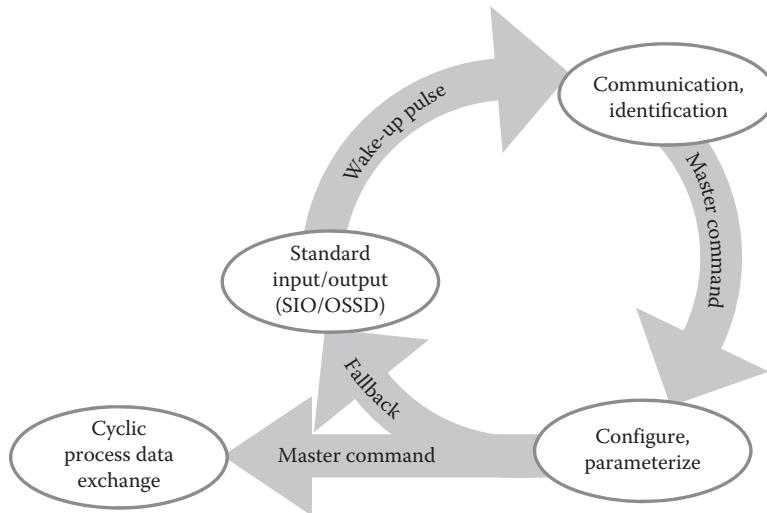

FIGURE 5.7 IO-Link communication states.

### 5.2.7 Mapping to Fieldbuses and System Integration

Integration of a Master within a fieldbus system, that is, the definition of gateway functions for exchanging data with higher-level entities on a fieldbus, is out of the scope of the IO-Link specification [1]. Examples of these functions include mapping of the PDE, realization of program-controlled parameterization or a remote parameter server, or the propagation of diagnosis information.

The integration of a PDCT into engineering tools of a particular fieldbus is also out of the scope of the IO-Link specification [1].

However, IO-Link integrations (gateways/Master) exist for the most important fieldbuses such as PROFIBUS, PROFINET, DeviceNet, Ethernet/IP, EtherCAT, Powerlink, CC-Link, and ASi. It is the responsibility of the fieldbus organizations to provide corresponding specifications.

### 5.2.8 Implementation and Engineering Support

A number of application-specific integrated circuits and software stacks facilitate the design and implementation of Masters and Devices. Information can be retrieved from [www.io-link.com](http://www.io-link.com).

### 5.2.9 Test and Certification

A comprehensive specification for the test of Masters and Devices exist (see [3]), and corresponding test tools can be acquired for both. A manufacturer declaration based on the positive results of the Device tester is required for the usage of the IO-Link word and picture mark. Certification of Devices is not required. Similar rules exist for Masters. The fieldbus organizations are responsible for the quality assurance of the combination of fieldbus gateway and Master.

### 5.2.10 Profiles

An IO-Link profile specification exists for sensors (see [4]). It describes the common part of a sensor model that should be valid for future Device profiles and a more specific part for the so-called Smart Sensors comprising recommended PD structures, identification objects, binary switching thresholds and hysteresis, best practice handling of quantity measurements with or without associated units, diagnosis objects, and teaching commonalities.

### 5.2.11 Functional Safety

Many fieldbuses provide additional profiles for functional safety communication (see [5]). For IO-Link, two possibilities exist in principle:

1. Tunneling of an existing fieldbus functional safety communication across IO-Link
2. A specific slim IO-Link functional safety communication profile with a functional safety gateway

The IO-Link community does not prohibit the tunneling solution, which is the responsibility of the corresponding fieldbus organization. In general, for sensor and actuator manufacturers, the second possibility is in favor due to less development and support efforts. A corresponding specification is going to be developed.

### 5.2.12 Standardization

The IO-Link technology is internationally standardized within IEC 61131-9 (see [6]).

## Abbreviations

AI	Analog input
AL	Application layer
AO	Analog output
ASIC	Application-specific integrated circuit
CM	Configuration manager
COM1	IO-Link transmission rates of 4.8 kbit/s
COM2	IO-Link transmission rates of 38.4 kbit/s
COM3	IO-Link transmission rates of 230.4 kbit/s
DI	Digital input
DL	Data link layer
DO	Digital output
DS	Data storage
DU	Diagnosis unit
IEC	International Electrotechnical Commission
I/O	Input/output
IODD	I/O device description
ISDU	Indexed service data unit
OD	On-request data
ODE	On-request data exchange
PC	Personal computer
PD	Process data
PDCT	Port and device configuration
PDE	Process data exchange
PLC	Programmable logic controller
SDCI	Single-drop digital communication interface for small sensors and actuators
SIO	Standard I/O mode according IEC 61131-2
UART	Universal asynchronous receiver transmitter
XML	Extensible mark-up language

### 6.1 AS-Interface Background

---

AS-Interface (AS-i) (actuator/sensor interface) was defined and developed by a consortium of 11 German and Swiss companies between 1990 and 1994. At this point in time, multiple different fieldbuses had already been developed, but none of them seemed to be suitable to connect simple sensors and actuators. Therefore, it was necessary to devise an entirely new type of a system with the primary goal to replace cable trunks and to minimize installation expenses. Thus, a system was designed based on a simple nonshielded two-conductor cable that was able to transfer data as well as 24 V power.

Since the implementation of the first automation processes using AS-i in 1994, multiple improvements to the system have been introduced. Among others, the number of slaves that can be connected to the system was doubled from 31 to 62, safety signals can now be transmitted via standard AS-i networks, and procedures were introduced that ensure the easy transmission of bytes, 16-bit words, and even longer chains of characters.

However, all these improvements were closely watched concerning their comparability with the current standard. Therefore, the first prototype slaves, developed in 1992, are still operational in all AS-i networks.

---

\* Reorganized and updated based on the publications of the AS-International Association: "AS-Interface die Lösung in der Automation" (2002), "AS-Interface Safety at Work" (2004), and "Automatisieren ist einfach mit AS-Interface" (2009).

AS-i (standardized as EN 50295-2 (1998, 2002) [1] and IEC 62026-2 (2000) [2]) is the fieldbus for the lower levels of the information pyramid in industrial automation technology, with a broad range of applications in factory automation, process automation, building automation, and mobile equipment automation. Today (2014), there are

- More than 27 Mio. installed nodes
- More than 350 members worldwide
- More than 1,800 certified products
- Worldwide over one million safety systems in use
- More than 2,500,000 AS-i safety devices
- Increase of 66% in the field of safety devices

## 6.2 AS-Interface Technology

---

### 6.2.1 AS-Interface System Data in a Nutshell

### 6.2.2 Data and Energy on One Wire

The AS-i transfers data and energy on a two-conductor cable; the two conductors are usually named AS-i+ and AS-i-. But AS-i- is different to the ground (GND), well known in direct current technology (Table 6.1).

To run an AS-i network, four basic requirements have to be established:

1. Power supply: supply of the outputs of the network with a nominal voltage of 24 V direct current (DC)
2. Safety: secure mains separation (PELV)
3. Balancing of the network: increased noise immunity
4. Data decoupling: separation of power and data

These are the reasons why it is not possible to feed AS-i networks directly with a standard power supply. Special AS-i power supplies or data-decoupling modules for the Power24 technology are required. A manifold range of power supplies are available that suit almost any individual use case, providing current in a range of 1-8A and more.

**TABLE 6.1** AS-i System Technical Data

	AS-i
Devices/addresses per system	62
Topology	Line, star, tree, ring
Available voltage	24 V at the outputs
Available current	Up to 8 A
Typical cycle time <sup>a</sup>	3 ms
Slave response time	154 µs
Network length	500 m <sup>b</sup>
Protection class	Up to IP 69K
Amount of I/O using the 8I/8O profile	496 inputs/496 outputs
Standardized analog value transmission	16 bit
Performance level according EN ISO 13849-1	Up to PL <sub>e</sub>
SIL according to IEC 61508	Up to SIL3
Hot swap/live insertion	Yes/yes

<sup>a</sup> AS-i uses the master-slave system with cyclic polling.

<sup>b</sup> 500 m by use of repeaters, optional enhancements with termination is not taken into account.

### Power Supply

In case of AS-i, the network cable supplies the power. This serves to supply the slaves and a part of the master over the two-conductor cable. And of course, the power for the connected outputs is provided, the common 24 V used in the cabinets. For this reason, the AS-i power supplies provide a DC voltage from 29.5 to 31.6 V at currents up to 8 A, to enable the 24 V at the end of the 100 m AS-i cable. For more details, see 6.2.2.2 AS-Interface cable.

### Safety

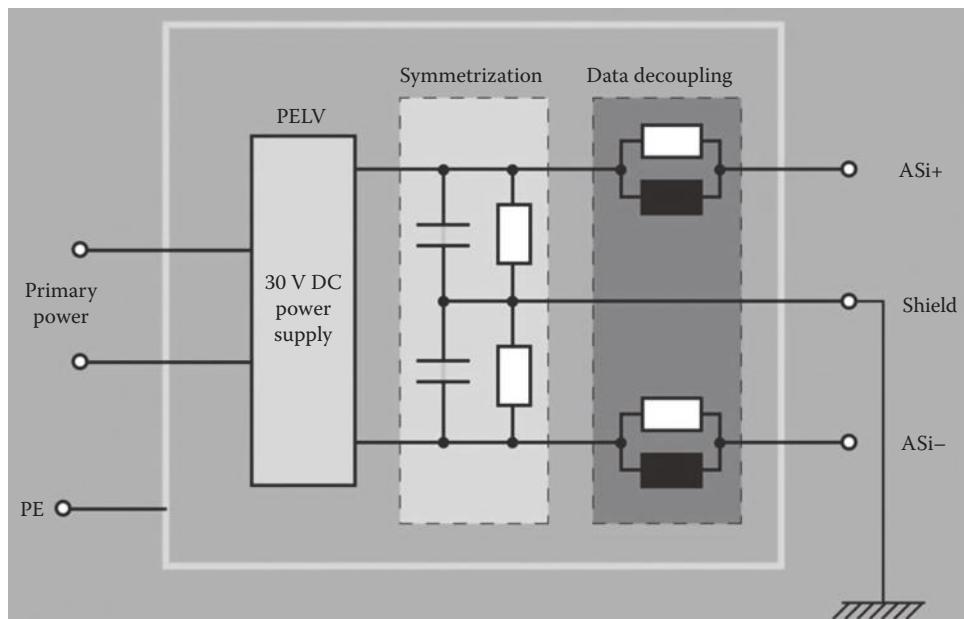

AS-i is designed as a system for low voltages with safe isolation (protective extralow voltage [PELV]). This means that according to the relevant IEC standards, *safe isolation* is required of the power supply between the supply network and the AS-i network.

### Balancing

The power supply is also used to balance the AS-i network. AS-i is operated as a symmetrical, non-grounded system. For optimum noise immunity against symmetrical noise coupling, the AS-i cable needs to be installed as symmetrically as possible. This is accomplished by the balancing circuit shown in Figure 6.1. The shield connection must be grounded at an appropriate point on the machine or system. AS-i allows only this point to be connected to system GND.

### Data Decoupling

The data-decoupling network, which is normally located in the same housing as the power supply, consists of two inductors of 50 mH each and two parallel-wired resistors of  $39\ \Omega$  each. The inductors use differentiation in voltage pulses to convert the current pulses generated by the AS-i transmitters. At the same time, they prevent the AS-i cable from being short-circuited by the power supply for data transmission. (For more information, see 6.2.2.3 Modulation procedure.)

**FIGURE 6.1** The AS-i power supply.

### 6.2.2.1 Power24 Technology

Using Power24 technology, the AS-i network power is supplied by a 24 V power supply. In this case, the data decoupling and balancing has to be done in a data-decoupling module. Sometimes, this module is integrated into the master housing. The use of this technology has the benefit that no additional power supply is necessary. This saves costs but it reduces the functionality as well. The reduced input voltage has consequences, the network length is reduced to 50 m, and, of course, the outputs can provide voltages below 24 V only.

### 6.2.2.2 AS-Interface Cable

Two different two-conductor unshielded cables were specified as the transmission medium for AS-i. One is a flexible high-voltage cable conforming to CENELEC or DIN VDE 0281, designated *H05VV-F 2 × 1.5*, which is very inexpensive and easily obtainable. The other is an AS-i-specific flat cable with very similar electrical properties but with the additional installation characteristics. The transmission media otherwise found in fieldbus systems (e.g., twisted-pair two-conductor cable, coaxial cable, fiber-optic cable) are not suitable for simultaneous transmission of data and power, complicated to install, or too expensive.

There are two electrical considerations involved in the selection of the suitable transmission medium: the DC resistance for power transmission and the transmission characteristics in the frequency range that is used for communication. At least 2A should be able to be transmitted for powering the slaves.

*Assuming*

- A cable length of 100 m
- 62 slaves evenly spaced along the cable
- All slaves having the same current requirement on average so that a total current of 2 A flows

the result is a maximum voltage drop between the feed point of the power supply and the terminal point of the last slave that depends on the selected conductor cross section as shown in the Table 6.2.

Since actuators with a permissible voltage tolerance of 24 V + 10%/-15% can be connected on Interface 1 of the slave and since a technically feasible voltage tolerance must be allowed for the power supply, a maximum permissible voltage drop for the cable of 3 V and a conductor cross section of 1.5 mm<sup>2</sup> (AWG 16) was specified for the cables. This solution should cover the vast majority of practical applications. In cases that deviate greatly from the earlier assumptions, a thorough analysis of the power distribution and voltage conditions at the remotest point in the network should be carried out.

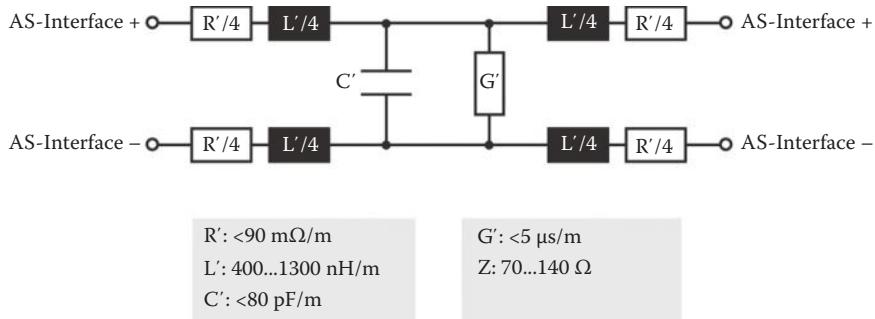

Using Power24 technology, the outputs could provide less power only because of the reduced supply current (24 V).

From a purely technical point of view, other conductor cross sections in a range from 0.75 to 2.5 mm<sup>2</sup> (AWG 18 to AWG 14) could be used. This makes the use of special cables possible, such as in applications where motion cables are required or where higher currents are demanded.

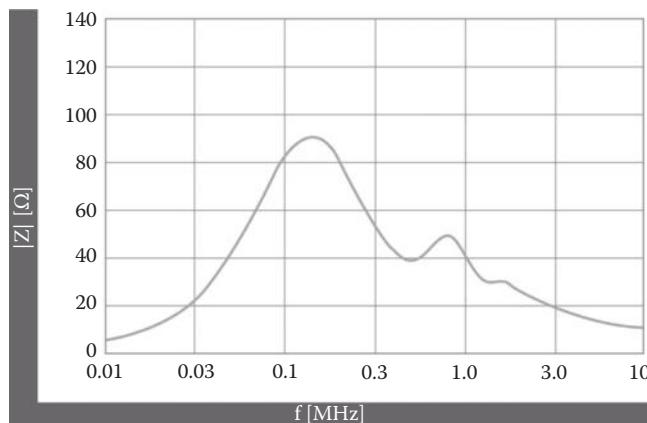

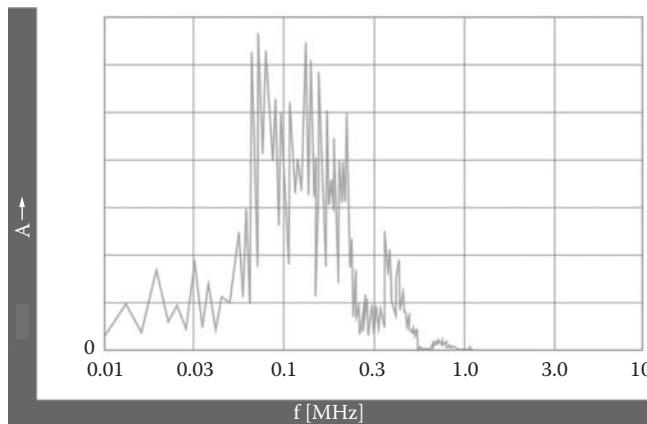

The other aspects in selecting the AS-Interface transmission cable have to do with the cable properties in the transmission frequency range. These can be described by the cable models shown in Figure 6.2. Shown are the maximum ratings that must be met by any proposed cable.

**TABLE 6.2** DC Resistance and Maximum Voltage Drop as a Function of Conductor Cross Section

Conductor cross section [mm <sup>2</sup> ]	0.75	1.5	2.5
DC resistance [mΩ/m]	52.0	26.6	16.0
Maximum voltage drop [V]	5.4	2.7	1.6

**FIGURE 6.2** AS-i cable model and limits.

The transmission properties of the AS-i cable, especially the impedance curve over the frequency, which is critically defining for the transmission behavior, are shown in Figure 6.3. You can see that both lower and higher frequencies up to 167 kHz are strongly attenuated, which has a very positive effect on the behavior of the AS-i system especially when it comes to asymmetrical interference (Figure 6.4).

**FIGURE 6.3** Transmission properties of the AS-i cable—impedance curve with data decoupling and 30 slaves.**FIGURE 6.4** Transmission properties of the AS-i cable. Frequency spectrum of a typical master poll.

### 6.2.2.3 Modulation Procedure

When selecting a suitable modulation procedure for AS-i, there are a number of requirements that need to be taken into consideration, the most important of which we will detail here. The message signal superimposed on the supply voltage for the sensors and actuators must be free of DC. The slave's sender (and where possible the master's sender) must be able to generate the signal in a cost-effective and space-saving manner. Since the AS-i cable has an impedance that increases greatly over the frequency (see Figure 6.3), the message signal must be relatively narrowbanded. Nor is it allowed to radiate unacceptable levels of electromagnetic noise. No previously known, and already-used, modulation procedure was able to meet all these requirements. Therefore, it was necessary for AS-i to specify and develop a new procedure.

The result was alternating pulse modulation (APM), a procedure for serial transmission in the base band whose functionality will be explained with reference to Figures 6.5 and 6.6. The send bit sequence is first encoded into a bit sequence that performs a phase change whenever the send signal changes. The result is a send current that, in conjunction with a single inductor in the system, uses differentiation to generate the desired signal voltage level on the AS-i cable.

Each rise in the send current thus results in a negative voltage pulse and each drop to a positive voltage pulse. In this way, it is quite simple to generate signals in slaves that have a higher voltage than their actual supply voltage. This means inductors can be eliminated in the slave, which keeps the electronics integrated in the sensor or actuator small and inexpensive. On the receiver side, these voltage signals are detected on the line and converted back into the send bit sequence. The receiver synchronizes itself with the first detected negative pulse, which it interprets as the start bit of a message.

If the voltage pulses approximate  $\sin^2$  pulses, then the requirements for low limit frequency and low noise emission are met at the same time. This is done by means of suitable shaping of the send current pulses, which are generated like the integral of a  $\sin^2$  pulse. A frequency spectrum for a typical send pulse sequence is shown in Figure 6.3. A comparison with Figure 6.4 shows that the attenuation curve and the signal spectrum are optimally matched. Using this modulation procedure and the available topologies, bit times of 6 ms are attainable. This allows a gross transmission rate of 167 kbit/s.

The nonterminated cable results in the amplitudes of the AS-i messages that a receiver has to process being able to have the fluctuations shown in Figure 6.7, both within the individual telegrams and between

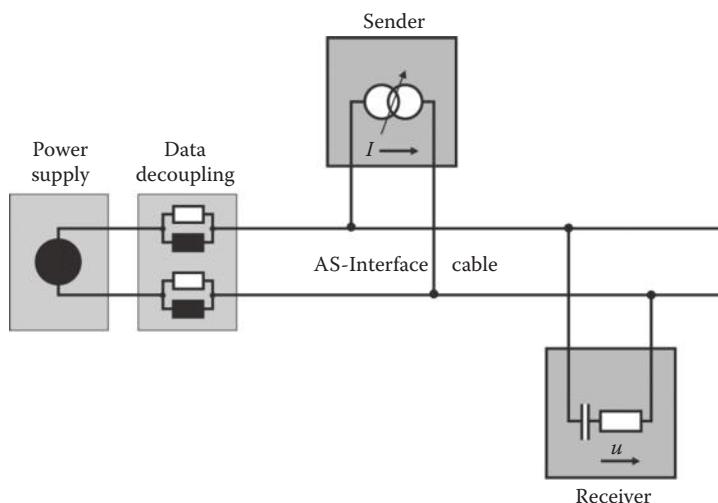

FIGURE 6.5 APM—signal generation.

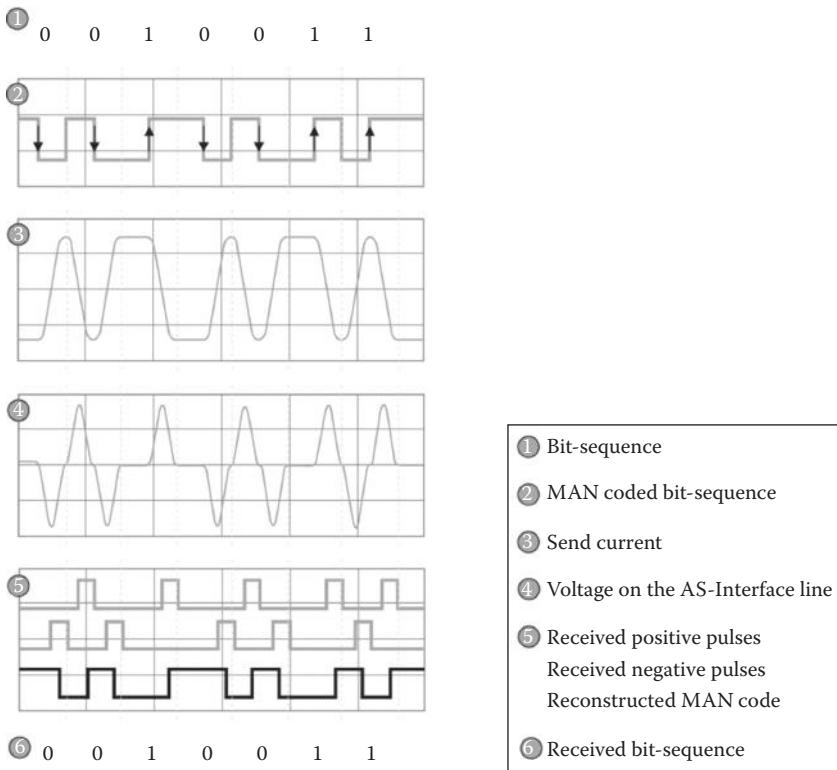

FIGURE 6.6 APM—MAN code.

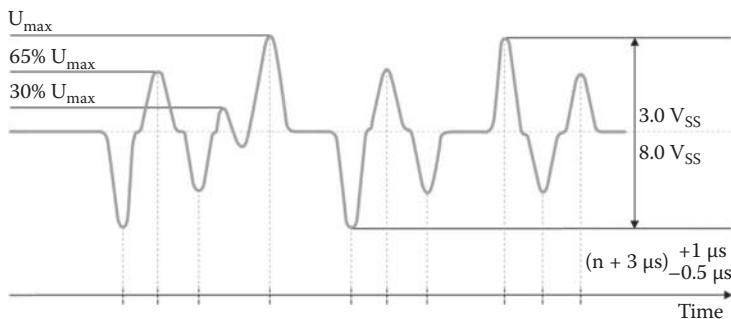

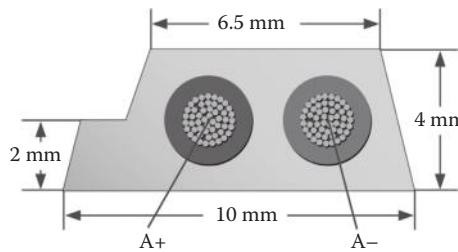

FIGURE 6.7 Slave reply at master receiver.

the telegrams from various slaves. The differences within the message arise from the fact that reflections at the cable end affect higher frequencies (and thereby more densely packed  $\sin^2$  pulses) more than lower frequencies. In addition, ringing is not allowed to affect the receiver. Managing these amplitude tolerances ensures that AS-i is extremely robust with respect to any cable topology.

The absolute size of the slave reply depends both on the topology and on the location of the slave. If the slave is located near the power supply, which forms a cable terminator, this slave will generate the reply with the smallest amplitude. Whereas a slave only communicates with a station (the master) that is located at a fixed location along the line, the master must be able to process every slave reply from any location along the cable.

**FIGURE 6.8** The yellow AS-i profile cable with a conductor cross section of  $1.5 \text{ mm}^2$ .

### 6.2.3 AS-Interface Electromechanics

The standardized electromechanics of AS-i offer an innovative installation and implementation technology. This technology adds considerably to the simplicity of the system and thus to cost reductions. Figure 6.8 shows the yellow AS-i flat cable for installation in the field. This cable has become the trademark of AS-i.

The cable is available with a *traffic yellow* jacket for the AS-i network and with a *black* jacket for auxiliary power, which can be routed separately to some field devices.

The available jacket materials with their chemical and mechanical properties cover most of the requirements found in industrial automation applications:

- EPR rubber mixture EM3 according to DIN DE 0207 part 21
- TPE YM5 according to DIN VDE 0207 part 5
- PUR according CENELRC HD 22, T 10

The yellow cable has a conductor cross section of  $2 \times 1.5 \text{ mm}^2$  and is equipped with a coding strip ensuring correct polarization and contact on the specified side. The connection is achieved via piercing contact piercers, penetrating the cable jacket and thus establishing a secure contact to the specifically designed fine stranded wire (Figure 6.9). Cutting, stripping, installing ferrules, and attaching a shield can be omitted. Even prelengthening the cable is no longer necessary since the cable can be connected at any arbitrary point. This shows how easy connecting a slave can be—with AS-i!

Many modules and field devices can be directly connected to the yellow flat cable. The product database of AS-i—[www.as-interface.net/products](http://www.as-interface.net/products)—offers a multitude of accessories to establish branches, drop cables, etc., to route and attach the flat cable and cable glands to bring it into junction boxes.

A black profile cable with the same measurements as the yellow cable is used to provide additional power for some field devices or modules with 24 V DC.

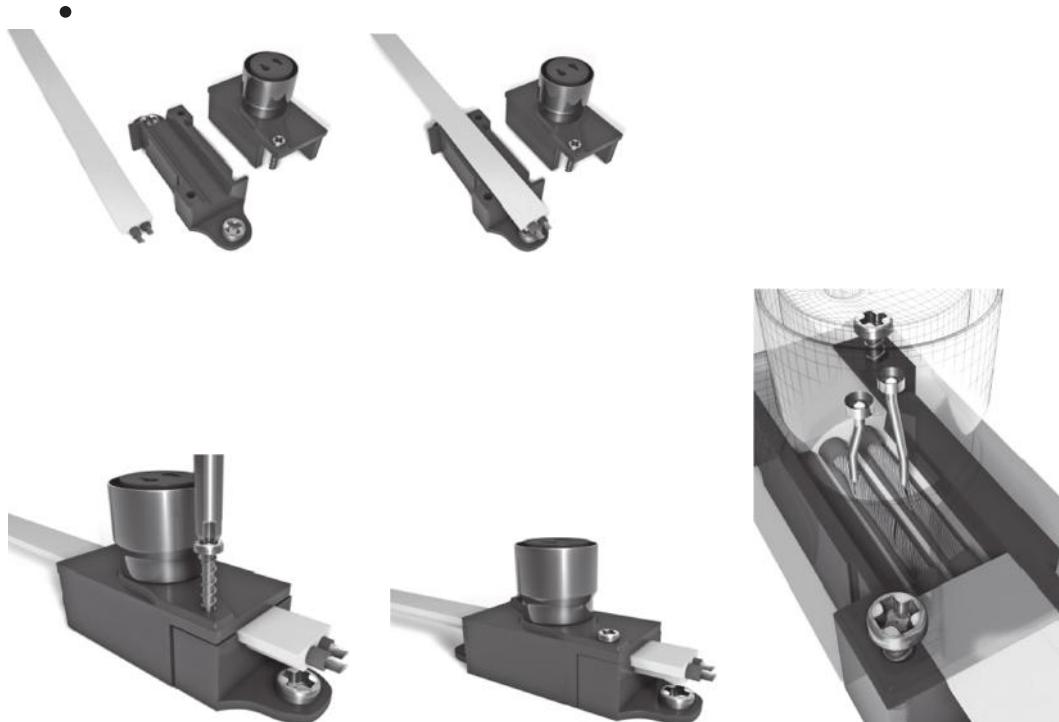

In addition to the AS-i flat cable, a two-conductor cable for applications in IP20 environments (in cabinets, distribution boxes, and similar protected environments) was introduced.

The IP20 two-conductor cable has a conductor cross section of  $2 \times 0.75 \text{ mm}^2$  and is mechanical coded with a tab. This two-conductor cable is optimized for connections via piercing technology. For this purpose, each conductor is pressed into a tool, very similar to a fork, while the insulation is cut and a secure contact is achieved. Processes like cutting, stripping, installing ferrules, or attaching a shield are also omitted. This AS-i two-conductor cable is more flexible and easier to handle than the yellow flat cable—due to its single-layer insulation and thus smaller conductor diameter. However, this makes it unsuitable for field installation.

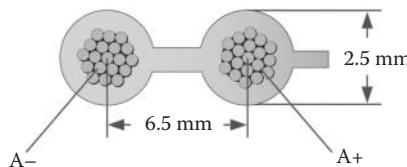

### 6.2.4 AS-Interface Communication System

#### 6.2.4.1 Access Procedure

Since AS-i was designed to replace star-type two-point connections (traditional cable tree), a bus access procedure was selected, which reproduces this topology and is able to ensure a defined response time

**FIGURE 6.9** M12 adapter for the AS-i profile cable with *piercing* technology.

**FIGURE 6.10** AS-i two-conductor cable for use in IP 20 applications has a conductor cross section of  $2 \times 0.75 \text{ mm}^2$ .

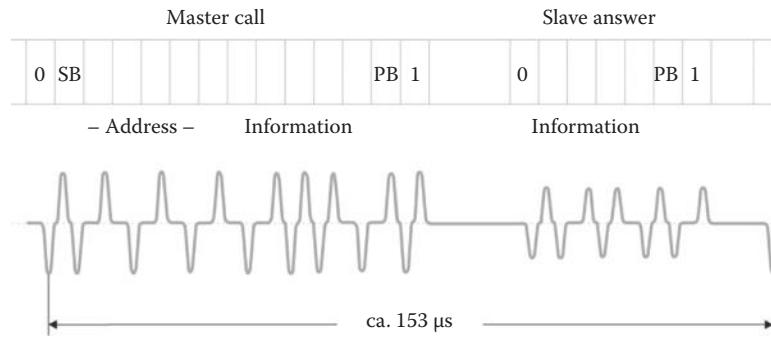

(the master–slave access with cyclical polling). The master sends a telegram that is received at a particular slave address, and the slave contacted at this address replies within the provided time (Figure 6.11). From the viewpoint of the transmission system, only one master and a maximum of 62 slaves can be involved at any one time.

The procedure chosen for AS-i allows the construction of very simple and thereby cost-effective slaves while providing at the same time the greatest possible flexibility and integrity. In case of a brief disturbance on the line, for example, the master can repeat telegrams for which it received either no reply or an invalid reply. This means it is not necessary to repeat the entire cycle over again.

The single-master access procedure does not preclude operation with a second (standby) master. The latter can also listen to the data traffic and assume responsibility for communication should the first master fail.

#### 6.2.4.2 AS-Interface Messages

An AS-i message consists, as shown in Figure 6.11, of a master request, a master pause, a slave response, and a slave pause. All master requests are exactly 14 bit times in length, and all slave responses have a length of 7 bit times. A bit time corresponds to a uniform 6 ms.

**FIGURE 6.11** Structure of an AS-i message.

The master pause is allowed to be at least 2 and a maximum of 10 bit times in length. If the slave is synchronized, it can begin to send its response after as soon as 2 bit times. If it is not synchronized, it requires 2 bit times longer, since it is monitoring the master pause during this time for any additional information before it can accept the poll as valid. If the master, however, has not received the start bit for the slave response after 10 bit times, it can assume that there is no response forthcoming and it can begin with the next request. The pause (slave pause) between the end of the slave response and the next master request should be no more than 1.5 to 2 bit times in length.

The signal sequence shown in Figure 6.11 represents the bit sequence 00101010111011Bin, which means a data request to a standard slave having address 21 and user data EHEX. The slave responds with the bit sequence 0011001Bin, which contains the user data 6HEX.

A master poll of a standard slave is listed in Table 6.3.

The slave response is listed in Table 6.4.

4 bits of user data are contained in a master request, while the slave returns 4 bits of user data in response. AS-i Specification Version 2.1 (1998) created the possibility of connecting 62 slaves to an AS-i network instead of the previous 31. This made it necessary to define an additional address bit without however losing compatibility with the existing systems. For this reason, the following definition of the master request was agreed on for all slaves having the ID code “AHEX,” which are operated in the so-called expanded address mode (Table 6.5).

The message shown in Figure 6.11 could also be directed to a slave in expanded addressing mode. In this case, it contains address 21A and user data 6HEX. This means that in a master request to a slave

**TABLE 6.3** Master Request

Bit	Reference
Start bit ST	Identifies the beginning of the master request = 0: valid start bit; = 1: not allowed.
Control bit SB	Identifies the type of request = 0: data, parameter request, address assignment = 1 command request.
Address A0–A4	Address of the contacted slave (5 bit).
Information I0–I4	These 5 bits contain in order to the type of request, the information to be transferred to the slave. Details are described by the respective call type.
Parity bit PB	Parity bit the number of all “1” in the master call has to be even.
End bit EB	Identifies the end of the master request = 0: not allowed; = 1: valid end bit.

**TABLE 6.4** Slave Response

Bit	Reference
Start bit ST	Identifies the beginning of the slave response = 0: valid start bit; = 1: not allowed.
Information I0–I3	4-bit information.
Parity bit PB	Parity bit the number of all “1” in the slave response has to be even.
End bit EB	Identifies the end of the slave response = 0: not allowed; = 1: valid end bit.

**TABLE 6.5** Master Request in Extended Address Mode

Bit	Reference
Start bit ST	Identifies the beginning of the master request = 0: valid start bit; = 1: not allowed.
Control bit SB	Identifies the type of request = 0: data, parameter request, address assignment; = 1: command request.
Address A0–A4 13	Address of the contacted slave (5 bits and select bit).
Information I0–I2, 14	These 4 bits contain in order to the type of request, the information to be transferred to the slave. Details are described by the respective call type.
Parity bit PB	Parity bit the number of all “1” in the master call has to be even.
End bit EB	Identifies the end of the master request = 0: not allowed; = 1: valid end bit.

in this mode, only 3 bits of user data are contained. The response from a slave in expanded addressing mode remained unchanged.

#### Data Convention

In addition to the described message format, the data convention shown in Figure 6.12 has been established for AS-i. From the point of view of the host system or Interface 3, the value 0 for a data bit means that the sensor, the actuator of the function of the slave, is *turned off* or *inactive*; a value of 1 means *turned on* or *active*.

Since this convention does not apply in the same way to the AS-i telegram level, the master must invert the data bits when outputting (and only then!). One must also note that this definition does not apply to outputting of parameters. Since parameters are system-internal data, the master does not invert them.

	Data input		Data output		Parameter input		Parameter output	
Host	0	1	0	1	0	1	0	1
AS-Interface telegram	0	1	1	0	0	1	0	1
LED on the slave	Off	On	Off	On	↑	↑	↓	↓
Actuator/sensor/ function	Off inactive	On active	Off inactive	On active	On active	Off inactive	On active	Off inactive

**FIGURE 6.12** Convention for data transmission.

### 6.2.4.3 Data Safety

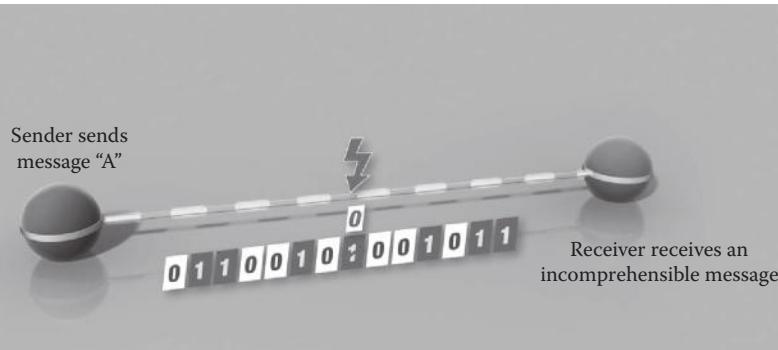

No communication system works without any faults. Therefore, it is crucial to be aware of possible interruptions that could affect the fieldbus by falsifying a transmitted message. Consequently, one of the tasks when designing a fieldbus system is to assure that falsified messages can be safely recognized and will not be processed (Figure 6.13).

Of note, even fieldbuses that use optical cables to transmit information are not entirely immune to the danger of potential interruptions. Because optical senders and receivers need to be supplied with electronic energy and interruptions can be transmitted via the supply cable, these systems can also experience bit falsifications (Figure 6.14).

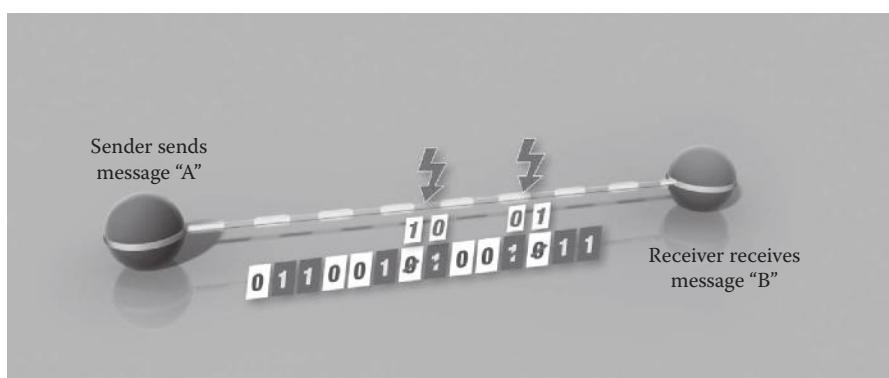

It is easy to see that the probability for an interruption to affect a long message is greater than for a shorter message. A short message can be laid out more fortified against the influence of interruptions.

Falsifications that changed the message during the transmission from sender to receiver need to be recognized on the receiver side. Therefore, the receiver needs to add additional information (proof or safety bits), following a specified algorithm, to the actual information. The receiver has the task to check the received message for potential falsifications and to repeat the calculation via the same algorithm. If the result is correct, the message is determined to be correctly transmitted. Otherwise, it is determined to be lost and a repeat is requested by the sender.

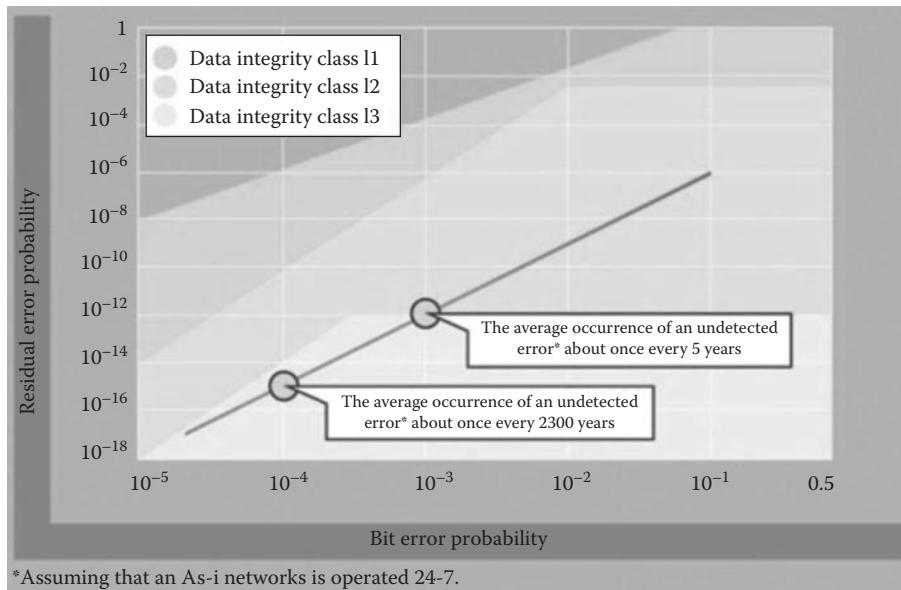

Particularly critical is the unlikely but still possible case that interruptions interfere with a message in a way that several data bits are falsified. In this case, it is possible that a sent message *A close valve*

**FIGURE 6.13** Loss of a message.

**FIGURE 6.14** Falsification of a message.

**FIGURE 6.15** Data integrity classes according to EN 60870-5.

turns into a valid message B, for instance, *open valve*. This message will be accepted as seemingly correct despite error checking. The statistical probability for the occurrence of such a case is called *residual error probability*. It can create a very dangerous situation for a machine or plant and the human operator and must therefore, under all circumstances, be reduced to an extremely small value.

The standard EN60870-5 defines three data integrity classes that, depending on the kind of controlled process, require the observation of certain residual error probability limits (Figure 6.15). The residual error probability can be used to calculate the average time between two unrecognized falsified messages. Very often, this is the more intuitive value.

#### *AS-Interface Data Integrity and Error Response.*

Reliable error recognition is of great importance for faultless communication over the AS-i cable, which is generally unshielded. Error detection is done in the *receive* state.

Data checking in AS-i is accomplished according to a different principle than that used in most of the familiar bus systems. One reason for this lies in the very short telegrams that are exchanged.

The master request contains 11 bits of data to be checked and the slave response 4 bits. To check this conventionally using a hamming distance of 4 ( $HD = 4$ ), you would have to send an additional 7 bits for the master telegram and 4 bits for the slave telegram. This would drastically reduce the achievable network transmission rate.

So instead, AS-i performs greater checking on the bit transmission itself. This makes use of the knowledge of redundancies in the code and the fixed lengths of the telegrams. As a result, the following errors can be distinguished (Figure 6.16):

- Start bit error
- Alternating error
- Pause error
- Information error
- Parity error
- End bit error
- Telegram length error

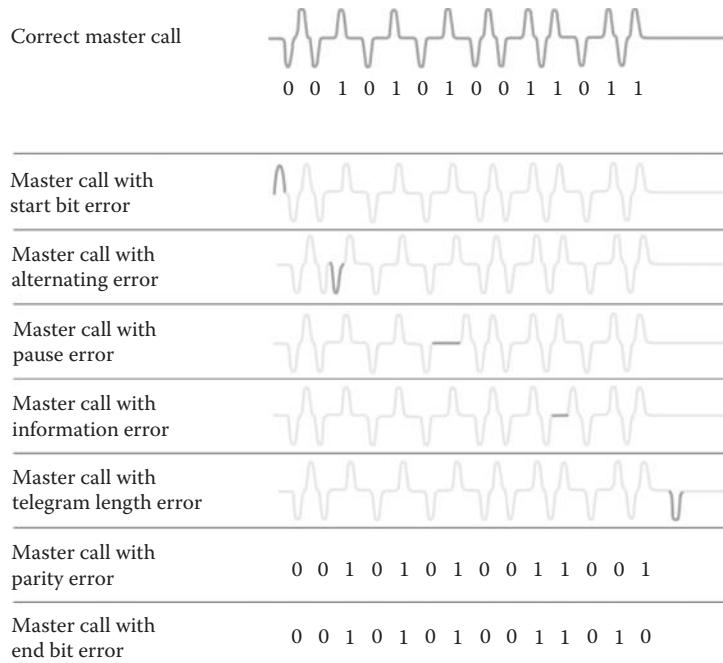

FIGURE 6.16 Error detection on the bit level.

Each master request and each slave response is subjected to these checks. If one of the errors named is detected, the request is considered faulty. The checks can be performed with just a few logical operators, which have little effect on the processing time.

If the slave receives a master request and when checking the received bit sequence detects an error, it goes into *asynchronous* state and waits for the next pause so it can then again read in the next master request in the *receive* state (see Figure 6.22). In this case, the slave does not generate a response telegram, since the error could lie in the address range of the telegram and the telegram could have been meant for a different slave. The master can determine that no slave response has arrived by means of the master pause monitoring and repeat the request if necessary.

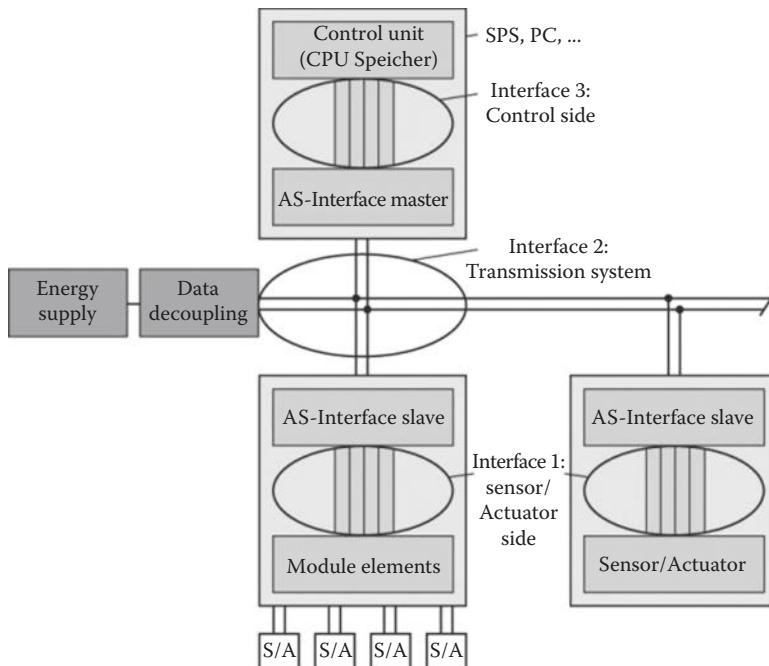

If the master request is received without error but does not contain the correct address or contains an unrecognized command code, the slave goes into *synchronous* state and in this case does not generate a slave response.

Only if a command does in fact trigger a response in a slave is a slave response generated and returned to the master as a positive acknowledgment. If this reply is likewise received without error, the message is considered to have been successfully exchanged. It can still happen, however, that the master detects an error in the response and then repeats the request, even though the slave has already correctly executed the command.

An exception to this acknowledgment principle is the broadcast commands (see next section). Here, of course, a slave is not allowed to generate a response. The gross transmission rate of AS-i is 167 kbit/s, which enables a net data rate of maximum 53.3 kbit/s including all pauses necessary for the various functions. The resulting efficiency of the user data transfer can then be calculated as 32%. This is an excellent value compared with other bus systems.

#### 6.2.4.4 System Interfaces

The AS-i system consists, as shown in Figure 6.17, of several hardware components that are connected to each other and to the environment. These components include the transmission system, the slaves, and the master.

**FIGURE 6.17** AS-i components and interfaces.

#### *Transmission System*

This system consists of the AS-i two-wire cable that connects the slaves to each other and to the master in freely selectable topologies, the energy (power) supply, and the data decoupling. Both data traffic and the power distribution are handled on this two-wire transmission system.

#### *Slave*

The slave uses Interface 1 to create the sensor/actuator side, the connection to the sensor or actuator, where the AS-i is configured so that the slave function can be fully integrated into the sensor/actuator.

#### *Master*

The master uses Interface 3, the control side, to create the connection to the host system, which in turn consists of a PLC, a PC, or a coupler to a higher-level fieldbus system. In addition, the master controls the entire data traffic over the transmission system and assumes responsibility for the necessary management functions.

The AS-i standard describes Interface 2 as a transmission system fully and completely. All the conditions necessary for data and power transmission are specified and all the functions for data and parameter transmission, addressing and identification, or status polling of the slaves are defined.

In the standard cited, Interface 1 is described only conceptually, with its specific realization left to the product manufacturer. Profiles, which describe the most common slave types, are used for a more precise description of how the functional interchangeability of the products from various manufacturers is ensured.

Due to the wide variety of structures that a host system can embody, Interface 3 is also described only conceptually. The specific realization is determined by the implementation in a PLC, PC, or fieldbus coupler.

Among the other components of AS-i, which are used only as needed, are repeaters, which allow an extension of the cable length to over 100 m, and GND fault detectors as well as addressing and service devices, which can be used for assigning addresses to slaves and, in case of a fault, provide quick problem diagnostics.

#### 6.2.4.5 Transmission Layer

The transmission layer in the master is responsible for exchanging individual telegrams with the slaves. Along with the *raw* data from the sequence control, it gets data exchange jobs. When a telegram is sent, frames (start and end bit) and parity are added. The correctly received slave reply without parity, or the frame, is returned to the sequence control.

Data exchange between master and slave always consists of a master pause and a slave reply, which is followed by a send pause (Figure 6.18). The master pause is the pause that the slave needs to observe after receiving a master request. The send pause is the time during which the network is in the idle state after the end of a slave reply.

The master specification requires that the send pause be no longer than 2 bit times in undisturbed, normal operation. This ensures that the specified short cycle times can be maintained. When measuring the pause time, note that the last (positive) pulse of the slave reply starts in the middle of the end bit and the first (negative) pulse of the next master request not until the middle of the start bit. The send pause may be extended to a maximum of 500 ms if this does not result in the complete cycle time being longer than 5 ms. This increase in the cycle time for systems having fewer than 62 slaves allows dedicating more processor power for administration functions. The function for data transmission offers the sequence control two transmission methods (Figure 6.19):

##### One-Time Transmission

Absence of a slave response or receipt of a defective response is immediately reported. The master request is not repeated. This version is used when looking for new slaves.

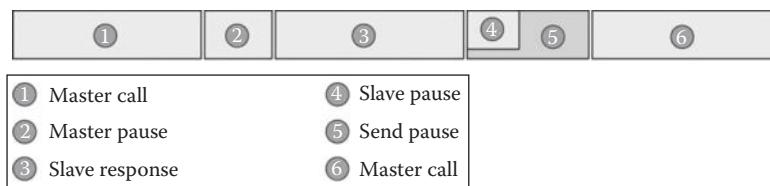

FIGURE 6.18 Timing structure of the AS-i messages.

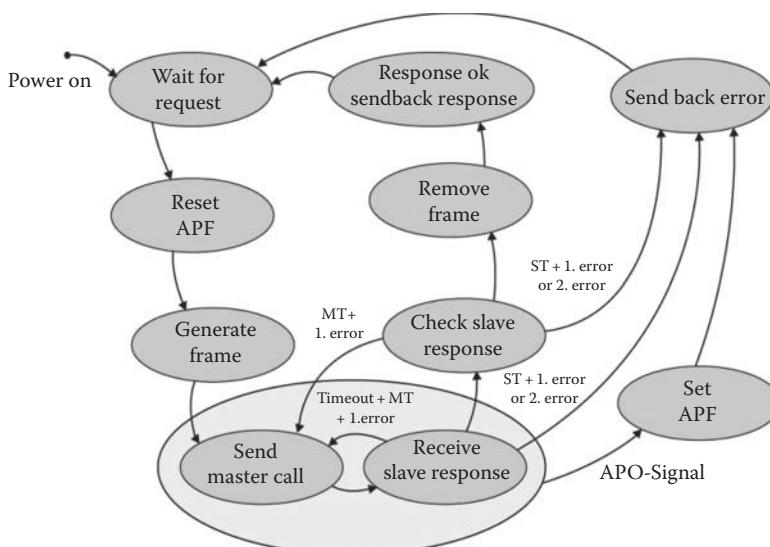

FIGURE 6.19 State diagram of the master transmission level.

### *Repeatable Transmission*

The transmission control repeats the master request one time when a slave response is absent or is defective. This allows single errors to be caught at the lowest level without having to significantly delay the signals from individual slaves.

A transmission is considered successful if after the minimum master pause time has expired and before 10 bit times have passed a slave response begins and is then received without error. The time-out of 10 bit times takes into account the response time of the slave (master pause) of 3–5 bit times and a propagation time on the cable of one bit time. The remaining 4–6 bit times allow for the use of repeaters, which regenerate the signals.

When a slave response is received, Manchester coding, start, end, and parity bits of the incoming telegram are checked. The vast majority of all transmission errors are detected by the Manchester coding, so that only errors in multiple  $\sin^2$  pulses of a telegram result in parity errors. When direct repetition of the master request results in a second error, this is reported to the sequence control, which then takes over the error handling.

During transmission of the master request and receipt of the slave response, the transmission control monitors the AS-i power *on* (APO) flag. If within this time the supply voltage on the line is too low, AS-i power fail (APF) is reported to the sequence control.

#### **6.2.4.6 Transmission Phases**

At the sequence control level, two procedures work in parallel:

1. The transmission phases for controlling data exchange with the slaves
2. Administration, which carries out the function requests on the master layer and takes care of automatic addressing

The sequence control distinguishes between two operating modes that control the behavior when activating and polling slaves:

1. In the projecting mode, all connected slaves are activated regardless of the nominal configuration and are included in the data exchange. This mode allows start-up of a system without prior projecting.
2. In the protected mode, the master communicates only with projected slaves and thereby allows for automatic checking of the configuration. Only slaves that are noted in the list of projected slaves (LPS) and whose nominal and actual configurations agree are activated. Missing or incorrectly connected slaves result in an error message; automatic addressing is possible.

After the supply voltage has been turned on, the master cycles through the various transmission phases (Figure 6.20). First, initialization takes place in the offline phase. Once initialization is complete, start-up operation begins, in which all connected slaves are detected in the detection phase and are then activated in the activation phase. Following this, the actual data exchange begins in cyclical normal operation.

#### *Initialization*

Initialization during the offline phase places the master in the base state. The data in the input data image (IDI) for all slave inputs are set to zero ("0," inactive) and the output data to one. One is the value that is also assumed by the slave outputs after turning on the supply voltage and after a reset. This ensures that the state of the slave outputs does not change when the master is turned on. Since a programmable logic controller sets outputs to zero after a reset, the *write output data* sequence control level function inverts the data that are transferred from the controller. After the supply voltage is turned on, the projected parameters are copied to the parameter field so that at the next activation the preset parameters are used.

The sequence control can be brought from any other state to the offline phase by setting the offline flag. The offline flag thus has the function of resetting the complete network and the master, which corresponds roughly to the *stop* function of many programmable logic controllers.

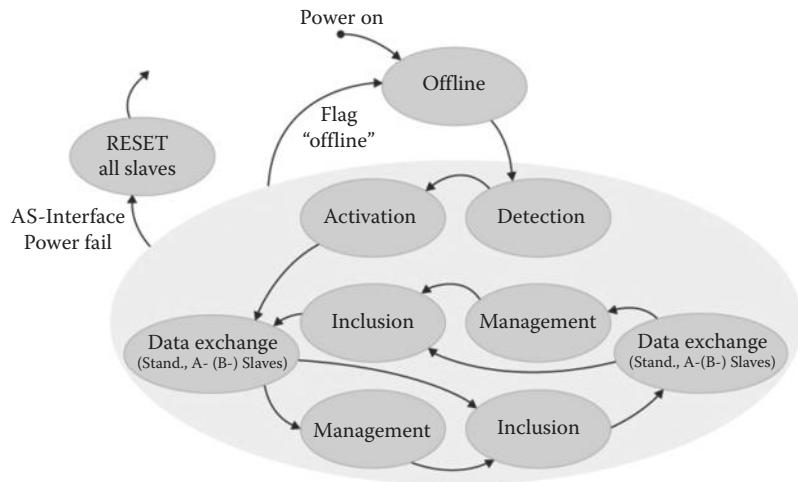

FIGURE 6.20 Transmission level phases.

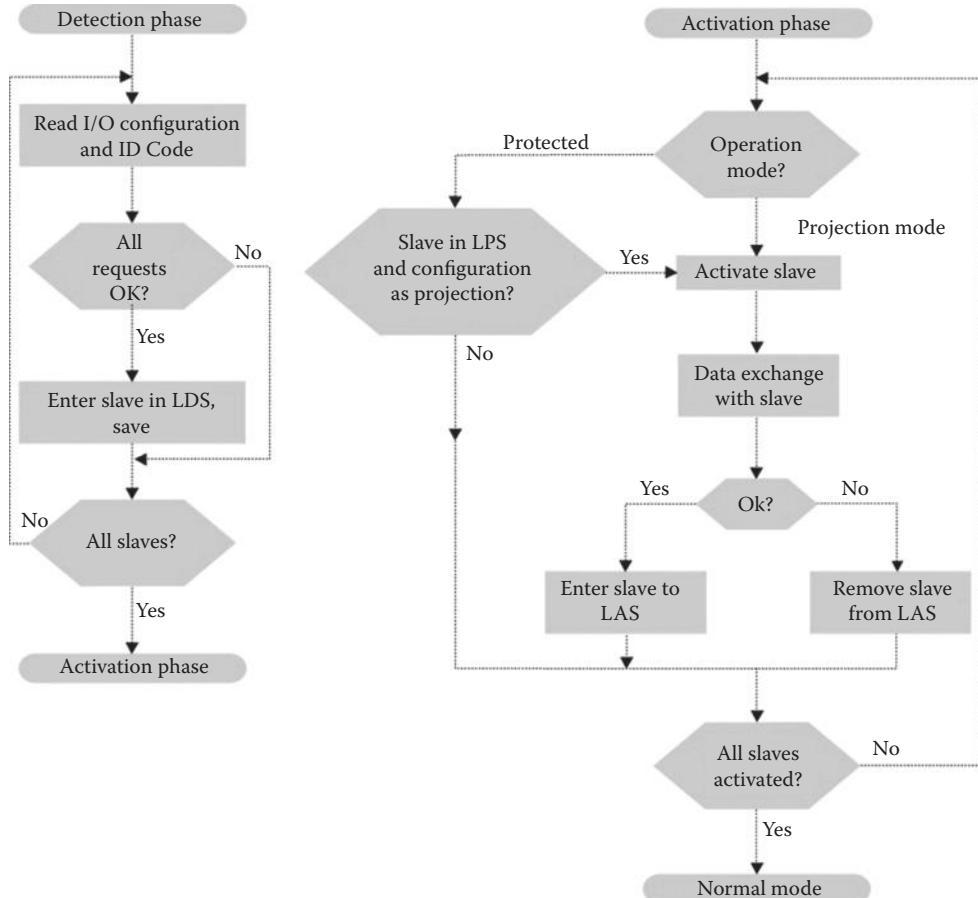

FIGURE 6.21 Start-up operation with detection and activation phase (simplified).

### *Start-Up*

In start-up operation, the sequence control detects all the connected slaves and activates them. Start-up operation consists of the detection phase and the activation phase (inclusion phase); see Figure 6.21.

In the detection phase, the slaves on the AS-i string are searched for by reading the I/O configuration and ID codes. Slaves that respond to all requests are entered in the list of detected slaves (LDS). Their I/O configuration and their ID codes are stored in the configuration data image (CDI). In the activation phase, the previously found slaves are activated by writing the parameter outputs. The IDI is filled with valid values by means of a first data exchange.

In project mode, all detected slaves (with the exception of the zero address) are activated. In protected mode, only the detected slaves that are also listed in the LPS and whose I/O configurations and ID codes agree with the projected configuration data are activated. The master thus exchanges data only with slaves that are intended by the projection. At the end of the activation phase, a check is made to see whether the nominal and actual configurations agree and then the Config\_OK flag is set.

### *Normal Mode*

Normal mode is where the actual data exchange with the connected sensors and actuators takes place. A cycle consists of data exchange, management, and inclusion phase.

## 6.3 AS-Interface Devices: Sensors/Actuators

---

Communication partners of the master are slaves. They have the task to take the information that is directed to them out of the data stream and to provide their information to the master. To achieve this, the master sends out a telegram with a specific slave address and the slave with this address responds during the time allocated for this process. Thus, every message is acknowledged. After the receipt for the reception of the message was correctly received, the message is deemed correctly sent. The only exception to this rule is the master request *broadcast*. Since it goes out to all slaves at the same time, it cannot be answered.

The duration of the entire message, consisting of the master request and slave reply, is only 152 µs. Therefore, 6500 of these individual messages can be exchanged during 1 s.

Should the master not receive a reply or if the reply cannot be decoded without errors, the message can be repeated. Since the messages are extremely short, isolated repetitions do not exceed the specified time limits. This characteristic contributes considerably to the excellent noise resistance of AS-i.

### 6.3.1 Function Request in the Slave

The states that the sequence control can assume in the slave and the possible transitions between them are shown in the state diagram Figure 6.22. After a *reset*, the AS-i goes into the *initialize* state.

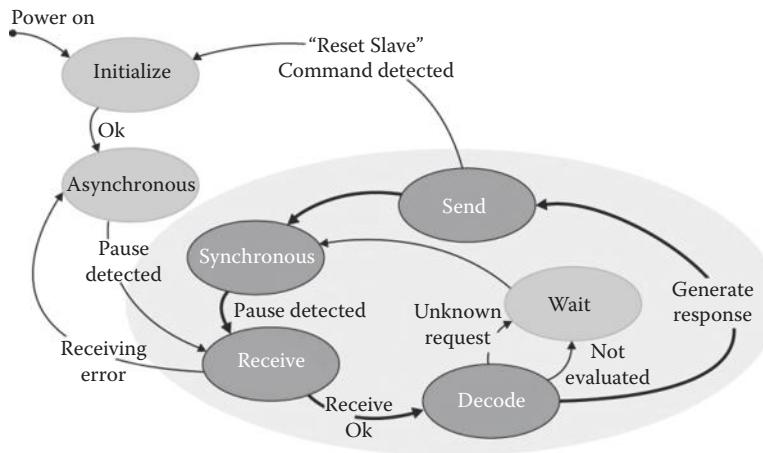

Here, it performs the following functions:

- Resetting the outputs, the internal registers, and the flags
- Loading the address, the I/O configuration, and the ID codes from the nonvolatile memory
- Switching to the state *asynchronous*

If the sequence control detects errors in reading the nonvolatile memory, it sets Flag S3 in the status register. This could happen, for example, if there is a power loss while the addressing request is being executed, so that the save in nonvolatile memory cannot be completely finished.

In *asynchronous* state, the slave examines the data stream arriving on the line and waits for a pause. In *receive* state, a data telegram is read in starting with the next start bit, and the check described in Section 6.4.5.3 is performed. If there was a receiving error, the slave returns to the *asynchronous* state, where it waits for the next pause. If no errors were detected in the check, it goes into the *decode* state.

In the *decode* state, first, an address comparison is made. Only if the addresses agree is the command analyzed and, where appropriate, a response generated. This is sent to the master in the *send* state.

**FIGURE 6.22** Main states for sequence control in the slave.

Since communication with the nonvolatile memory can take up a longer time (depending on the request and type of IC up to 500 ms), it runs in the background. It does not disturb data traffic between master and slave, but the master must still take the execution times into account.

After initializing, the slave will execute all commands but not immediately reply to data requests. Only after a valid parameter request has been received is data exchange enabled. This procedure is intended to ensure that the slave is in the desired operating state before the data are output.

### 6.3.2 Device Profiles

A device profile consists of data and parameters that can be exchanged with a device, as well as the status diagram that provides information about the behavior of the device on the communication network. Device profiles are independent of the characteristic of the fieldbus system being used. In the case of AS-i, these device profiles are called *slave profiles* (in contrast to *master profiles*). A slave profile specifies the following properties of a slave uniquely and bindingly:

- Which data bits carry information and what this information means
- Whether parameters are used and, if yes, what they mean
- Whether the peripheral error bit may be evaluated
- How the slave behaves

An example of a typical status diagram for a simple slave is shown in Figure 6.23. In the case of a slave that, for example, communicates digital data distributed over several cycles, the status diagram is of course more complex. But this is information that has meaning only for the master and slave developer; the user does not have to be concerned about these processes. The unique assignment of a slave to a profile is given by the combination of the I/O configuration, ID code, and extended ID Code 2.

The profile also specifies the following in many cases:

- Which logic levels are defined for the inputs and outputs of the slave module
- Which time delays need to be taken into account for in- and/or output signals
- Which pin configurations need to be observed and what the labeling of the module has to look like

Figure 6.24 shows the pin assignments provided for in the profiles for the most commonly used M12 connector method. These specifications are—as much as possible—compatible with the standards for the connected products. These additional specifications support the interoperability between products made by different manufacturers.

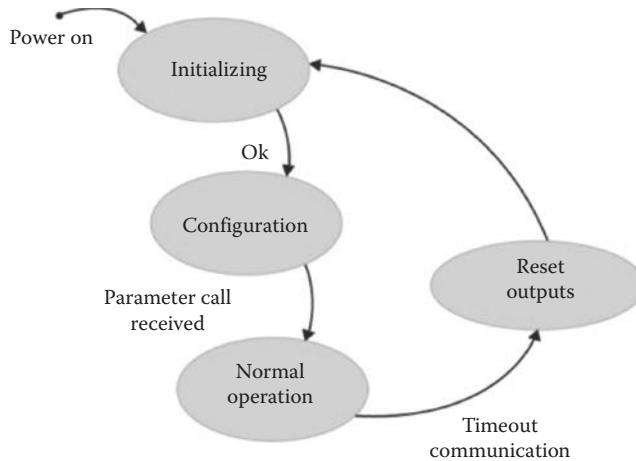

FIGURE 6.23 Status diagram of a slave according to a device profile.

AS-Interface	Auxiliary energy	AS-Interface and auxiliary energy	Binary input	Binary output (semiconductor)

In order to not inhibit advances or the offering of specialized modules with too narrowly defined profile definitions, the *free profile* with ID code FHex is provided. Here, essential parts of the device profile definition may be defined between the manufacturer and user.

The overview in Figure 6.25 shows which profiles are currently available. Additional profiles are permanently being reviewed and approved by the technical commission of the AS-International Association.

FIGURE 6.25 Slave profiles (i, input; O, output; B, bidirectional port; T, tristate; R, reserved).

*I/O Configuration*

The I/O configuration refers to the data ports on Interface 1 of the slave and is defined as shown in Table 6.6 I/O configuration. Here, *in* means a process input, *out* a process output, I/O a bidirectional behavior of the port, and *tri* a tristate output with no function. The latter state is assumed if during the reset no unambiguous I/O configuration can be determined from the slave's own data memory due to a read error.

TABLE 6.6 I/O Configuration

Code	D0	D1	D2	D3
0 <sub>HEX</sub>	IN	IN	IN	IN
1 <sub>HEX</sub>	IN	IN	IN	OUT
2 <sub>HEX</sub>	IN	IN	IN	I/O
3 <sub>HEX</sub>	IN	IN	OUT	OUT
4 <sub>HEX</sub>	IN	IN	I/O	I/O
5 <sub>HEX</sub>	IN	OUT	OUT	OUT
6 <sub>HEX</sub>	IN	I/O	I/O	I/O
7 <sub>HEX</sub>	I/O	I/O	I/O	I/O
8 <sub>HEX</sub>	OUT	OUT	OUT	OUT
9 <sub>HEX</sub>	OUT	OUT	OUT	IN
A <sub>HEX</sub>	OUT	OUT	OUT	I/O
B <sub>HEX</sub>	OUT	OUT	IN	IN
C <sub>HEX</sub>	OUT	OUT	I/O	I/O
D <sub>HEX</sub>	OUT	IN	IN	IN
E <sub>HEX</sub>	OUT	I/O	I/O	I/O
F <sub>HEX</sub>	TRI	TRI	TRI	TRI

Wherever an output *out* (and no bidirectional behavior) is defined, this means that the corresponding information bit is undefined in the slave response. Likewise, the information bit from the master call remains without meaning, even though it is sent, where an input *in* is defined. Unneeded information can thus be hidden with this I/O configuration. At the same time, the I/O configuration together with the ID codes for identifying slaves is employed. These refer to the slave profile. The I/O configuration is 4 bits long, is determined by the manufacturer, and is stored in the slave, where it cannot be changed.

#### *Actual ID Code*

This is used to identify various types of slaves. The ID code *A*, for example, means that the slave works in *extended addressing mode* and interprets master calls differently at times. The ID code *B* indicates a *safety at work* slave, which is designed for sending safety-related signals. The ID code is 4 bits long, is determined by the manufacturer, and is stored in the slave, where it cannot be changed.

#### *Extended ID Code 1*

This part of the ID code can be modified by the user. It can be used for identifying slaves that from the manufacturer's point of view are identical but that from the user's perspective are different. One could, for example, assign motor starters having an adjustable overcurrent limit with different ID Code 1 values, so that they cannot be confused when replacing a unit in the system. For the standard slave, this code is 4 bits long, and for a slave with extended addressing mode, 3 bits long.

#### *Extended ID Code 2*

This part of the ID code is used for extending the identification possibilities of AS-i slaves. Like the actual ID code, it is 4 bits long, is determined by the manufacturer, and is stored in the slave, where it cannot be changed.

Together with the I/O configuration, the ID codes refer to a device profile. This contains specifications for the meanings of the data and parameter bits that are expected by or sent by the slave, specifications regarding the behavior of the slave, as well as any additional definitions that support the interchangeability of slaves from different manufacturers but having the same function.

The extended ID code is not implemented for slaves conforming to Specification 2. In the case of these slaves, the master expands the missing codes to FHex.

### **6.3.3 Extended Profiles: Combined Transaction Types**

Although most AS-i slaves get by with just a few cyclically exchanged data and acyclically sent parameter bits of information, there are numerous applications where this alone is not sufficient. For these situations, several solutions were created in Version 3.0 of the specification, which will be described in the following text in some detail.

The common denominator of these solutions is that several messages are exchanged one after the other between the master and slave, with the contents of these messages having a defined relationship. This type of communication between master and slave is therefore referred to as *combined transaction types*, abbreviated CTTs. The master recognizes from the profile of a slave that it would like to communicate in one of the defined CTTs and automatically starts with exchange of the necessary information and cyclical data transfer.

For comparison, the data and parameter exchange with a standard slave is shown in Table 6.7. The left half of the illustration shows cyclical data exchange: In each AS-i message, 4 bits of data are sent from the master to the slave and 4 bits of data from the slave back to the master. In the worst case, the slave is contacted every 5 ms with a data telegram, so that the cycle time is maximum 5 ms.

The right half of the illustration shows the acyclic data exchange using the parameter call. Here again, 4 bits of parameter information are sent from the master to the slave. In the new Version 3.0 of the specification, however, the back transfer of 4 bits of parameter data from the slave to the master is also defined, so that these bits may be used for indicating, for example, simple diagnostics information.

**Table 6.7** Simple Transaction

Cyclic Data			Acyclic Data (Parameter)		
	Data Length	Cycle Time		Data Length	Transfer Rate
⇨ Binary output	4 bit	5 ms	⇨ Binary output	4 bit	25 Bd
⇦ Binary input	4 bit	5 ms	⇦ Binary input	4 bit	25 Bd

Since only one parameter telegram per AS-i cycle can be sent and, in the worst case, each slave has to be provided with parameter data, a minimum transfer rate of 25 baud (bits/s) in each direction results. Reference to a cycle time does not make sense here, since these data are not sent cyclically.

To exchange cyclical digital data, such as a measured and digitized temperature value, a counter state, a rotational speed set point, or a displacement or angle value, the master has been equipped with the *analog input data image* (AIDI) and the *analog output data image* (AODI), each having a capacity of 124 words (see Section 6.4.4).

For the acyclic data, which are typically diagnostic data, parameter data, or data that identify the slave in detail, the masters have a data channel that is constructed similar to the familiar parameter channel. It allows data packets with lengths up to 32 bytes to be exchanged with the slave.

In the meantime, five different possibilities for byte-by-byte data communication between the master and slave have been specified by AS-International. These are described in greater detail in the following. The data amounts shown in the illustrations are net data, and the cycle times, the maximum times that may occur in the worst case. The prerequisite for using these transaction types is having a master that supports them.

### CTT1

Combined transaction type 1 (CTT1) is intended for simple and complex sensors or actuators such as temperature, pressure or flow transmitters, displacement and angle measurement systems, scanners, speed-controlled motors, analog process valves, and displays with up to eight characters or similar field devices. The slave can only be operated in standard addressing mode. It is not possible to change the transfer direction for the cyclical data on the fly.

Whereas slaves having Profile S-7.3 can only receive or send cyclical data and setting of parameter is only possible using the 4-bit parameters (Table 6.8), Profile S-7.4 offers expanded possibilities for communication. Here, you can switch to the parameter channel to query the ID data and diagnostic data for the slave and exchange parameter data records (Table 6.9). The ID data contain among other things the vendor ID and the device ID in code. Furthermore, the operating mode of the slave (analog mode, transparent mode, 4-bit mode) is transmitted.

In analog mode, the available number range of -32768 (8000Hex) to 32767 (7FFFHex) is generally divided into five ranges (Figure 6.26 shows this using the example of a 4–20 mA signal):

1. Error range *wire break*. The measured value is invalid, and the overflow bit is set.
2. Underrange. The measured value is valid but has a greater measuring uncertainty because it is outside the nominal range.
3. Working range. The measured value is acquired at the specified accuracy.
4. Overrange. The measured value is valid but has a greater measuring uncertainty because it is outside the nominal range.
5. Error range *short circuit*. The measured value is invalid, and the overflow bit is set.

The exact limits of the nominal and over-/underflow ranges as well as the error ranges are defined in the vendor's data sheet. The default value, which is substituted in the receiver, for example, when communication is interrupted, is 7FFF<sub>Hex</sub>.

In transparent mode, 16 bits of data can be transmitted in any desired format. There is no over- or underflow state of the measured value, and the corresponding bit is not set. The default value, which is substituted in the receiver, for example, when communication is interrupted, is 0000<sub>Hex</sub>.

<sup>a</sup> selectable.<sup>b</sup> Cycle times apply as long as no acyclic data is being exchanged.

**FIGURE 6.26** Warning and working ranges of an analog sensor having a 4-20 mA signal.

In a 4-bit mode, the slave behaves like a standard slave, cyclically exchanging 4 bits of data in both directions. Here, the CTT1 is used only for identifying the slave, for detailed diagnostics, and to set parameter.

The worst-case times and data transfer rates shown in Tables 6.8 and 6.9 can be halved (resp. doubled) through optimal use of the possibilities of the AS-i, namely, when the slave sends back its response to the master call in the same message and does not allow an entire cycle to elapse.

It should be noted that switching between cyclical data communication and parameter communication can take a certain time (several 100 ms) and that during acyclic data exchange no cyclical data can be sent.

### CTT2

Combined transaction type 2 (CTT2) is intended for simple and complex field devices such as temperature regulators, displays with more than eight characters, speed-controlled motors with actual value feedback, analog process valves with position feedback, or similar field devices in which digital data need to be sent in both directions (Table 6.10). CTT2 can also serve as an alternative to a HART

<sup>a</sup> Cycle times apply as long as no acyclic data are being exchanged.

interface to a field device, albeit with some minor limitations. The slave can be operated in standard addressing mode but not in extended addressing mode. Data exchange is full duplex, that is, both binary data and digital input and output data can be sent at the same time. No special switching of the data transfer direction is required.

This transaction type allows use of *combi field devices*. This includes devices that have both binary and digital input and output capability. The binary inputs and outputs can be used, for example, for rapid display of an over- or underlimit violation, and the simultaneously available digital transmission of the precise measured value can be used for diagnostics and maintenance purposes.

The parameter channel can be used in this transaction type as well to transmit the ID data for the slave including vendor ID, product ID, and operating mode. Comprehensive diagnostics and parameter data records can also be exchanged. If acyclic digital data are exchanged, the cyclical digital data traffic is interrupted for the duration of the transmission, whereas the cyclical transmission of the binary data remains unaffected.

The data formats used are the same as for CTT1.

The worst-case times and data transfer rates shown in Table 6.10 can be halved (resp. doubled) through optimal use of the possibilities of the AS-i, namely, when the slave sends back its response to the master call in the same message and does not allow an entire cycle to elapse.

In order to handle the resulting variety of parameters, work is currently underway to incorporate AS-i into the FDT standard. This will result in an OEM neutral platform, which can be used to conveniently set parameters and process remote diagnostics and maintenance.

### CTT3

Combined transaction type 3 (CTT3) is intended for binary sensors, actuators, and field devices including keypads with signal light feedback, valve terminals, status indicator columns, and similar devices where binary data need to be transmitted in both directions. Simple analog sensors or actuators can also be operated using CTT3 if the resolution of 8 bits is sufficient. The slave is operated in extended addressing mode (Table 6.11).

Profile S-7.A.7 makes the output data bit *lost* due to the extended addressability available again. This is, however, at the expense of response time, which for this transaction type can be up to maximum 40 ms.

The worst-case times and data transfer rates shown in Table 6.11 can be halved respectively, doubled through optimal use of the possibilities of the AS-i, namely, when the slave sends back its response to the master call in the same message and does not allow an entire cycle to elapse.

If one were to equip an AS-i network with 62 slaves having Profile S-7.A.A, a total of 496 binary inputs and 496 binary outputs would be available, that is, nearly 1000 I/Os in all.

**TABLE 6.11** CTT3 for Keypads, Valve Terminals, and Similar Devices

		↳ Binary output	3 bit	10 Bd
		↳ Binary input	4 bit	13 Bd
2 byte ↳ Digital input or 4 byte	80 ms 160 ms			

**CTT4**

Combined transaction type 4 (CTT4) is intended for simple analog sensors such as temperature, pressure or flow transmitters, and similar devices in which digital data only need to be transmitted from the slave to the master. The slave is operated in extended addressing mode (Table 6.12).

This transmission type is an extension of CTT1.

**CTT5**

Combined transaction type 5 (CTT5) is optimized for fast data transmission. It can be used for fast sensors such as angle encoders, actuators, and field devices that are, for example, components in dynamic digital control loops. 8, 12, or 16 bits of data can be sent full duplex in 5 ms (Table 6.13). This is organized as follows using several slave addresses: The lowest address of 2, 3, or 4 successive addresses is the physical address of the slave. This slave uses the next higher addresses for widening its data channel. In this way, a digital value of up to 16-bit resolution can be sent in full in a single AS-i cycle. The *shadow addresses* may not of course be assigned to other slaves. The slave occupies 2, 3, or 4 standard addresses.

The output value is provided in the output data image (ODI) of the slave with the lowest address and the input value in the corresponding field of the AIDI. The fields of the *shadow slaves* remain empty.

In the case of slaves that use this transaction type, it must be noted that the mechanisms for automatic addressing do not work in the same way as for other slaves. It may therefore be necessary for the user to take other measures if he or she is using slaves with CTT5.

Communication with safe slaves is also part of CTT. Here, however, communication takes place not primarily between the master and the slave but rather between the slave and the safety monitor. This is covered in detail in Section 6.4 of this book.

**TABLE 6.13** CTT5 for Fast Analog Sensors, Actuators, and Field Devices

1 byte ↳ Digital input ...	5 ms			
2 byte				

In summary, there are now various complementary methods available for simply exchanging analog data, parameter data, ID data, and detailed diagnostic data over AS-i. The task of the product developer is to select the most appropriate procedure for the task at hand from among the variety of possibilities. For the user, this means new types of communication are available that are as simple to use as one has come to expect from AS-i. *Click and go* is now here for the analog world as well.

### 6.3.4 Device Addressing

The address of every AS-i slave must be set before it is connected to the network. An exception is the replacement of a defective slave in the network during operation (see *automatic addressing*). Addressing is not performed with DIP switches, which are commonly used in other fieldbus systems, but requires the use of an addressing device. The addressing device is connected to the addressing and diagnostics interface, reads the address and the profile of the slave, and enables writing of the target address into the EEPROM of the slave. In general, the addressing device has the approximate size of a multimeter and is battery powered, allowing addressing and diagnostics directly at the location of the slave.

For reasons of compatibility with older versions of the AS-i specifications, two different addressing methods are offered:

1. Standard slaves: with an address between 1 and 31
2. A/B slaves: share the address of a standard slave

For this reason, addresses 1A to 31A as well as 1B to 31B are provided. A/B slaves can be recognized by the ID code "A" (refer to Section 6.3.1.2).

An address can either be used by a standard slave, an A slave, a B slave, or an A and a B slave at the same time.

Every slave address is preset to 0 by the manufacturer. Before an AS-i slave can be connected to the AS-i network, it requires an address between 1A and 31B to enable data exchange with the master.

This address is stored in nonvolatile memory (EEPROM) in the slave. This is the reason why switches to set the address are not used on AS-i. The address can be sent by a master command or the addressing interface on the slave could be used. This interface should really be called *addressing and diagnostics interface*, because it can be used not only to write a new address into the slave but also to thoroughly test all available functions of the slave.

#### *Addressing Interfaces*

Due to the large number of very different slaves in the AS-i environment, multiple slave addressing alternatives are available (Figure 6.27):

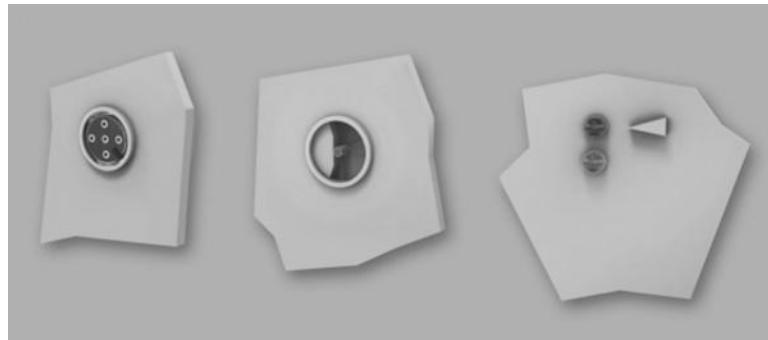

##### Alternative 1

Slaves with an M8 or M12 connection to the AS-i network can use this interface to connect to the addressing device and receive their target address. This alternative is usually used on compact IP67 devices designed for harsh environment application.

For addressing, the device has been designed to directly plug into the addressing device. During this process, the addressing device has to supply power to the slave.

##### Alternative 2

If the slave has a standardized addressing jack, it can be connected to the addressing device using a matching cable to receive its address. This alternative is most commonly used for slaves that are intended for enclosures applications. For IP67 modules, the addressing plug is located behind a cover that needs to be closed thoroughly after use. When connecting the cable to the addressing jack, the slave is separated from the network and connected to the addressing device through the internal contacts in the plug. The addressing device supplies power to the slave as well. The advantage of this alternative is that a slave, already installed and fully wired, does not have to be separated from the network and its peripheral devices.

**FIGURE 6.27** Standardized addressing interface.

### Alternative 3

Many slaves are equipped with an infrared interface that can be used for addressing. By employing an IR adapter that can be connected to the addressing device instead of the mechanical addressing plug, the connection to the slave can be established and the desired address can be programmed. This alternative is most commonly used on field devices for IP67 environments, since the protection class is not reduced.

Also, this alternative requires no separation between the device and its periphery. The slave recognizes the request to communicate via the IR interface through a special data sequence (*magic sequence*) and interrupts normal communications with the master. During the addressing process, the power for the slave is still supplied by the AS-i network. This can potentially be an advantage for devices with high-power requirements.

### Addressing Device

Depending on the device version, an addressing device offers the opportunity to test the connected slave, that is, to control the outputs and read the input information.

Network diagnostics devices are used to search for specific network errors (for instance, electrical connection problems or double addressing). When necessary, these devices can be used to determine the network status, to count and statistically evaluate telegram errors on the network, or to record data traffic in order to identify the causes of rare and sporadically occurring network interruptions.

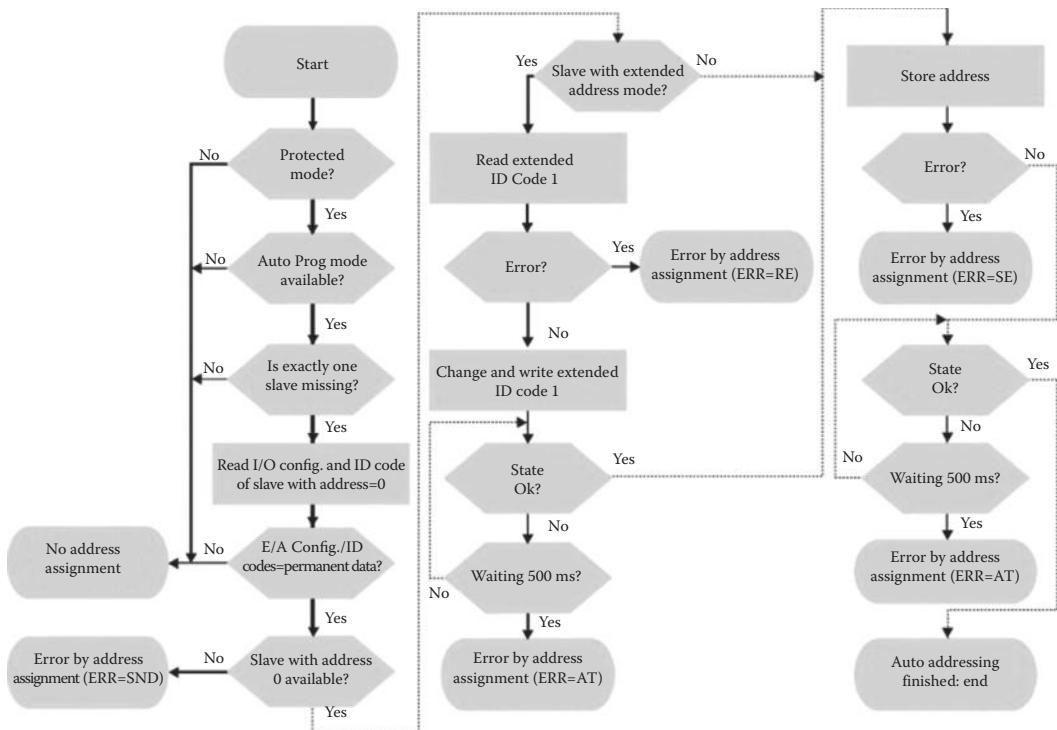

Some of the diagnostics characteristics mentioned here are already integrated into available masters. For instance, there are masters that permit addressing of individual slaves through the user interface or masters that, for the purpose of statistical evaluation record, collect and store telegram errors over longer periods of time.

### Automatic Addressing

Automatic addressing is an important feature of AS-i. It allows a failed sensor or actuator to be replaced without requiring a special procedure for assigning an address to the new one. This speeds up the repair process immeasurably.

If a slave fails (e.g., mechanical damage), it must be replaced by a slave of the same type whose address is set to zero. If exactly one slave has failed, the master can then automatically perform the necessary parameterization of the operating address. The prerequisite for automatic addressing is that the network is projected in the master and it therefore has information about the type and addresses of the correctly operating slaves in the network. Since reassigning of slave addresses is a critical procedure that could also result in errors, some restrictions need to be noted (Figure 6.28, Automatic addressing).

Automatic addressing is possible if in protected mode one projected slave is missing in the LAS and automatic addressing is enabled (Auto\_Prog set). This state is indicated by the Auto\_Prog\_Available flag.

**FIGURE 6.28** Automatic addressing.

If all the conditions are met, then when a slave with address zero is connected, the sequence control performs the “Change\_operating\_address” function to set the slave with address zero to the address of the previously failed slave. Of course, the new slave must be of the same type as the old one (I/O configuration and ID codes correspond to the projected configuration data).

### 6.3.5 Device Coupling to Sensors/Actuators

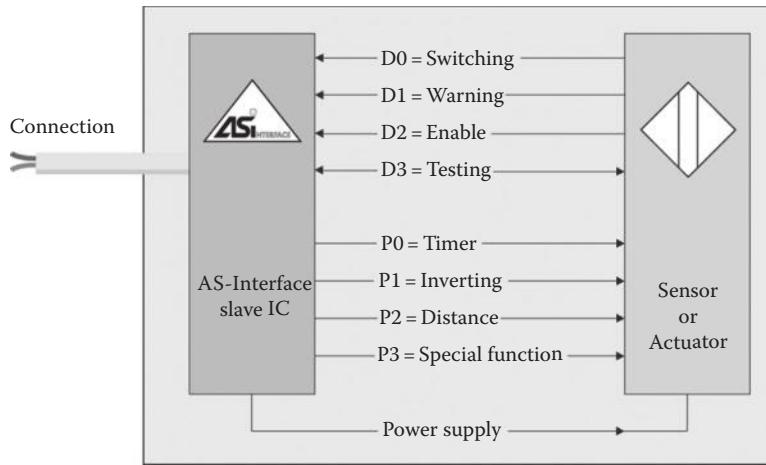

During each cycle, 4 data bits are sent back and forth between each slave and the master. Corresponding to these are the voltage levels on the ports of the AS-i slave IC. These ports can be configured for each IC individually as inputs or outputs or as bidirectional ports. The configuration of the ports is specified as *I/O configuration* when the IC is installed in the slave. This means the same AS-i slave IC can control both sensors and actuators.

The use of AS-i can also be expanded to include peripheral elements having more than 4 bits of information, analog devices, or decentralized intelligent devices with low information exchange needs for control. In bidirectional mode, a slave can receive 4 bits of output data per request and send back 4 bits of input data. Multibit transmissions can be realized by distributing the information over multiple cycles. AS-i can thereby be used for all simple sensors and actuators while not being limited to binary peripherals.

There is also a *write parameter* request, which sends 4 bits as parameter values to the slave. This can be used to control special functions of the slave, such as changing the switching sensing distance for optical sensors or a filter function. Parameter requests are acyclical, meaning only one slave can get new parameter values in each AS-i cycle.

#### Integrated Sensors and Actuators

The AS-i slave IC can be integrated directly into sensors and actuators. This results in a sensor or actuator with *integrated AS-i* (Figure 6.29). All the data and parameter bits are available to this device.

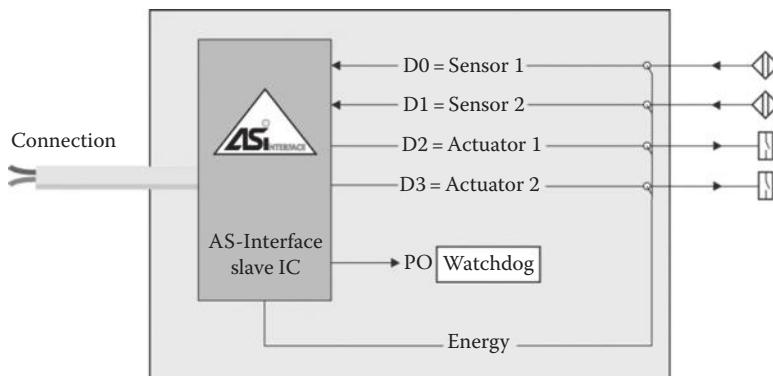

**FIGURE 6.29** Sensor or actuator with integrated AS-i.

The communications structure—the AS-i network—is then used not only for transmitting a binary switching bit but also for additional information. Thus, a gradual failure (e.g., contamination of an optical sensor), a spontaneous failure (e.g., a short circuit), an overload on the power supply, and similar cases are reported to the controller and protected against over AS-i. This allows user systems to be constructed in which certain error types cause immediate shutoff in order to save tools and machinery and to prevent longer downtimes. Other error types can generate a maintenance request for preventing any downtime at all (e.g., contamination indicator) or to provide targeted diagnostics to help reduce the downtimes.

From this perspective, the use of *intelligent* peripheral components is especially effective for the user. Only these will allow a diagnosis that includes the sensor or actuator.

#### *Connection by Module Technology*

The AS-i IC can be integrated into a module so that conventional sensors and actuators can also be connected to it: *sensor or actuator with external AS-i* (see Figure 6.30). Most of the sensors and actuators currently available on the market can be easily connected to any AS-i network through modules. These modules provide power and data on the device side through sockets or terminals. Shown is a 2I/2O module to which 2 binary sensors and 2 binary actuators are connected. An optional watchdog can be activated and deactivated using Parameter 0. It monitors the communication and disconnects the actuators from power when there is a communication failure.

**FIGURE 6.30** Module for coupling sensors and actuators without their own slave IC to the AS-i network.

### 6.3.6 Structure of the AS-Interface Slave

As shown in Figure 6.31, the AS-i slave represents the link between the AS-i transmission system and Interface 1, to which the sensors and actuators are connected. The slave powers the sensors/actuators and handles communication between them and the master. It was clear from the very beginning of the development that the slave, if it was to be integrated directly into the sensor or actuator, needed to be small and compact as well as extremely inexpensive. This can be achieved only through the use of a highly integrated circuit, which will be described at the end of this section.

Regardless of whether the slave is implemented using the integrated circuit or some other way, it will have the structure shown in Figure 6.31 and will have the following connections, whereby the connections for Interface 1 may be physical or logical, and those for Interface 2 must be physically present.

In the supply voltage, the data path is separated from the power path by an inductance. In order to implement it in an IC, this inductance is realized electronically. The supply voltage provides the power for the sensor or actuator on the  $V_{out}$  terminal and ensures that the slave remains of sufficiently high resistance in the frequency band of data communication.

In the receiver, the voltage pulses detected on the AS-i cable are filtered, digitized, and written to the receive register. At the same time, the received signal is subjected to various plausibility checks to ensure that no noise pulses have corrupted the master request. Since the signal amplitude can fluctuate over a fairly wide range, the receiver has adaptive response to the trigger level to improve receiving integrity.

In the sender, the information from the send register is encoded and sent out over the AS-i cable as a current pulse sequence according to the modulation procedure described in Section 6.2.2.3. For security reasons, the sender is monitored by *jabber inhibit* logic, which prevents continuous sending and therefore blocking of the AS-i network by a defective slave.

The sequence controller finally decodes the master requests, checks them for errors, carries out the commands encoded in them, and, if appropriate, causes a reply to be sent. The sequence controller

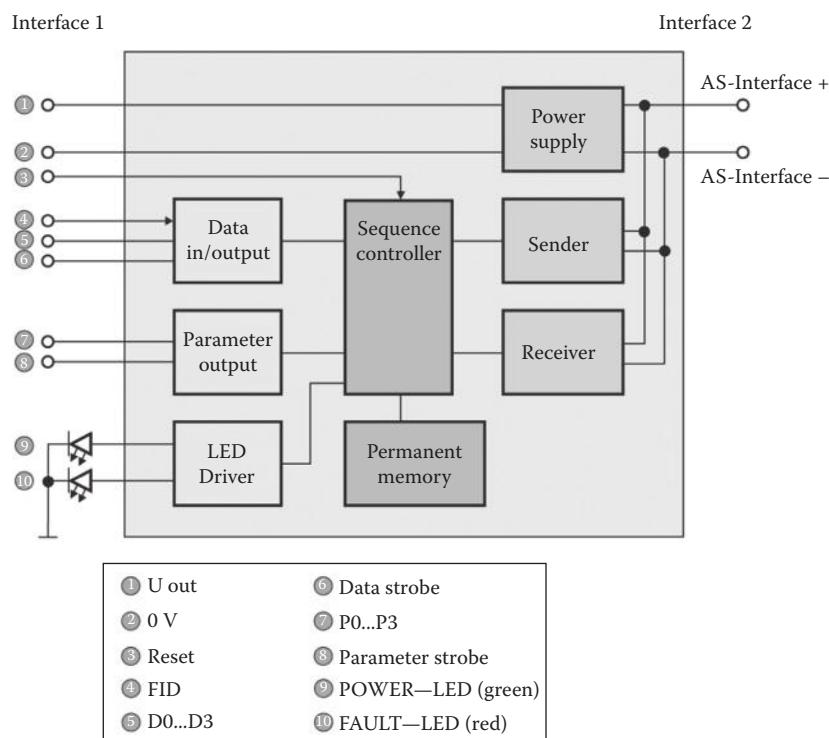

FIGURE 6.31 AS-i Slave block diagram.

also has a memory that is used for recording the slave address and that can store it for an unlimited time without power (nonvolatile).

#### *Address Register*

This 5-bit-wide register contains the current slave address. If the address sent in a master request agrees with the address contained in this register, then this slave will reply. After a *reset*, the register is loaded with the address contained in the nonvolatile memory. Its contents can be changed by the master using the commands *delete address* or *address assignment*.

#### *Identification Register*

These 4-bit-wide registers contain the I/O configuration shown in Table 6.6 and the ID codes of the slaves. They are permanently stored and are loaded from the nonvolatile memory after a *reset*. They are (with the exception of ID Code 1) fixed at the time the slave is manufactured and cannot be modified.

#### *Data Output Register*

The *data output* register is 4 bits wide and contains the data from the last *data request*, which was received without error by the slave. Those bits that are allocated to an output in accordance with the I/O configuration are output on the respective data port, and the information from the other bits is ignored. After a *reset*, the register is loaded with the default value FHex.

#### *Parameter Output Register*

This 4-bit-wide register contains the parameters from the last *write parameter* request from the master that was received without error by the slave. The bits are output on the corresponding parameter ports.

#### *Receive Register*

The 12-bit-wide receive register contains the last message sent by the master for further processing in the sequence controller.

#### *Send Register*

The 5-bit-wide send register is loaded by the sequence controller with the slave response to be sent.

#### *Status Register*

The status register contains three flags for indicating certain status conditions or errors:

1. Flag S0 is set during address storage if the new address has not yet been permanently stored.
2. Flag S1 is set if the input FID reports a peripheral error.
3. Flag S3 is set if an error has occurred while reading the address from the permanent memory.

The status register can be evaluated by the master for the purpose of analyzing error status conditions.

#### *Synchronization Flag*

If the slave has correctly received a master request, decoded it, and, if appropriate, acknowledged with a reply, the *synchronization* flag is set. In synchronized state, the master pause is monitored after the master request for only one bit time so that the slave response can start after 2 bit times.

#### *Data Exchange Blocked Flag*

This flag is set by a *reset* and is reset by errorless receipt of the first parameter request to its own slave address. This prevents data requests from being accepted as long as the parameter ports have not been loaded with the nominal parameters.

This behavior is necessary for preventing *misunderstandings* between the master and slave. It could happen, for example, that due to poor electrical contact on the AS-i cable, a slave—without the master knowing it—receives no supply voltage for a brief time and performs a *reset*. Then the parameter ports are reset and any associated functions of the slave are set to the default state. As a consequence, the slave could respond differently than the master expects.

### 6.3.7 Device Interface and Diagnostics

As already indicated by Figure 6.31, Interface 1 of the slave has four data ports, which, depending on the selected I/O configuration, can be used either as input ports, as output ports, or for bidirectional communication. A data strobe output is also provided, which signals when output data are present and when input data are expected.

For actuator slaves, it is recommended that the time-out monitor, also called a watchdog and that is integrated in the slave IC, be activated. If, while a timing member is running, no new correctly received *data request* arrives at the address of the slave, the actuator can use the watchdog to place the system in a safe state. Such time-out monitoring allows a variety of error possibilities to be covered, such as hardware faults in the master, interference on the transmission cable, or loss of the address in a slave. Where necessary, an AS-i system can thus be made more secure. A time of 40–100 ms is specified as the time-out period.

In addition to the data ports, which are provided for cyclical data exchange with the master, additional ports are available, which are used for (acyclic) parameter output. Here again, an additional strobe output indicates when a new parameter message has arrived.

The FID input is used to signal peripheral errors. If the slave electronics detect an error (such as an overloaded supply voltage caused by an external short), this input can be used to display the event locally (the red error LED on the slave flashes) and to report it to the master using the status register. The master makes an entry in the list of peripheral errors and sets a collective flag. It is the job of the error handling routines in the master or host system to recognize this situation and take appropriate measures (such as reactivating the slave or reporting the error to the operator). In the case of serious errors, the reset input on the slave IC can also be activated. This will, however, generate a network configuration error.

Finally, a DC voltage is provided to the connected sensor or actuator on the  $V_{out}$  port, which generally lies within the tolerance range of 24 V + 10%/-15%.

The new uniform status display on the AS-i slaves (Figure 6.32) supports rapid fault analysis and thus minimizes error times.

Symptom	Possible Reason	Flags in the Master		Indication at the Slave	Indication at the Slave
		Config. error	Periph. fault		
Normal operation	Everything Ok?	Reset	Reset	● ○	● ○
No data exchanges	Master in STOP Mode Slave not in LPS Slave with wrong IO/ID Reset am Slave aktiv	Set	Reset	○ ○	○ ○
No data exchanges because Address = 0	Slave address = 0	Set	Reset	○ ○	○ ○
Peripheral fault	To be defined by the manufacturer	Reset	Set	○ ○	○ ○
Serious peripheral error with reset	To be defined by the manufacturer	Set	Undefined	○ ○	○ ○

FIGURE 6.32 Status display on the slave.

## 6.4 AS-Interface Master: Coupling to Other Automation Systems

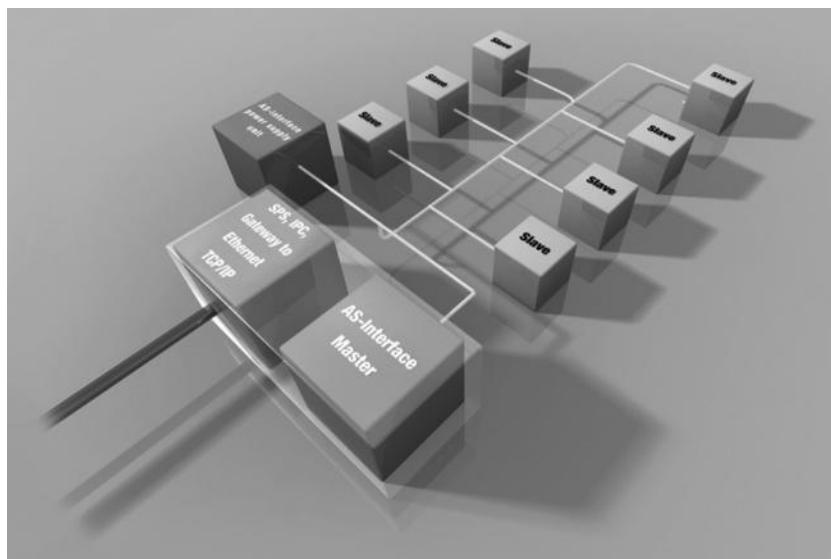

The AS-i master establishes the connection between the network and the higher-level control system (Figure 6.33). It independently manages the data traffic on the AS-i cable. Special expertise about baud rates and extensive files with the description of the specific characteristics of the bus devices are not necessary for start-up. Due to the specific design of the AS-i master, the network is mostly self-managed. Additionally, the AS-i master supports *live insertion* of new slaves during operation and allows the exchange of defective slaves during operation (*hot swap*) by using automatic address assignment (see Section 6.3.1.4).

### 6.4.1 Function Sequence in the Master

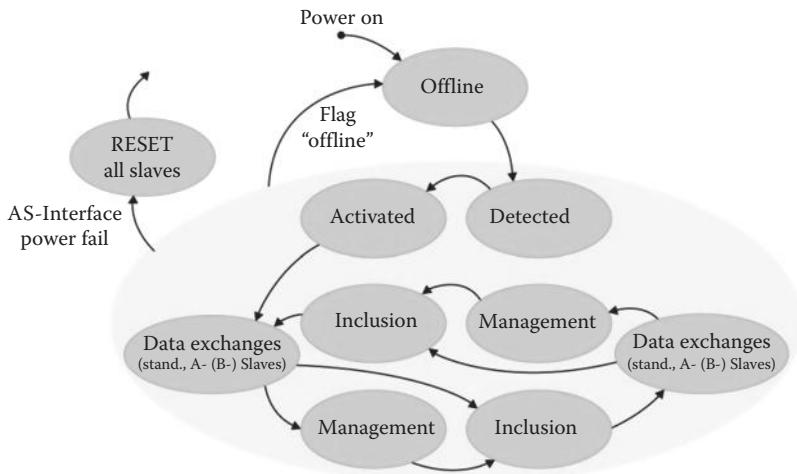

In normal operation, after conclusion of the detection and activation phase (which is described in greater detail in Section 6.2.4.6), cyclical communication takes place between the master and all connected slaves. Such a cycle consists of the data exchange phase, the (optional) management phase, and the inclusion phase. The two data exchange phases illustrated in Figure 6.34 differ from each other, only when A and B slaves exist in the network at one address. In the data exchange phase, the master queries all activated slaves one after the other with a data call; the states from the ODI are sent to the slave and the input signals that are contained in the slave response are stored in the IDI. If the transmission level reports an error, the call is repeated in up to three successive cycles. If the third attempt also fails, it is assumed that the corresponding slave is absent or defective. The slave is then removed from all master lists and the IDI is set to zero. This error handling spread out over several cycles is necessary because given these short telegrams a noise burst with extremely high amplitude can interfere with several cycles.

The repetition of the calls also ensures reliable operation under these conditions. Individual noise pulses or interference such as is typically encountered in industrial environments are caught by the immediate repetition already on the transmission level without having a noticeable effect on the time response.

After the data exchange phase is finished, one can transition, if needed, to the management phase. In the management phase, *acyclic* telegrams are sent. Exactly one master call can be performed per cycle.

**FIGURE 6.33** The AS-i master provides the device data to the control unit.

**FIGURE 6.34** Main status diagram (simplified) of the master.

With the data necessary for carrying out the functions of the sequence control level (e.g., setting parameters or changing an operating address) can be sent, in part distributed over several cycles. If there is no job, the cycle moves on to the inclusion phase and no telegram is sent.

The following jobs can be executed during the management phase:

- Setting parameter values
- Reading a slave status
- Reading the I/O configuration
- Reading the three ID codes
- Writing the extended ID Code 1
- Resetting the operating address of a slave to 0
- Assigning a new operating address to Slave 0
- Resetting a slave
- Carrying out a broadcast

After the management phase is finished, the inclusion phase is entered, in which at the end of each cycle, newly arriving stations are searched for. During each inclusion phase, a search is made for exactly one slave using the *read status* call. This call is performed from the transmission level without repetition in case of error, since a transmission error at this point is not time critical. The peripheral error information of the slaves is collected for activated slaves in the inclusion phase. This has the advantage that no lengthening of the cycle is required. On the other hand, the querying of all peripheral error information takes several cycles. Already activated slaves also get the *read ID code* call, so that any passive devices connected later in the network (e.g., diagnostic devices) can identify the slaves.

If a slave that is already activated replies, or if there is no slave reply, the next slave is searched for in the next activation phase. If a slave that was previously unknown replies, the complete identification of the slave is determined in the next inclusion phases. Then in the following inclusion phase, the slave is activated depending on the selected operating mode. Activation is accomplished by writing the parameters from the parameter field.

An inclusion or reinclusion of a slave therefore extends over several inclusion phases. The procedure, which here is divided over several cycles with one telegram per cycle, is the same as that used to search for and activate slaves in start-up mode.

If you were to view the sequence of an AS-i cycle described here with an oscilloscope connected to the AS-i line, the screen would look as illustrated in Figure 6.35.

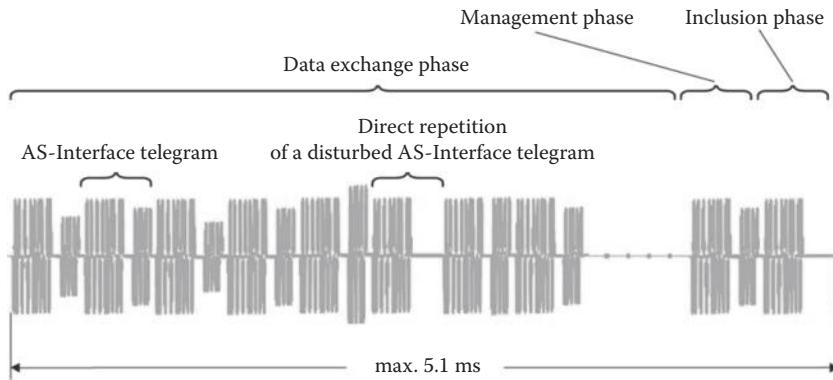

FIGURE 6.35 AS-i cycle.

#### 6.4.2 Master Levels

The specification divides the master into three layers, which describe the master from the AS-i cable to the host interface (e.g., to the PLC) (Figure 6.36).

An important task of all the layers is the handling of errors, or *not normal* operating states, without sending false sensor or actuator signals.

Such states could include, for example, the following:

- Errors in pauses
- Errors in slave responses
- A failed slave
- A slave connected during operation
- An unexpected slave connected

The transmission physics of the master basically has to meet the same requirements as that of a slave. Here is where the actual bit transmission takes place.

The lowest logical layer is the transmission layer, which is responsible for transmitting and receiving individual telegrams. Automatic repetition of telegrams when a slave reply is missing or defective ensures integrity for the higher layers.

The sequence control is just above the transmission layer and passes requests for data transmission to the latter. The sequence control controls the sequence of telegrams. In addition to the actual sequence

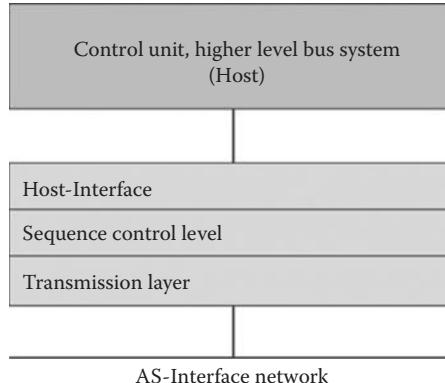

FIGURE 6.36 Logical structure of the AS-i master.

control, the sequence control layer processes functions that are requested by the host through the master layer. The highest layer is the master layer, in which the AS-i functions are adapted to the respective host system. This layer is where profiles are formed, which allow a restriction of the master functions usable by the host.

### 6.4.3 Master Calls

Table 6.14 summarizes the stipulated AS-i master calls to a standard slave. The following section describes them and the response of the slave in detail.

#### *Read I/O Configuration*

The call *read I/O configuration* allows the master to read the set I/O configuration of a slave. This is sent in the slave response to this call and is used together with the calls *read ID code* for unambiguous identification of a slave. The I/O configuration refers to the data ports on Interface 1 of the slave and is defined as shown in Table 6.6. Here, *in* means a process input, *out* a process output, *I/O* a bidirectional behavior of the port, and *tri* a tristate output with no function. The latter state is assumed if during the reset no unambiguous I/O configuration can be determined from the slave's own data memory due to a read error.

Wherever an output *out* (and no bidirectional behavior) is defined, this means that the corresponding information bit is undefined in the slave response. Likewise, the information bit from the master call remains without meaning, even though it is sent, where an input *in* is defined. Unneeded information can thus be hidden with this I/O configuration. At the same time, the I/O configuration together with the ID codes for identifying slaves is employed. These refer to the slave profile. The I/O configuration is 4 bits long, is determined by the manufacturer, and is stored in the slave, where it cannot be changed.

**TABLE 6.14** Overview of the Master Calls to a Standard Slave

	ST	CB	5-Bit Address						5-Bit Information				PB	EB
Data request	0	0	A4	A3	A2	A1	A0	0	D3	D2	D1	D0	PB	1
Parameter request	0	0	A4	A3	A2	A1	A0	1	D3	D2	D1	D0	PB	1
Address assignment	0	0	0	0	0	0	0	1	1	1	1	1	PB	1
Command request: write extended ID Code 1	0	1	0	0	0	0	0	0	D3	D2	D1	D0	PB	1
Command request: delete address	0	1	A4	A3	A2	A1	A0	0	0	0	0	0	PB	1
Command request: reset slave	0	1	A4	A3	A2	A1	A0	1	1	1	0	0	PB	1
Command request: read I/O configuration	0	1	A4	A3	A2	A1	A0	1	0	0	0	0	PB	1
Command request: read id code	0	1	A4	A3	A2	A1	A0	1	0	0	0	1	PB	1
Command request: read extended ID Code 1	0	1	A4	A3	A2	A1	A0	1	0	0	1	0	PB	1
Command request: read extended ID Code 2	0	1	A4	A3	A2	A1	A0	1	0	0	1	1	PB	1
Command request: read status	0	1	A4	A3	A2	A1	A0	1	1	1	1	0	PB	1
Broadcast (reset)	0	1	1	1	1	1	1	1	0	1	0	1	PB	1

#### Read ID Code

The command calls *read ID code* apply to the identification code of the slave. This together with the I/O configuration is used for unique identification of a slave.

#### Data Call

The master call *data call (data exchange; see [1])* is the most important and frequently used AS-i call. It is used to cyclically send the bit pattern for the data outputs on Interface 1 of the slave accessed by address and then to read the input level and send it back in the slave response.

The data ports can be used in various ways: as outputs to the process, which can be set and cleared by the call, and/or as inputs from the process whose state, initiated by the call, is read in. Determinant here is the slave profile, which is defined by the I/O configuration and the ID codes.

If the data ports are configured as outputs, the last sent value is stored in the slave until it is overwritten by a new value or reset by a reset. Slaves can also be equipped with a watchdog function that resets the outputs when communication with the master is interrupted for longer than 40 ms. After a reset, such as would be caused by turning on the supply voltage, the slave does not send replies to the data call until it has first received a valid parameter call.

A data call to address 00Hex is not possible, as this would be interpreted by the slave as an addressing call.

#### Parameter Call

The master call *parameter call* is used to send the bit pattern acyclic for the parameter outputs on Interface 1 and then to read the input levels and send them back in the slave response. This parameter port can be used to remotely control certain functions in the slave, such as activating a time function, changing the switching distance of the sensor, or, in the case of a multisensor system, changing from one measuring process to a different one. The last sent value is stored in the slave until it is overwritten by a new value or reset by a reset. Reading the information in on the parameter ports can be used to send simple diagnostics information.

After a reset, the parameter ports are set to a defined state. They are set only after a *parameter call* has been received without error. Only then are *data call* messages properly exchanged.

A standard slave has 4 bits of parameter data available or 3 bits for a slave in extended addressing mode. A parameter call to address 00Hex is not possible, as this would be interpreted by the slave as an addressing call.

#### Addressing Call

This command allows the master to permanently set the address of the slave that previously had address 00Hex to a new value.

The slave first acknowledges errorless receipt of the command with the reply 6Hex and can then be accessed under the new address. At the same time, the slave starts internally storing the new address in a nonvolatile memory. This procedure can take up to 500 ms and may not be interrupted by a power interruption or a reset command.

The addressing unit uses this call to give the slave a new address over the AS-i line. The master can also use this call to assist in replacement of defective slaves.

#### Reset Slave

The command *reset AS-i-slave* can be used to reset a slave to its base state. It has the same effect as does the reset after applying power or the reset on the reset input of Interface 1. The slave acknowledges errorless receipt of this command with the reply 6Hex. The reset procedure may take a maximum of 2 ms.

#### Clear Operating Address

The command *clear operating address* is used for temporary deleting of the slave operating address and is needed in connection with the address assignment, since the *addressing call* can only be carried out

**TABLE 6.15** Flags of the Slave's Status Register

Flag	Meaning
S0 <i>Address volatile</i>	This flag is set when the internal slave routine for permanent storing of the slave address is running.
S1 <i>Peripheral error</i>	This flag is set when the slave has detected an error in its peripheral. This may indicate, for example, an overload of the sensor supply voltage.
S3 <i>Nonvolatile memory read error</i>	This flag is set when an error occurs during a reset while reading the nonvolatile memory.

by a slave having operating address 00Hex. If, for example, a slave that used to have address 15Hex needs to be reprogrammed to the new address 09Hex, this can only be done using the following command sequence: *clear operating address* and *addressing call* (09Hex).

The slave acknowledges errorless receipt of *clear operating address* with the reply 0Hex and is then accessible under the new address 00Hex. Clearing the operating addressing by means of this command is not permanent; if after executing this command you need to reload the originally nonvolatile stored address, you can do this using the *reset AS-i-slave* command.

#### *Read Status*

The command call *read status* can be used to read out the status register of the contacted slave. Its contents are sent in the slave response to this call. The slave's status register contains three flags (Table 6.15) having the following meanings:

Flag S2 is not yet used and is reserved for future expansions. Simultaneous with the reply to the call, an address comparison is performed by querying the nonvolatile memory. If the address in the address register is not equal to that in the nonvolatile memory, Flag S0 is set. The information from the status register can be used by the master for diagnostic purposes. Version 2.0 slaves do not support the *peripheral error* flag. When the master is communicating with a slave having extended ID Code 2 = FHex, it does not evaluate Flag S1.

#### *Broadcast*

Command calls containing 15Hex are defined as *broadcast calls*. They may not be replied to by the slaves. To this extent, they are untypical for normal AS-i data exchange. At the present time, only the broadcast command *reset* is defined. Additional broadcast commands will be implemented in future versions of the specification. Version 2.0 slaves do not support the broadcast function.

Table 6.16 provides an overview of the master calls. This applies to a slave with extended addressing mode:

From Table 6.16, it can be seen that an information bit is used in numerous calls as a *select bit* for distinguishing between the A slave and the B slave. The definition of the select bit is selected such that the A slave behaves just like the standard slave. This enables you to operate *new* slaves in AS-i networks even when they are connected to *old* masters.

### 6.4.4 Data Fields and Lists on the Sequence Control

The sequence control takes care of initializing, starting, and normal data exchange on the network. The interface to the master level—the interface to the host—consists of several functions that pass along the actual user data, control, and configure the system. The sequence control stores the data required for this in several data fields and Table 6.17 provides an overview of these data.

The data can be categorized into four groups:

1. The user data are information that is exchanged directly with the slaves.
2. The configuration data provide information about the status of the slaves. This makes possible detailed diagnostics of the network.

**TABLE 6.16** Overview of the Master Calls to a Slave with Extended Addressing Mode

	ST	CB	5-Bit Address					5-Bit Information				PB	EB	
Data request	0	0	A4	A3	A2	A1	A0	0	<i>Sel</i>	D2	D1	D0	PB	1
Parameter request	0	0	A4	A3	A2	A1	A0	1	<i>Sel</i>	D2	D1	D0	PB	1
Address assignment	0	0	0	0	0	0	0	A4	A3	A2	A1	A0	PB	1
Command request: write extended ID Code 1	0	1	0	0	0	0	0	0	D3	D2	D1	D0	PB	1
Command request: reset slave	0	1	A4	A3	A2	A1	A0	0	<i>Sel</i>	0	0	0	PB	1
Command request: reset slave	0	1	A4	A3	A2	A1	A0	0	<i>Sel</i>	1	0	0	PB	1
Command request: read I/O configuration	0	1	A4	A3	A2	A1	A0	0	<i>Sel</i>	0	0	0	PB	1
Command request: read ID code	0	1	A4	A3	A2	A1	A0	0	<i>Sel</i>	0	0	1	PB	1
Command request: read extended ID Code 1	0	1	A4	A3	A2	A1	A0	0	<i>Sel</i>	0	1	0	PB	1
Command request: read extended ID Code 2	0	1	A4	A3	A2	A1	A0	1	<i>Sel</i>	0	1	1	PB	1
Command request: read status	0	1	A4	A3	A2	A1	A0	1	<i>Sel</i>	1	1	0	PB	1
Broadcast (reset)	0	1	1	1	1	1	1	1	0	1	0	1	PB	1

3. The projecting data are stored in nonvolatile memory in the master and represent the nominal configuration of the connected network. By comparing the nominal and actual configuration, the master can determine whether there are errors, report them, and, if appropriate, clear them by means of automatic addressing.
4. The flags inform the host (PLC, PC, etc.) about the status of the master and are used to influence it:
  - a. Config\_OK: Nominal and actual configuration are in agreement. The Config\_OK flag enables simple monitoring of the configuration.
  - b. LES.0: Slave with address 0 is present.
  - c. Auto\_Prog: Automatic addressing is enabled.
  - d. Auto\_Prog\_Available: Automatic addressing is possible.
  - e. Projecting\_active: Projecting mode.
  - f. Normal\_mode\_active: Set in cyclical normal mode.
  - g. NOT APO: Low voltage was detected.
  - h. Offline\_Ready: Offline phase is active and function requests to the sequence control are being processed.
  - i. Periphery OK: No slave is reporting a periphery error.

The flags on the master layer are set by the master layer or by the host and affect the function of the master:

- Data\_exchange\_Active: Enables data exchange between the master and the slaves
- The offline flag: Switches the sequence control to offline phase
- Auto\_Address\_Enable: Enables automatic addressing

#### 6.4.5 Master Analog Part

The transmission physics of the master describes the electrical coupling to the cable, the analog section of the hardware structure (Figure 6.37). Implementation of this interface has key significance

**TABLE 6.17** Data Fields and Lists on the Sequence Control

		Feldgröße
Input data image (IDI)	This array contains the latest actual copies of the received data of all received slaves. Input data of inactive slaves is set to zero (0).	$62 \times 4 \text{ bit} = 31 \text{ byte}$
Analog input data image (AIDI)	This array contains the received analog data of the analog inputs from the slaves with profiles 7.3 or 7.4.	$31 \times 4 \times 3 \text{ byte} = 372 \text{ byte}$
Output data image (ODI)	This array contains the data to be transmitted to the active slaves at the next data exchange.	$62 \times 4 \text{ bit} = 31 \text{ byte}$
Analog output data image (AODI)	This array contains the analog data to be transmitted to the outputs of the active slaves with profiles 7.3 or 7.4 at the next data exchange.	$31 \times 4 \times 3 \text{ byte} = 372 \text{ byte}$
Configuration data image (CDI)	This array contains the input/output configuration and the ID codes (ID, ID1, ID2) of all slaves. The data of inactive slaves are set to the default value 1.	$62 \times 4 \times 4 \text{ bit} = 124 \text{ byte}$
Permanent configuration data (PCD)	This array contains the projected I/O configurations and ID codes (ID, ID1, ID2) data of all slaves. The data of not projected slaves are set to the default value 1.  The data are stored in nonvolatile memory.	$62 \times 4 \times 4 \text{ bit} = 124 \text{ byte}$
Parameter image (PI)	This array contains the parameter data that have been sent to parameter outputs of all active slaves. The data of inactive slaves are set to the default value FHex.	$62 \times 4 \text{ bit} = 31 \text{ byte}$
Permanent parameter (PP)	This array contains the configured parameter data of all slaves. The data are stored in nonvolatile memory, after master power on the data is stored in the array of PI by the sequence control level.	$62 \times 4 \text{ bit} = 31 \text{ byte}$
List of detected slaves (LDS)	In this list, one bit is set for each detected slave.	63 bit = 8 byte
List of activated slaves (LAS)	In this list, one bit is set for each active slave.	62 bit = 8 byte
List of projected slaves (LPS)	This list contains all projected slaves that are expected to be in the AS-i network. This list is stored in nonvolatile memory.	62 bit = 8 byte
List of peripheral faults (LPF)	In this list, one bit is set for each slave sending a peripheral fault.	63 bit = 8 byte

for the noise immunity of the system. To prevent excessive signal distortion, the impedance between the interface terminals must, as in the case of the slave, meet certain requirements. Like the slaves, the master is not allowed to disturb the symmetry of the network, since the cable would otherwise become an antenna for radiating noise. The difference in the terminal impedances to GND must therefore be kept as small as possible. In addition, galvanic isolation between the controller and the AS-i network is mandatory.

A comparator checks the DC voltage on the line and uses the APO signal to report when the voltage is sufficient for reliable operation of the slaves at every location along the line.

#### 6.4.6 Master Host Interface: Master Profile

The host interfaces can be designed to be as versatile as the user interfaces. This is due to fact that an AS-i master—as described earlier—can be part of a simple PLC as well as part of a gateway to a higher-level complex fieldbus. The information in the data fields described earlier can be exchanged with the higher-level control system via this interface to the host system.

AS-i gateways are available for all commonly used higher-level fieldbus systems. As mentioned earlier, AS-i is an excellent addition for these systems since it enables the economical collection and

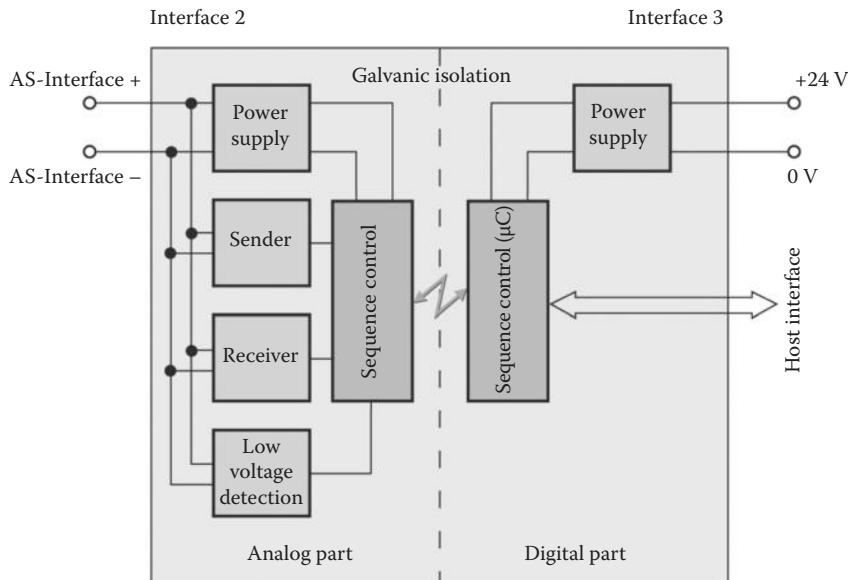

FIGURE 6.37 Hardware structure of the AS-i master.

combination of frequently widely scattered inputs and outputs on a machine or in a plant. Figure 6.38 shows the electronic data sheet (GSD file) of a PROFIBUS/AS-i gateway. The input data field of 152 byte maximum length holds the entire IDI and about half of the AIDI. The ODI and AODI fit similarly. Additionally, 68 bytes are provided for diagnostics.

Due to the fact that AS-i underwent numerous innovations and functional enhancements since its introduction, different master profiles exist that support a variety of different functions. Table 6.18 shows the most current status:

#### Coupling to Fieldbus Systems

Due to its functionality, AS-i is located directly at the technological process. If you want to make the sensor and actuator data available to the higher levels of the automation hierarchy as well, consistent networking structures are necessary. In the simplest case, this is done by coupling to the PLC in which the master is located. For virtually every commonly available PLC, there are interface modules available for fieldbus systems such as PROFIBUS, InterBus, and DeviceNet. The application program in the PLC is then responsible for providing the data on the fieldbus system, but there is no direct link between the AS-i and the fieldbus (Figure 6.39).

It therefore seemed obvious to provide the AS-i master itself with an interface to a fieldbus system, that is, to create a coupler between AS-i and a fieldbus system. The resulting networking structure (Figure 6.39) offers numerous advantages. The spatial separation of the networked components is increased by the network length of the fieldbus system. The simple cabling of the sensors and actuators using AS-i remains intact. The master interfaces (couplers) can be assigned to multiple PLCs, which make the automation process more flexible. Redundant solutions are then also possible.

The following sections describe a typical coupler between AS-i and a fieldbus, using PROFIBUS as the example. Typical network transitions take place on layers 2 and 3 of the ISO/OSI reference model. In the case of PROFIBUS, layers 1, 2, and 7 are defined, whose functionality differs in the variants DP and FMS. Above this is the application layer interface (ALI), which describes the link between the communication system and the application program. In the case of the AS-i master, such a strict association with the OSI layers is not possible. The sequence control takes over the functionality of multiple layers, with the master layer comparable to the ALI.

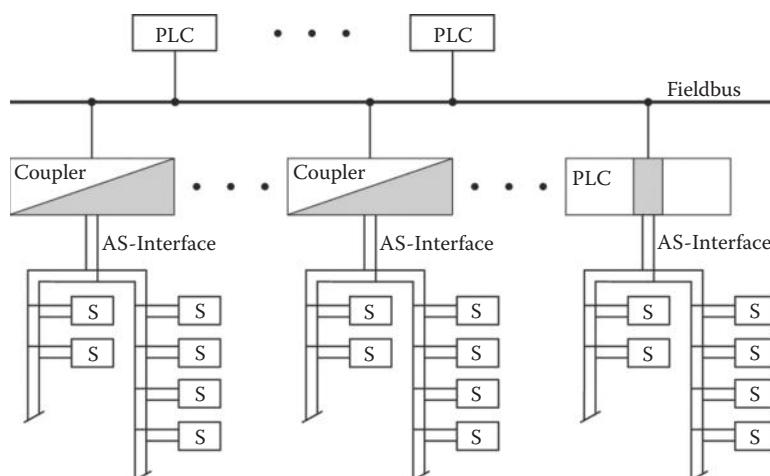

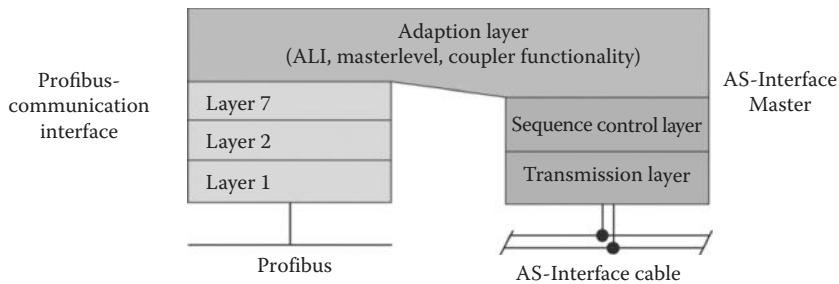

FIGURE 6.39 AS-i in the network.

**FIGURE 6.40** Structure of the AS-i/PROFIBUS coupler.

Based on the earlier text, the following structure of the coupler with three function units can be outlined (Figure 6.40):

1. The communications interface
2. The AS-i master
3. The adaption layer

For the PROFIBUS interface, a slave implementation is sufficient. The master contains the complete implementation of transmission control and sequence control.

For a PROFIBUS station, AS-i represents the application process. Likewise, from the point of view of an AS-i master, the PROFIBUS is the host control system with which it exchanges data through the master layer. As a result of the strongly differing system properties of AS-i and PROFIBUS, the coupler is preferably located at the application interface. Direct conversion of an AS-i message into a PROFIBUS message and the reverse is not possible. Rather, the logical approach is to combine the data from AS-i and send them in groups over the PROFIBUS. How this grouping is done and which actions are associated with it can be determined only on the application level.

The adaption layer combines the properties of the PROFIBUS ALI, the AS-i master layer, and a coupler process. It is responsible for the following tasks:

At the interface to layer 7, indicated PROFIBUS application services (reading and writing) must be mapped in communication-related operations to the AS-i interface to the sequence control and, if appropriate, a reply sent to layer 7. Likewise, the administration services such as opening and closing a connection have to be processed. In addition, the coupler must itself invoke several services of layer 7, for example, to initialize the PROFIBUS parameters. The way in which AS-i system information is grouped into PROFIBUS telegrams essentially determines the performance capability of the entire data transmission between the user and AS-i. If all the inputs and output data from the AS-i slaves were stored in separate PROFIBUS telegrams, 124 PROFIBUS telegrams would be necessary for a complete exchange of the data; the data throughput would thus drop to an unacceptable level.

By grouping the 4 input data bits for all AS-i slaves into a single telegram, the IDI (cf. Table 6.17) of AS-i can be sent over PROFIBUS in a single request-response sequence. But the AS-i user still does not know whether the data are valid or not. For this, the list of activated slaves (LAS) needs to be read. Reading of the input data and the LAS in two separate PROFIBUS telegrams runs the risk, however, that the state of an AS-i slave changes between the two requests. Consistent transmission is then only assured if input data and the LAS are sent in the same telegram. If in addition one assigns the readable flags of the AS-i master to this telegram, the user gets additional status information over AS-i each time the input data are read. He can then check the Config\_OK flag and does not have to take any additional measures to isolate the error unless the flag is not set. The analog data fields of the AS-i master (AIDI and AODI, Table 6.17) can be handled similarly.

Programmable logic controllers use a process map to cyclically exchange the user data with their environment. This procedure can be supported in PROFIBUS with the help of a cyclical connection

whereby the communication software automatically takes care of regular data exchange. For users who are not working cyclically (e.g., programming device, control station) and only occasionally access the AS-i data, an acyclical connection is recommended. Data exchange over a cyclical connection takes place in general faster than for an acyclical connection, since multiple procedures can be running concurrently. The AS-i PROFIBUS coupler allows both connection types for accessing the AS-i data.

By opening a connection, an AS-i user opens a channel over which it can then exchange data with the coupler. The user ends proper data exchange by closing the connection, such as when the PLC program is stopped. Connection opening and closing are essential prerequisites for reliable operation of the coupler. If there is no longer a connection between the coupler and the AS-i user, the master also no longer has any valid user data in the coupler that it could exchange with the slaves. It should therefore end the data exchange with the slaves and place them in the base state. Likewise, data exchange in the AS-i system should not be activated at the same time a single connection is opened through which any projecting of the AS-i master needs to take place. The specification for the coupler is, therefore, that data exchange in the AS-i system be activated when the first cyclical connection is opened and deactivated when the last cyclical connection is closed.

## 6.5 Functional Safety with AS-Interface Safety

---

In automation procedures affecting the safety of people through dangerous movements, the high basic data transmission reliability for standard input and output data for AS-i is not sufficient by itself. Therefore, additional measures, depending on the level of expected danger of the machine movement, and according to the guidelines for machines of the EU (guideline 2006/42/EG) and to the workplace safety guidelines of the member countries (general framework for regulations *safety and health protection for employees* 89/391/EWG), have to ensure that

- Along the entire transmission path, data cannot be falsified (including through errors in the master or slave electronics)
- Data are not delayed for an inadmissibly long time or get lost entirely
- Data are used from an incorrect source
- It is impossible to wrongly interpret data because of defective repetitions or mix-ups in the sequence

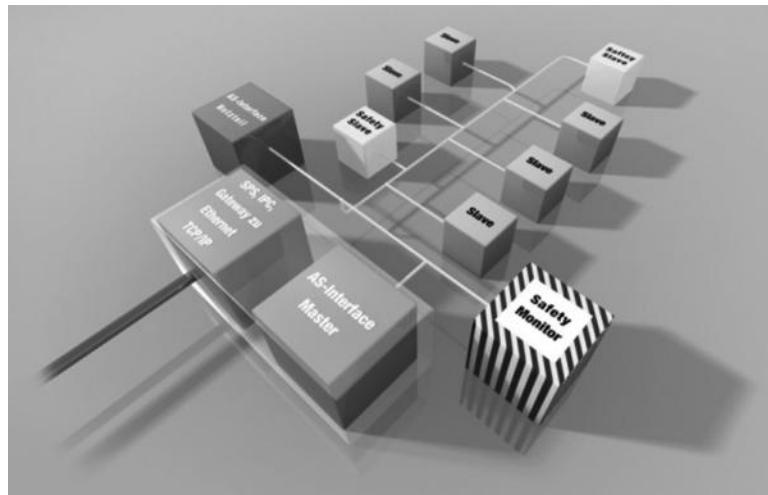

In order to fulfill these requirements, two additional components are added to AS-i:

1. The safe sensor or the safe actuator, respectively
2. The safety monitor

Like any standard AS-i slave, these components can be implemented at arbitrary positions on the network and can be combined with standard components without limitations or restrictions. However, the safe sensor and the safety monitor (as well as the safety monitor and the safe actuator) are in a special communication connection.

*AS-i Safety at Work* is approved for applications that require safety according to safety integrity level (SIL3) according to IEC(EN)61508 or performance level *e* according to EN ISO 134849-1:2006 (Figure 6.41). *AS-i Safety at Work* offers a guaranteed switch-off reaction time of under 40 ms, independent of the AS-i network configuration. As a result, the switch-off reaction time does not have to be evaluated after changes or expansions of the network.

TUV and trade associations (German BiA) carefully checked and approved the concept and the products *AS-i Safety at Work*. Since its introduction in 2001, Safety at Work has developed into the most successful system in the field of safety technology.

**FIGURE 6.41** AS-i network with safety at work components.

### 6.5.1 Transmission Principle

The Electrical Engineering Committee of the German employers' mutual insurance association (BIA) formed a working group that developed a *proposed basis for testing and certifying bus systems for the transmission of safety-related messages*. This describes, among other things, the faults that can occur when sending messages and measures for overcoming them. For example, in safe bus systems, the message *E-STOP not actuated* often includes a reference to the sender and time information, plus a checksum (e.g., 32-bit CRC) for data integrity. With only seven bits net or four bits of user data per message (slave response), this procedure cannot be used for AS-i.

In AS-i Safety at Work, each slave encodes the information *E-STOP not actuated* into a 32-bit-long code word and sends it as a data frame of 4 bits each per AS-i cycle. Because the transmission takes place in eight sequential telegrams, AS-i refers to this code word as a code sequence. At the receiver, at any desired point in time, a complete code sequence results that is uniquely associated with this slave based on the telegrams received in the last eight AS-i cycles. This is accomplished by means of the rules applied to the encoding. For 32 bits, there are 232 different code sequences, which results in more than 4 billion possibilities. A maximum of 950,000 of these are actually used, or 1 in 4,000. Each safe slave uses a different code sequence from these 950,000, which is stored in the slave when it is manufactured. This procedure is patent protected.

That the process is simpler than it sounds can be seen by looking at the block diagram of a safe slave (Figure 6.42). The code sequence is stored in a  $4 \times 8$  bit memory. With each AS-i telegram, the next four bits from the memory are sent in the slave response. The data strobe signal is used in the slave for advancing to the next value. Actuating the E-STOP interrupts the connection between the memory and the AS-i slave IC. Instead, the value 0000Bin is then present on the inputs of the IC and is transmitted in the slave response.

The receiver of the messages—mostly a safety monitor that listens in on the slave response—has a memory for each connected slave in which the code sequence is also stored. It compares each slave response with the reference value contained in the memory, and in normal operation, the complete code sequence is received after eight slave responses—and thus is the message *E-STOP not activated*. If the slave response contains the value 0000Bin, this corresponds to the message *E-STOP actuated*. If the received message corresponds to neither the expected value in the code sequence or the value 0000Bin, there is a fault or an error. The  $8 \times 4$  bits of the code sequence are chosen so that any error, such as a short circuit between 2 bits or a constant 1 level on an input of the AS-i slave IC, results in discrepancies after the comparison.

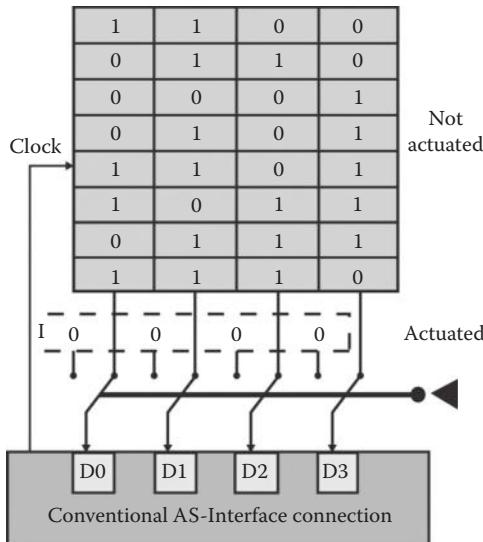

FIGURE 6.42 Block diagram of a save slave.

The error handling for safety performance level e according to EN ISO 13849 requires that a single error shall not result in a loss of function. An E-STOP button is therefore equipped with two normally closed contacts, so that when there is a fault in one contact, the redundant second contact can initiate the standstill. As implemented in the safe slave, this means that the code sequence is divided into two groups of  $8 \times 2$  bits each and each contact affects one respective group. If only one of the contacts opens upon actuation, 2 bits are at zero while the remaining 2 bits of the code sequence are further transmitted. The receiver recognizes this and, in the case of the E-STOP function, generates an error message in addition to the standstill.

Not every deviation from the expected code sequence is caused by a defective slave or sensor. Contacts have mechanical tolerances or bounce. Both when actuating and when unlocking, transition states can arise. The receiver therefore always considers multiple slave responses when determining the state of the sensor. Table 6.19 and Figure 6.43 show the states of a sensor in the process image and the associated state transitions.

These states form the process image and represent the respective current state of a slave or sensor. Only an on-state represents the information *E-STOP not actuated*. A change between two of the first four states shown always involves the transition state, since at least eight slave responses are necessary in order to determine the state of the contacts.

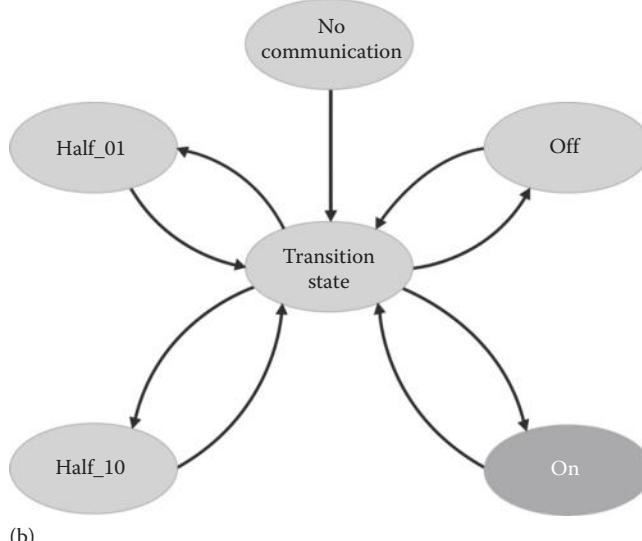

### 6.5.2 Safety Monitor

In principle, the function of the safety monitor is the same as that of a safety relay. The safety monitor with two output circuits includes two redundantly constructed OSSDs that may be used up to control system of performance level e. Due to additional integrated safe logical elements, the function of the safety monitor extends far beyond that of an individual safety relay. Depending on the application, a safety monitor may replace several conventional safety relays. This reduces the wiring effort significantly and saves space in the switch cabinet.

During the configuration of the safety monitor, the designer must ensure that the safety components match the respective safety functions in order to achieve the required control system category. He must not rely on the safety monitor for this purpose as the monitor can accept configurations that do not guarantee the desired control system performance level. If, for example, a standard slave, that is, a simple non-safety-related switch, is configured as safety component into a safe output circuit, this can neither

Contact 1	Contact 2	Received Valves	State
Open	Open	More than eight times 0000Bin	Off
Open	Closed	More than eight times 00-	Half_01
Closed	Open	More than eight times -00	Half_10
Closed	Closed	More than eight valves of the code sequence	On
		None	No communication
		Others	Transition state, state of the sensor

(a)

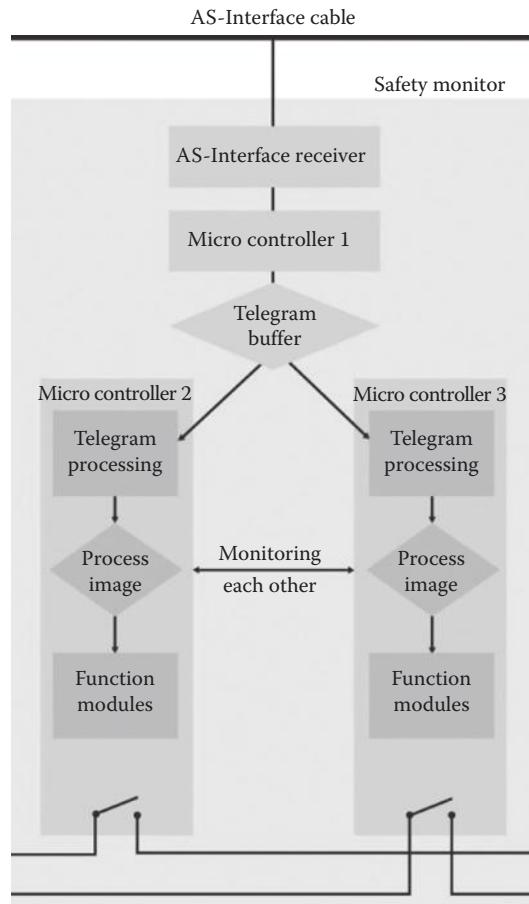

(b)

**FIGURE 6.43** (a) States in the process image and (b) state transitions in the process image.

be detected in the safety monitor nor in the configuration software. Only the person who creates or checks the configuration can detect this.

It is important to print out and sign the configuration log included in the safety monitor and ensure that it is attached to the plant documentation. With his/her signature, the designer documents the correctness of the safety configuration. For all further changes or additions to the plant configuration, a new log must be printed, signed, and attached to the plant documentation. Discrepancies can be detected by simply comparing the printed version to the current log stored in the safety monitor.

The safety monitor listens in on the data communication between the master and slaves. A first microcontroller receives both master requests and slave responses and places them in a buffer (Figure 6.44). Every 5 ms, a timer starts evaluation of the telegrams. This task is assumed by two additional microcontrollers that monitor each other. They consider the addressing sequence of the master requests and thus can detect missing slaves, for example. Depending on the user configuration (see the following), they distinguish between safe slaves, for which they create the safe process image, and conventional slaves, whose input and output data they also store. Once all the telegrams from the buffer have been processed, the AS-i-specific part of the safety monitor ends. In the standard AS-i, this corresponds to the interface between the AS-i master and the host (PLC).

**FIGURE 6.44** Structure of the safety monitor.

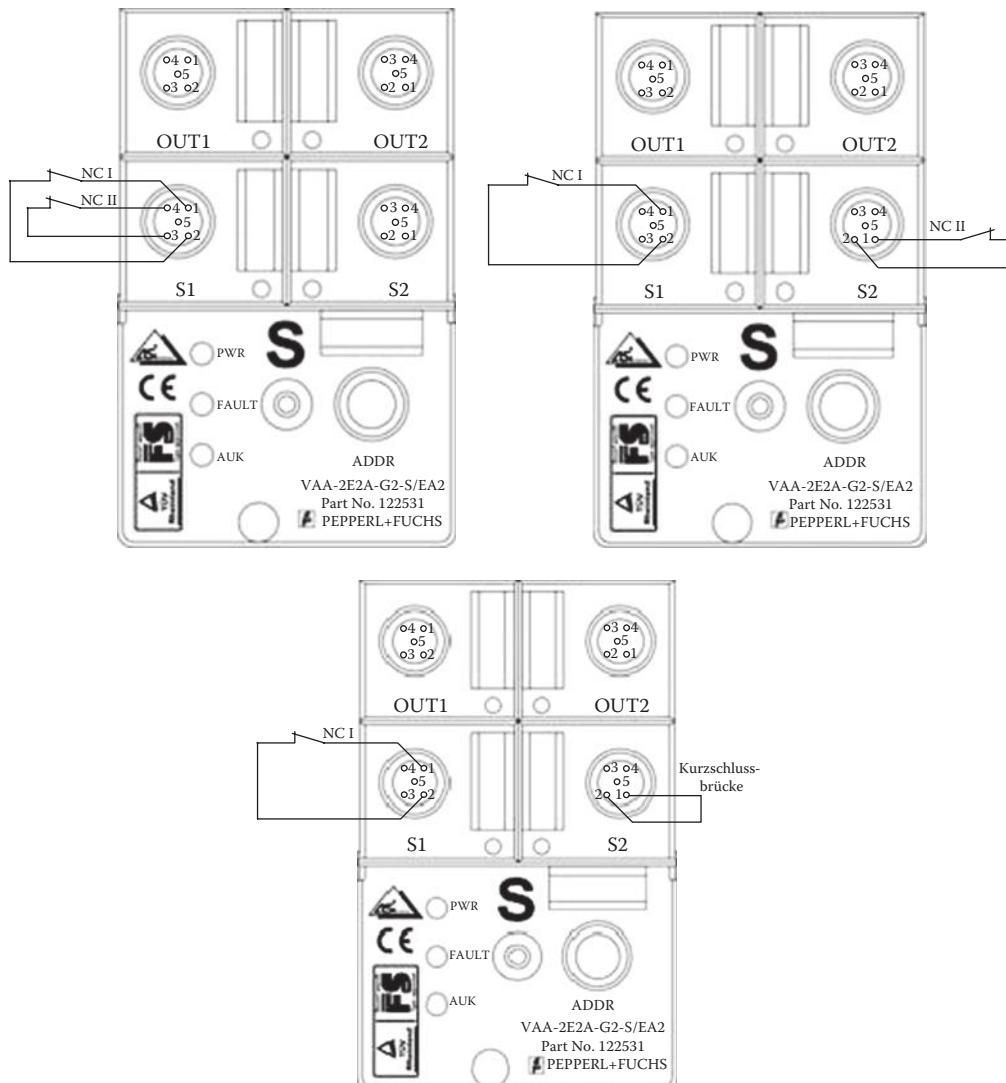

The next task is to determine from the process image the conditions under which the output relay should be turned on to be able to start a machine—the task of a safety controller. The safety monitor contains software function modules for this purpose that can take on certain monitoring tasks. These function modules are implemented as a state machine. They use the current state (behavior of the slave in the past) and the value in the process image (how do the signals currently look on the slave) to determine the new state. The state is recalculated for each slave every 5 ms. Thus, the implementation of an E-STOP function meets performance level e with a *two-channel forced* function module. It checks whether both contacts in the slave are always in the same state, that is, both open or both closed. Should the safe process image of the associated slave be in one of the two *half* states, it means there is a fault in the E-STOP button. The function module therefore goes into the *slave is defective* state and indicates this, normally by a red flashing LED on the safety monitor. Even if now the process image again displays a proper state for the slave, the error status is not cleared until the operator has acknowledged it. The function module *two-channel dependent* is intended to monitor a safety door with two separate switches. Here, *half* states are allowed, for example, when the operator opens the door just a crack. The function module does not go into an error state but rather into the *test required* state and indicates this normally by a yellow flashing LED on the safety monitor. The operator is thus prompted to open the door fully and close it again to verify correct function of both switches for the safety monitor.

### 6.5.3 Safe Inputs

Besides the safety monitor that switches the safe signals und starts the actions, the other components connected do have a significant impact to the usability of the system. For AS-i, a huge product range of safe inputs and outputs is available.

This example shows how to connect protective switches to a module with M12 plug connection. For each channel, one or several protective switches may be connected in series but the requirements of the applicable control system category must be observed for this (Figure 6.45). One must also choose a manipulation-proof mounting.

Safe modules usually contain two independently implemented input channels, each of which meets the requirements of control system performance level e according to EN ISO 13849. To assign only a single contact mechanical switch to such safe modules designed for parallel connection, a short-circuit jumper must be installed on the free socket of the emergency-stop connection. This short-circuit jumper must be protected against dirt and falling out.

**FIGURE 6.45** Connection of a two-channel mechanical switch or of two or one single-channel mechanical switch(es).

#### *Short-Circuit Monitoring*

Usually, the inputs of a safe module are monitored for short circuits between each other. For active optoelectronic protective devices with electronic outputs, the short-circuit monitoring is implemented in the sensor. Safe modules without short-circuit monitoring must be used for the connection to the AS-i branch.

#### **6.5.4 Safe Outputs**

Besides, the safe outputs integrated to the safety monitor allow the connection to decentralized safe outputs. These might be combined to groups for common switching. Typically, the safe outputs provide external device monitoring to guard the functionality of the relays.

A safe output module has two AS-i addresses: one for switching on operation and one for the safe switch-off. The two addresses need to be different.

The safe address is monitored by the safe output. The safety monitor is sending at this address the known code table. When the safety monitor switches the safe output, it sends the code table 0000 and the safe output will be switching off. Several safe outputs may use the same safe address; this allows groups of safe outputs to be put in the safe state at the same time.

#### **6.5.5 Start-Up of a Safety System: Teaching the Code Table**

It is easy to start up an AS-i safety system. It continues the simple plug-and-play philosophy of the system. Nevertheless, you have to do the risk analysis. In the moment you know what protection you need in which position it is all the easy way of AS-i,

- Place the required safety devices with the required performance level in the machinery
- Address the devices and connect them to the AS-i network
- Configure the safety devices in the safety monitor device
- Learn the safe configuration (see next section)
- Print out the documentation by clicking the print button in the configuration software

#### *Learning the Safe Configuration*

After completion of the configuration transfer to the AS-i safety monitor connection, the code tables of the slaves to be monitored must be read. Before this, the AS-i bus must be switched on (*on*). This includes all safe slaves. For two-hand buttons, this means that they must be operated simultaneously during the learning of the safe configuration.

To start reading the code tables in the configuration software, click on the command “Teach code tables...” in the monitor menu. Once the code tables of all safe slaves to be monitored have been read without problem, the preliminary configuration log is transferred to the configuration software.

### **6.6 Open System: Interoperability and Certification**

---

EN 50295[1] and IEC 62026-2[2] are the standardization basis for AS-i. All AS-i components are developed based on these standards and on the complete specification. The internationally high market acceptance means that the broad AS-i product spectrum is constantly growing. That is another benefit of this open system.

The technical commission of AS-International has developed complete manufacturer-neutral documentation that ensures that the functionality of the system and safe operation in harsh industrial environments can be taken for granted. An important goal of the documentation is interoperability of the various components.

The documentation of the user organization consists of the *complete specification* with profiles and testing specifications. This specification describes the slave and master transmission systems, the minimum

requirements and the profiles, as well as everything necessary for a full understanding of the system. The specification also contains notes on technical implementation to simplify the development of new components. The testing specifications allow for verification that the specification has been met. The AS-International Association provides the documentation to its members. This availability of information is doubtless an important factor in the success of the system. Many companies are in this way able to design special solutions and make these individual solutions available for a variety of applications. The AS-i chips from a wide variety of manufacturers are the foundation of the economical product range.

#### Certification

Certified products are important for the user of a system. Certification guarantees function according to the specification, thus ensuring interoperability of components from different manufacturers in a network. All components in an AS-i network can be subjected to testing for certification. Thus, certification stands for a uniform and high-quality system. Certified products, even from different manufacturers, are guarantees of compatibility and a trouble-free AS-i network (Figure 6.46).

The certification agency is a manufacturer-neutral part of AS-International. Following an application to the certification agency and a type test, a certificate is issued for successfully passing the inspection.

The tests for a certificate can be performed only in a laboratory approved by AS-International in accordance with the AS-i testing specifications and accreditation guidelines. This ensures that the tests can be verified. A list of recognized laboratories is available from the AS-International Association.

The AS-i testing specifications include a detailed description of the certification test. Each testing specification contains precise test instructions to be used in verifying the logical behavior and communication-relevant properties of the AS-i network. The strictly defined measuring procedures and testing methods ensure correct function in the AS-i system.

Noise immunity of the components is subject to strict control and ensures a reliable AS-i network, even under difficult EMC conditions. The most important feature of all tests is to ensure functionality of the system in harsh industrial environments. Symmetry and impedance tests are combined with strict burst tests in *worst-case* topologies to test for EMC compatibility.

The tested products are easily identified by means of the certification sign (Figure 6.46) and associated test number. This logo is a registered trademark of the AS-International Association and may be used exclusively for certified products. The shadow logo together with the test number is a quality mark that is subject to strict controls.

FIGURE 6.46 AS-i certification sign.

## 7.1 Introduction

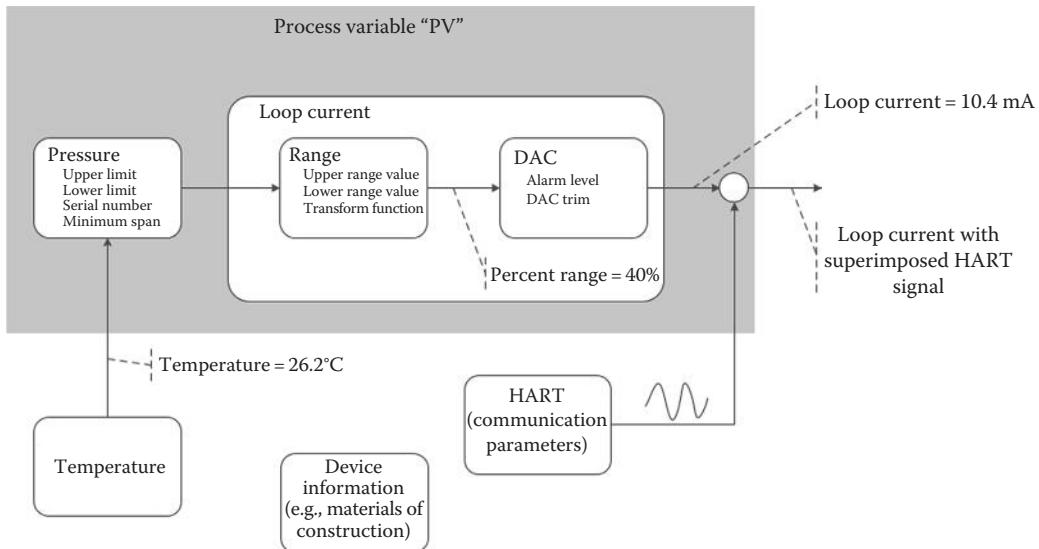

---

### 7.1.1 Evolution of HART

A Highway Addressable Remote Transducer (HART™) [1] device is a microprocessor-based process transmitter or actuator that supports two-way communications with a host, digitizes the transducer signals, and digitally corrects its process variable (PV) values. The HART digital signal is modulated on to the 4–20 mA signal at a higher frequency and then observed by process control equipment.

Since 4–20 mA transmitters provide a single PV to the control system via the loop current, early HART development focused on the primary PV. In HART, PV includes all of the properties and data items necessary to support the loop current as shown in Figure 7.1. HART commands provide access to all loop current data and properties. Process values associated with PV include the digital value, percent range, and loop current. Properties of the PV include upper- and lower-range values, upper and lower transducer limits, transducer serial number, and minimum span. Status information includes *loop current fixed*, *loop current saturated*, *PV out of limits*, and whether or not the device has malfunctioned.

Initial HART devices focused on improving accuracy and reliability. For example, adding an ambient sensor (e.g., temperature) along with linearization and compensation software dramatically improved accuracy. Today, virtually all HART field devices are multivariable. For example, there are pressure transmitters that provide the sensor temperature, level transmitters that can calculate volume, and flow meters that contain totalizers and perform data logging. The growth in multivariable

**FIGURE 7.1** HART pressure transmitter.

field devices continues to accelerate as microprocessor capabilities increase and power requirements decrease. As shown in Figure 7.5, HART provides access to variables in multivariable field devices and provides mechanisms to map parameters.

### 7.1.2 HART Signal

All HART field devices support two communication channels: the traditional current loop and HART communication. The current loop occupies the 0–25 Hz band used by all 4–20 mA devices to continuously transmit a single process value. HART communications reside in a higher 500–10,000 Hz band. The earliest HART communication protocol was based on the Bell 202 telephone communication standard and operates using the frequency shift keying (FSK) principle. The FSK digital signal is made up of two frequencies: 1200 and 2200 Hz representing bits 1 and 0, respectively. As shown in Figure 7.2, sine waves of these two frequencies are superimposed on the 4–20 mA analog signal. Because the average value of the FSK signal is always zero, the 4–20 mA analog signal is not affected. The digital communication signal has a response time of approximately two to three data updates per second without interrupting the 4–20 mA analog signal. A minimum loop impedance of  $230\ \Omega$  is required for communication. Phase shift keying (PSK), a later variation of the physical layer, is also supported. PSK supports the higher speed of 9600 Bd. PSK is not widely used.

AHART field instrument (slave) transmits a HART signal by modulating a high-frequency carrier current of about 1 mA p–p onto its normal output current. This is illustrated in Figure 7.2 for the same 10.4 mA analog signal used in Figure 7.1. The signal must be continuous at the 1200 and 2200 Hz boundaries.

### 7.1.3 HART System

Figure 7.3 shows a simple HART system setup with a single device connected to the host. In this setup, only one device is connected through the HART interface. As shown in Figure 7.4, it is also possible

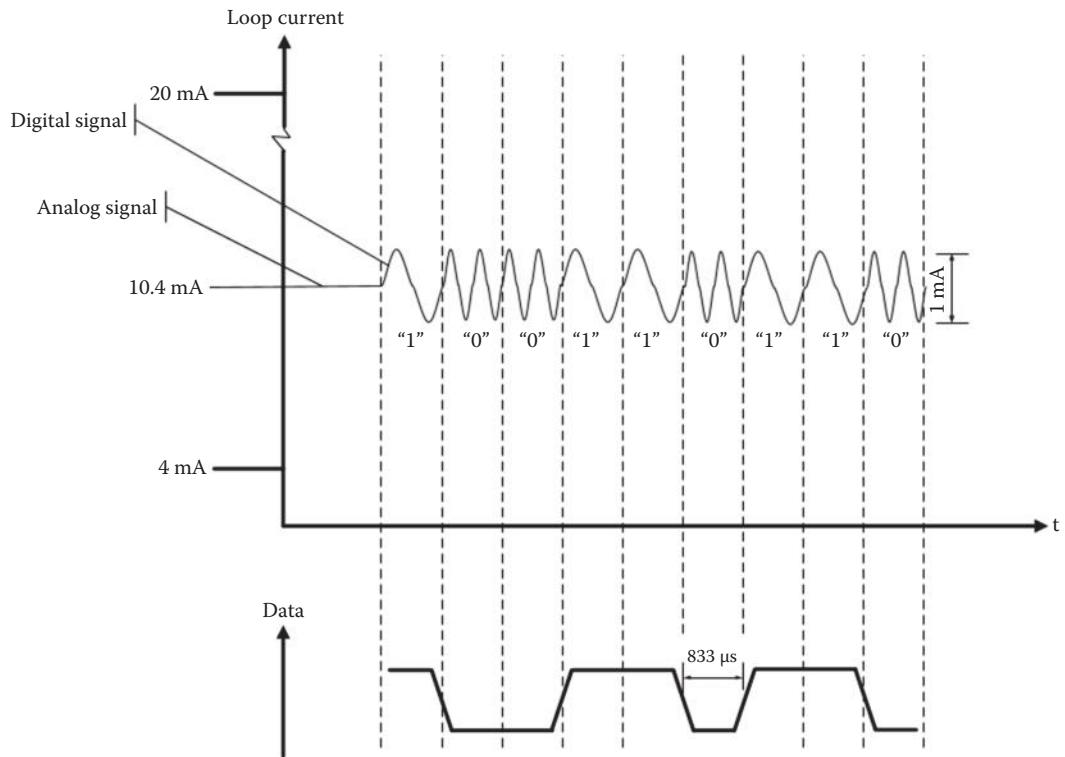

FIGURE 7.2 HART simultaneous analog and digital communication.

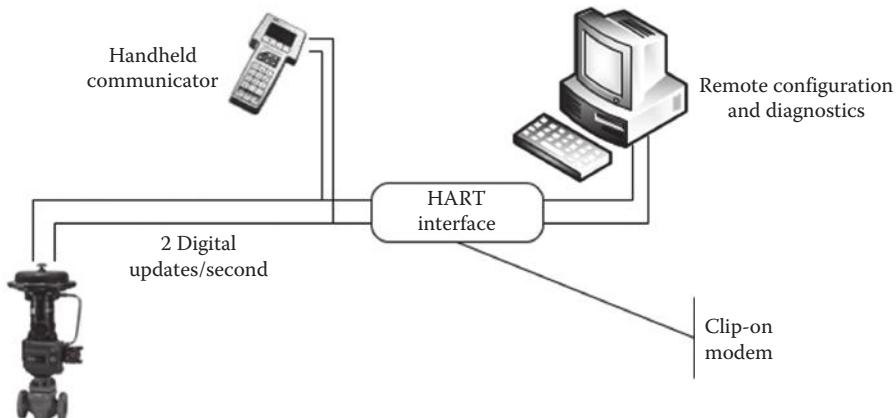

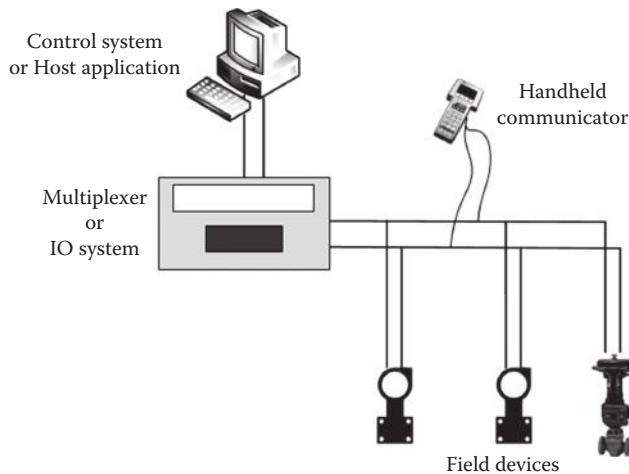

FIGURE 7.3 HART system.

to support more than one device using a multidrop setup. The wire connections, power, and isolation considerations are described later in this chapter.

The multidrop mode of operation requires only a single pair of wires and, if applicable, safety barriers and an auxiliary power supply for up to 15 field devices. All process values are transmitted digitally. In multidrop mode, all field device polling addresses are >0, and the current through each device is fixed to a minimum value (typically 4 mA).

**FIGURE 7.4** Multidrop mode of operation. Note: Instrument power is provided by an interface or external power source that is not shown.

#### 7.1.4 HART Field Devices

The minimum requirements, as described in a separate chapter, that all HART field devices must meet include

- Adherence to physical and data link layer requirements
- Support for minimum application layer requirements (e.g., device status information, engineering units, IEEE floating point)
- Support for all Universal Commands

Most HART field devices also support a variety of Common Practice Commands. Whenever a field device supports a Common Practice Command, it must implement that command exactly as specified.

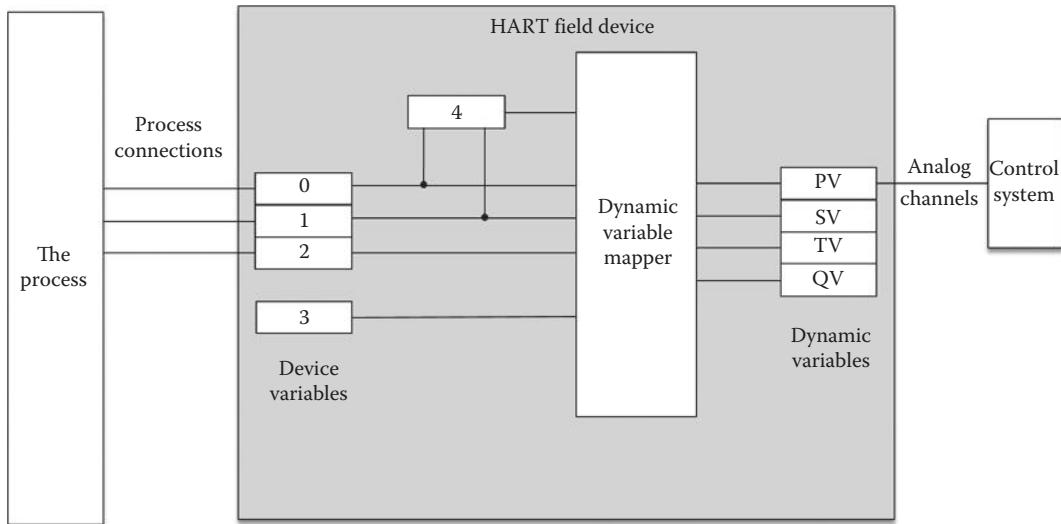

The 4–20 mA current loop communication channel connects the HART field device to the control system. The current loop is always connected to the PV (see the calibration subsection). Furthermore, some devices support more than one current loop connection. When this occurs, the second current loop is connected to the SV and so on. In other words, the dynamic variables connect a HART field device to control system.

A *device variable* directly or indirectly characterizes the connected process. As shown in Figure 7.5, dynamic variables may be mapped to process measurements, calculated parameters, or parameters within the device itself. In this example, device variables 0, 1, and 2 are connected to the process, and device variable 4 is calculated based on device variables 0 and 1. Device variable 3 is within the field device itself (e.g., it may be an onboard temperature sensor).

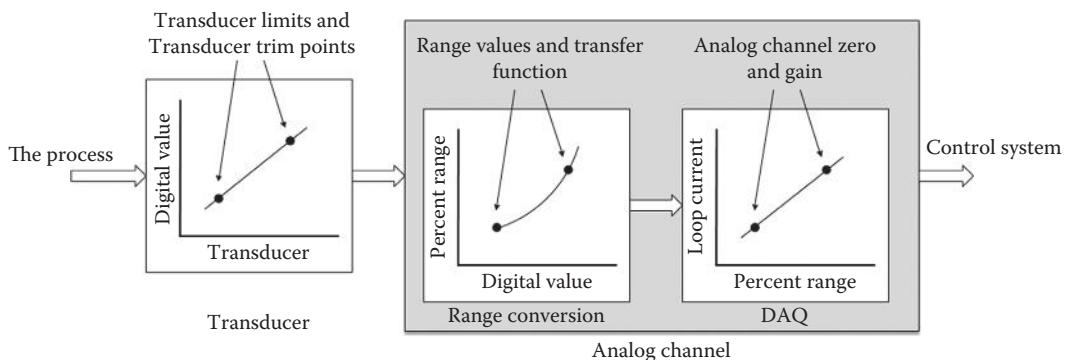

Multivariable field devices allow the device variable mapped to the PV (i.e., the current loop) to be configured based on application requirements. For example, a level gauge may measure level and calculate volume. In this example, the level gauge allows the user to choose whether the current loop reports level or volume. This allows the data that are most important to the user to be transmitted continuously via the current loop. Simultaneously on the same wire, the other PVs can be accessed using HART communications.

#### 7.1.5 Calibrating HART Field Devices

All field devices need periodic calibration. Calibration of HART devices includes calibrating the digital process value, scaling the process value into a percent of range, and transmitting it on the 4–20 mA

**FIGURE 7.5** HART device variables vs. dynamic variables.

**FIGURE 7.6** PV blocks that can be calibrated.

current loop. HART devices use standardized commands to test and calibrate the loop current, rerange a field device, and even perform a transducer trim [2][3].

Figure 7.6 is a block diagram showing the processing steps associated with generating PV and will be used to illustrate the calibration process. Three blocks are used for data acquisition and communication of PV via the current loop. From left to right, these blocks include the transducer block, range block, and DAQ block.

### 7.1.5.1 Calibrating the Process Variable

The transducer block is responsible for generating a precise digital value representing the connected process. In HART, the transducer block contains properties like the upper and lower transducer limits, transducer trim points, as well as device-specific transducer characterization data. Access to characterization data is usually not available or adjustable in the field. All devices require periodic calibration of the digital value produced by its transducers.

The calibration of the transducer blocks (i.e., transducer trim) consists of supplying a simulated transducer value and comparing the transducer value provided by the field device with the value measured by a traceable reference to determine whether calibration is required. If calibration is required, it is performed using the HART protocol. In general, calibration is performed by providing the field device

with correct transducer values: one near the lower limit and another near the upper limit. Using these values, the field device performs internal adjustments to correct its calculations.

There are documenting process calibrators that perform all of these functions. These documenting process calibrators

- Provide the simulated process signal and an accurate, traceable reference value
- Determine if adjustment is required
- Issue the HART commands to complete the calibration process
- Record the as-found and as-left calibration data

Some instrument management systems are capable of automatically uploading the calibration records for trending and later analysis.

### 7.1.5.2 Scaling the Process Variable

The next two blocks in Figure 7.6 translate the transducer value into a 4–20 mA signal. Traditionally, this has been referred to as the *zero and span* of the device. HART supports standardized commands to rerange a field device and to calibrate the loop current.

In the range block, HART uses the upper- and lower-range values to scale the transducer value into *percent range*. The lower-range value sets the transducer value that produces a 4 mA signal. The upper-range value specifies the transducer value that will produce a 20 mA signal. In many field devices, the upper-range value can be smaller than the lower-range value. For example, a level gauge could be configured to provide 4 mA when the tank is full and a 20 mA value when it is empty. This can be useful, for example, when the level gauge 4–20 mA signal is connected to a proportioning valve.

**Note:** The differences between ranging and calibrating a device are critical. Considerable confusion can result if the difference between calibrating the PV's digital value and reranging the instrument is not understood. Many hours can be spent attempting to get an *accurate* 4–20 mA signal if the function of the transducer and range blocks is ignored.

The range block can also apply a transfer function (e.g., linear, square root, and cubic spline) to the PV signal. Square root functions are frequently used to approximate a flow from a differential pressure measurement.

### 7.1.5.3 Producing the Loop Current

The DAQ block is responsible for the actual production of the 4–20 mA signal. HART provides standardized commands to calibrate the loop current. Since the range block already scales the process value, the responsibility of the DAQ block is to ensure 0% produces 4 mA and 100% produces 20 mA. The objective of calibrating this block is to ensure that when the device thinks the loop current is, for example, 7.956 mA, there is exactly 7.956 mA on the wire. The meaning of 7.956 mA, in terms of the process value it represents, has been already established in the previous two blocks.

From a system viewpoint, the purpose of the 4–20 mA current loop is to communicate with the control system. Consequently, the most critical requirement is that the field device and the control system both agree on the value of the current loop. Agreement between the field device and the control system on the milliamp value is much more critical than the absolute accuracy in many applications.

## 7.2 HART Networks

---

### 7.2.1 Understanding IO System Trade-Offs

All communications systems can be characterized by their throughput and latency:

- *Throughput* indicates the maximum number of transactions per second (tps) that can be communicated by the system.
- *Latency* measures the worst-case maximum time between the start of a transaction and the completion of that transaction.

Throughput and latency are affected by the communication protocol requirements and by implementation decisions. Knowledgeable end users will insist on receiving these two statistics when evaluating system components. The HART Application Guide includes a host capability checklist.

The performance (throughput and latency) of IO systems can vary dramatically. This subsection describes the design decisions and architecture that affect HART IO system performance.

HART can provide 2.65 PV updates per second (also referred to as transactions per second or tps). This is a typical value, and actual throughput can be less. For example, slave devices may begin their response later in the allotted transmit time window, or the message might be a HART command containing a longer data field. In addition, hosts have a small time window to begin their message transmission. If that window is missed, the HART network becomes *unsynchronized*, and the host must back off an extra time interval. The resulting extra time lowers performance to 0.88 updates per second (or about three times slower) or less.

### 7.2.2 Multidrop Connections

All HART-compatible host and slave devices must support multidrop. In multidrop, several HART field devices are connected via the same pair of wires. Latency is increased because several commands may be enqueued and waiting for transmission.

In multidrop networks, throughput remains the same (2–3 tps). However, latency increases and is proportional to the number of device on the loop. Even with the degraded latency, multidrop is suitable for many applications (e.g., temperature monitoring or tank inventory management).

### 7.2.3 Burst-Mode Communications

Burst-mode allows a field device to be configured to continuously transmit digital process values. All HART hosts must support burst-mode; however, utilization of burst-mode depends on the application. If common multivariable field devices are employed, burst-mode maximizes the update rate of secondary PVs. For example, secondary PVs can be normally updated (using Command 3) 1.8 times per second. With burst-mode, the secondary PVs can be updated 2.4 times per second (about a 30% improvement).

However, configuration of a field device can take somewhat longer. When burst-mode is enabled, the burst-mode device is responsible for token recovery. Consequently, hosts only have network access after a burst message from the field device. This results in a throughput of 0.80 configuration read commands per second. That is about 2.5 times slower than with burst-mode not in use.

### 7.2.4 Summarizing HART Performance

For optimum performance, I/O systems should include one (hardware or software) modem for each channel. With such an I/O system, using all HART capabilities is practical including continuous status and diagnostics, remote configuration of instruments, acquisition of secondary PVs from multivariable field device, and the deployment of multidrop networks.

Lower-cost I/O systems multiplex HART communications by using one HART modem chip to support several I/O channels. With multiplexed I/O, all transactions must be serialized, and the host must resynchronize its communications each time the HART channel is changed. Consequently, the execution of the last requested command may be delayed by the time required to process all commands already enqueued plus the resynchronization delay time.

Tables 7.1 and 7.2 summarize system performance vs. I/O architecture. While actual performance can vary, these tables provide a basis for evaluating I/O system designs. Multiplexed I/O is clearly the worst performer and is even worse than multidropped I/O. For 8 channel analog I/O (a common format in many systems), multiplexed I/O throughput is 14.5 times worse than when a modem is used for each channel. Clearly, the use of multiplexed systems dramatically degrades system performance.

**TABLE 7.1** Summary of Latency for I/O Systems

Number of Channels	Measured in Seconds			
	Point-to-Point	Point-to-Point (Unbuffered)	Multidrop	Multiplexed
1	0.38	1.14	0.38	0.38
4	0.38	1.14	1.51	2.73
8	0.38	1.14	3.02	5.46
16	0.38	1.14	6.04	10.92
32	0.38	1.14	12.08	21.84

**TABLE 7.2** Summary of Throughput for I/O Systems

Number of Channels	Measured in Transactions per Second			
	Point-to-Point	Point-to-Point (Unbuffered)	Multidrop	Multiplexed
1	2.65	1.14	2.65	1.47
4	10.60	4.56	2.65	1.47
8	21.19	9.12	2.65	1.47
16	42.38	18.24	2.65	1.47
32	84.77	36.48	2.65	1.47

## 7.3 HART Networks

### 7.3.1 Modulated Analog Signal

HART communication is designed to be compatible with existing 4–20 mA systems. HART communication is based on communication techniques long used in telephone and telecommunications, and consequently, HART is very forgiving. For example, there are several ways to calculate HART cable lengths. No matter the technique used, the result is very conservative (i.e., HART will normally be successful on cables 25%–50% longer than calculated.)

HART cable run lengths are a function of the quality of the cable used: the lower the capacitance, the longer the possible cable length. In many cases, the cable runs are determined by intrinsic safety (IS) capacitance limitations before HART limits are reached.

### 7.3.2 HART Physical Layer

All HART devices support two communications channels: (1) the traditional 4–20 mA signaling and (2) the modulated HART communications. These exist in separate communications bands (see Figure 7.2), and the signals do not interfere with each other. This allows both communications to occur simultaneously. In fact, a significant portion of the physical layer specification is dedicated to defining the filtering and response times to ensure the separation of these bands.

Process control equipment normally contains a low-pass filter to block out noise. Consequently, HART looks like noise to most existing systems and is filtered out. In most cases, this feature allows HART to be used with existing systems and with no special modifications.

All HART devices are required to support the HART FSK physical. The FSK physical layer is based on the Bell 202 modem standard. FSK modulates the digital data into frequencies (1 is 1200 Hz and 0 is 2200 Hz). FSK is quite robust, can be communicated long distances, and has good noise immunity. A single simple HART modem chip is used by a device to send and receive the HART modulated signals.

### 7.3.3 HART Network Guidelines

As previously discussed, HART was designed to work in typical 4–20 mA loops. Figure 7.7 illustrates a number of ways to connect devices. Table 7.3 summarizes the characteristics for networks shown in Figure 7.7. As shown in Figure 7.7, devices may be powered from the 4 to 20 mA connection (two wires) or powered from a separate connection (four wires). As an example, the loop with a two-wire transmitter has a current sensor (i.e., one low impedance device), a transmitter controlling the 4–20 mA signal (i.e., only one device varying the analog signal), and a single HART secondary host (when a handheld is connected to the loop). Most control systems use a  $250\ \Omega$  current sense resistor.

#### 7.3.3.1 HART Two-Wire Connection

HART devices (slaves) transmit by modulating the process 4–20 mA DC loop current with a 1 mA p–p AC current signal. Since the average value of the HART signal is zero, the DC value of the process loop remains unchanged. Receive circuits in a HART slave device amplify, filter, and demodulate the current signal.

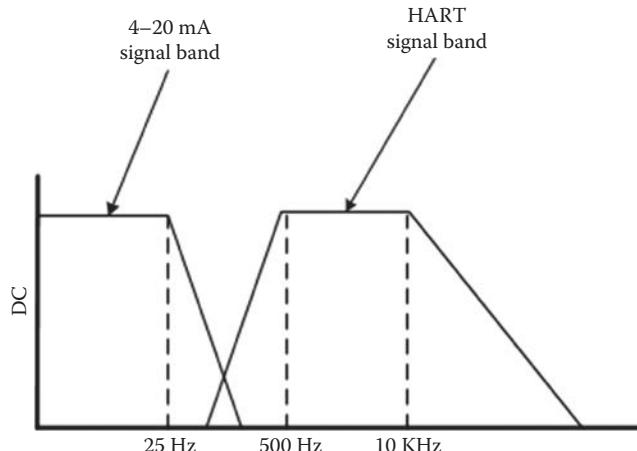

FIGURE 7.7 HART devices and networks.

TABLE 7.3 Characteristics of the HART Devices Shown in Figure 7.7

	Two-Wire Transmitter	Four-Wire Transmitter	Multidrop Network	Control System Current Input	Control System Current Output	Secondary Master	Valve Actuator
Loop-powered	Yes	No	Yes	No	No	No	Yes
4–20 mA signaling	Current sink	Current source	None	Current receiver	Current source	None	Current receiver
4–20 mA impedance	High	High	High	Low	High	Very high	Low
Hart signaling	Current High	Current High	Current High	Voltage Low	Current High	Voltage Medium	Voltage Low
Isolated from ground	Yes	No	Yes	No	No	Yes	Yes

### 7.3.3.2 HART Four-Wire Connection

HART devices (slaves) may also be powered from a separate power source. In these cases, the additional two wires are used to supply power to the device.

### 7.3.3.3 HART Multidropped Slave Devices

Some current loops use only digital signaling. The field instrument current is fixed at 4 mA or some other convenient value, and only digital communication occurs. Up to 15 such field instruments with unique addresses of values > 0 may be connected.

### 7.3.3.4 HART Primary and Secondary Master Devices

HART masters transmit by driving the loop with a low impedance voltage. Regardless of whether a master or field device is transmitting, a signal voltage of about 500 mV p-p is developed across the conductors of the current loop (assuming a 500  $\Omega$  current sense resistor) and is seen by both devices. Receive circuits in each device filter and demodulate the signal voltage.

In general, a HART primary master is the device that provides the communications between the control system (DCS) and the remote process instruments with the intent to receive process information and perform maintenance operations. A HART network that has a HART master interface integrated into the DCS will usually be configured as a primary master.

It is also possible to connect a second HART interface to a network; this second connection is referred to as a secondary master. An example of a secondary master is a handheld communicator that would be connected directly across a HART network. Such a network may have a primary master. A HART network can have only one primary and one secondary master connected at a time.

## 7.3.4 HART Networking Guidelines

The HART physical layers are simple. Most of the details are managed by a low-cost modem chip. HART signaling is in a separate frequency band from the 4–20 mA analog signal and, in most cases, does not interfere with existing 4–20 mA systems. The impedances, filtering, and signaling of HART devices are specified to ensure reliable HART communication when using standard 4–20 mA installation practices. HART network guidelines are summarized in Tables 7.4 and 7.5 [5].

**TABLE 7.4** HART Network Guidelines

Guideline	Description
1	A network must have at least one, typically only one, low-impedance device. Total loop resistance must be between 170 and 600 $\Omega$ .
2	A network must have no more than one device varying the 4–20 mA signal.
3	Only one secondary device is allowed.
4	Cable run lengths of 3000 m for single pair cable and 1500 m for multiconductor cables is typical. Actual length depends on the number of multidropped field devices and the quality of the cable used (refer to Table 7.5).
5	Low-capacitance shielded twisted pair cable is recommended. However, HART has been successfully used over poor-quality, unshielded wiring. Don't replace wiring until you have attempted HART communication.
6	HART is compatible with IS rules, and HART communicates across most IS barriers. In general, zener diode barriers are acceptable as they do not prevent two-way communication. However, isolating barriers must be HART compatible (i.e., some isolating barriers support one-way communication only).

**TABLE 7.5** Cable Capacitance

Number of Devices	65 pf/m (m)	95 pf/m (m)	160 pf/m (m)	225 pf/m (m)
1	2769	2000	1292	985
5	2462	1815	1138	892
10	2154	1600	1015	769
15	1846	1415	892	708

Note: Allowable cable lengths for 1.02 mm (#18 AWG) shielded twisted pair cable.

## 7.4 HART Circuits

### 7.4.1 HART Communications

Up until this point, the discussion has focused on HART networks. In this section, more details are provided around the actual circuits that may be used with HART. The section concludes with a number of installation examples.

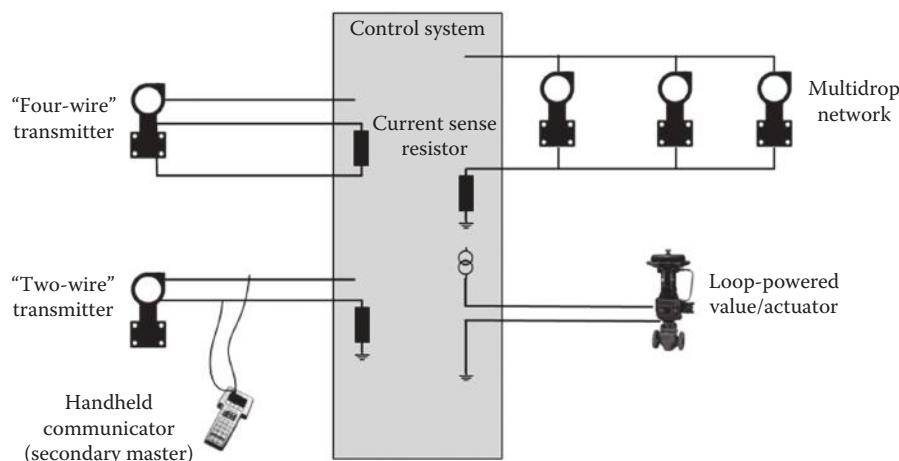

### 7.4.2 Analog Signaling

HART devices may be connected in a conventional current loop. As shown in Figure 7.8, the HART field device (slave) signals by varying the amount of current flowing through itself.

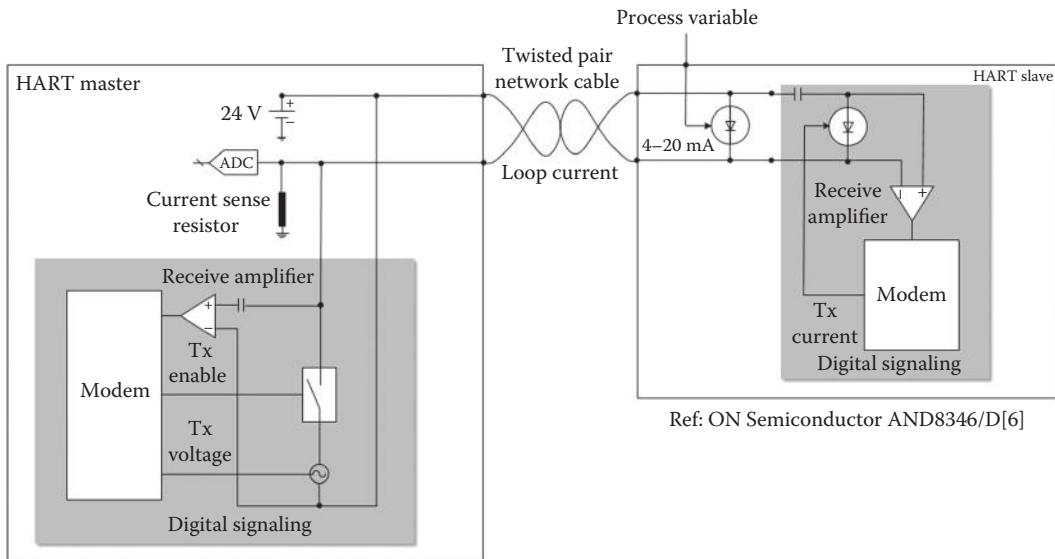

On the other side of the circuit, the HART master or controller (primary master) detects this current variation by measuring the DC voltage across the current sense resistor. The loop current varies from 4 to 20 mA at frequencies usually under 10 Hz (refer to Figure 7.9).

The HART (digital) signal is superimposed on the 4–20 mA (analog) signal. The master transmits HART signals by applying a voltage signal across the current sense resistor, and it receives a voltage signal by detecting the HART current signal across the sense resistor. Conversely, the slave transmits by modulating the loop current with HART signals and receives HART signals by demodulating the loop current. As discussed earlier in this chapter, the HART signal is at a high-frequency carrier current ( $I_1$  is 1200 Hz and  $I_0$  is 2200 Hz) of about 1 mA p-p and superimposed on the normal 4–20 mA current.

Depending on the device, the HART signal is modulated by varying the loop current or by directly modulating a voltage onto the loop. Process transmitters vary the loop current 1 mA p-p. On a typical loop,

**FIGURE 7.8** Current loop with HART signal sources.

**FIGURE 7.9** HART frequency bands.

the current sense resistor is  $250\ \Omega$ , which produces a 250 mV peak to peak HART signal. Other equipment (e.g., handhelds, DCSs, and valves) modulate a voltage on the loop. For each type, the HCF specifications establish signaling levels, device impedances, and internal filter requirements (refer to Table 7.3) [4].

The slave interface to the network is typically a current regulator. Its output current is controlled by varying a much smaller current into an op-amp summing junction. This junction is a convenient point at which to sum the analog and digital signals, thereby achieving superposition of the digital signal onto the analog. The digital transmit signal (Tx current) is capacitively coupled into the summing junction, to preserve the DC accuracy of the 4–20 mA analog signal.

The HART master interfaces to the network act as a voltage source. The network is driven by a low-output impedance (600 or less) voltage amplifier. The output of the voltage amplifier needs to be high impedance. Typically, a HART master uses a coupling capacitor to ensure that the transmitter circuit meets the output impedance requirements specified in the HART physical layer specification.

### 7.4.3 HART Inputs

Control systems support from 1 channel per HART modem to as many as 32 channels per HART modem. When multiple channels utilize a single HART modem, the modem must be multiplexed.

To function correctly, the two-wire AI circuits require that 24 VDC be supplied through the bussed field power connection. For four-wire circuits, a four-wire termination block is typically used. Power for four-wire transmitters must be provided from an appropriate external power source. Typical AI specifications are summarized in Table 7.6. Wiring diagrams for two-wire and four-wire AI circuits are shown in Figures 7.10 and 7.11.

### 7.4.4 HART Outputs

Control systems support from 1 channel per HART modem to as many as 16 channels per HART modem. When multiple channels utilize a single HART modem, the modem must be multiplexed. Typical AO specifications are summarized in Table 7.7. Wiring for AO circuits is shown in Figure 7.12.

TABLE 7.6 AI 4–20 mA Specifications

Item	Specification
Nominal signal range (span)	4–20 mA
Full signal range	1–22.5 mA, with over-range checking
Field circuit per channel	32 mA maximum
Resolution	16 bits
Roll-off frequency	–3 dB at 2.7 Hz, –20.5 dB at one-half the sampling frequency applies to the analog signal
HART scan times	600–800 ms (typical)

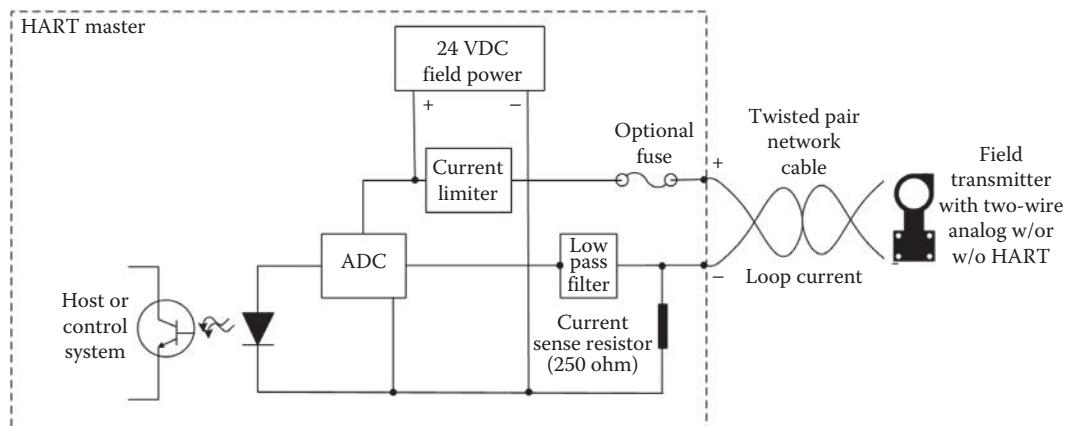

FIGURE 7.10 Wiring diagram for a two-wire AI device. [7]

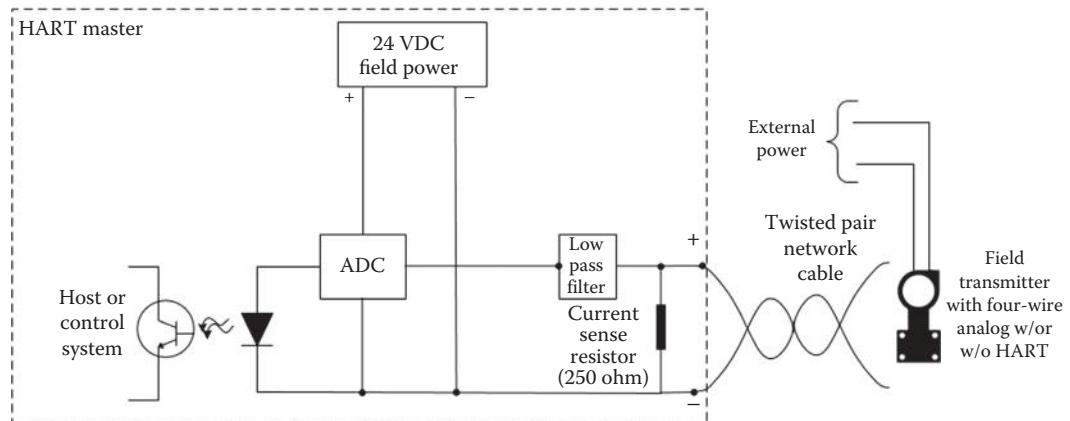

FIGURE 7.11 Wiring diagram for a four-wire AI device.

TABLE 7.7 AO 4–20 mA Specifications

Item	Specification
Nominal signal range (span)	4–20 mA
Full signal range	1–23 mA, with over-range checking
Resolution	12–16 bits
HART scan times	600–800 ms (typical)

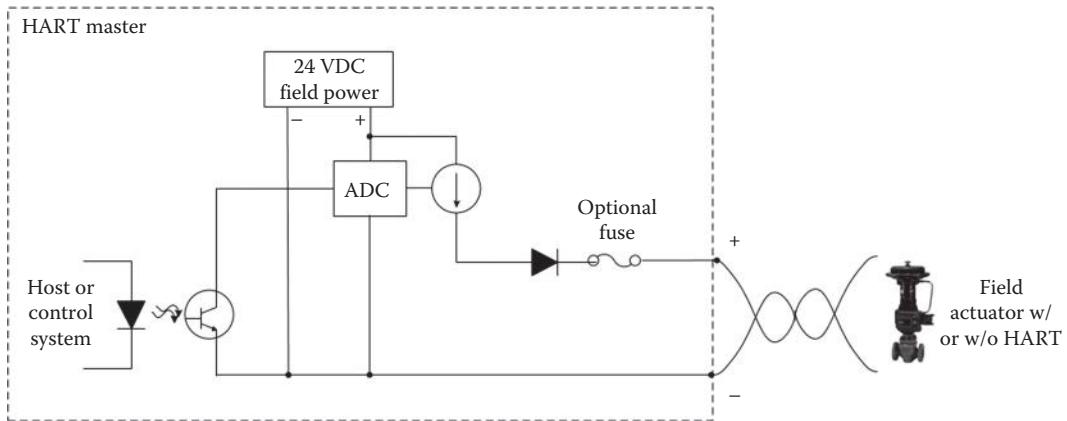

FIGURE 7.12 Wiring diagram for an AO device.

#### 7.4.5 HART Intrinsically Safe Circuits

IS is a method of providing safe operation of electronic process control instrumentation in hazardous areas. IS systems keep the available electrical energy in the system low enough that ignition of the hazardous atmosphere cannot occur. No single field device or wiring is intrinsically safe by itself (except for battery-operated, self-contained devices), but is intrinsically safe only when employed in a properly designed IS system.

HART-communicating devices work well in applications that require IS operation. IS devices (e.g., barriers) are often used with traditional two-wire 4–20 mA instruments to ensure an IS system in hazardous areas. With traditional analog instrumentation, energy to the field can be limited with or without a ground connection by installing one of the following IS devices:

- Shunt-diode (zener) barriers that use a high-quality safety ground connection to bypass excess energy
- Isolators, which do not require a ground connection, that repeat the analog measurement signal across an isolated interface in the safe-side load circuit

A Zener barrier is shown in Figure 7.13. Additional information can be found in the HART planning guide.

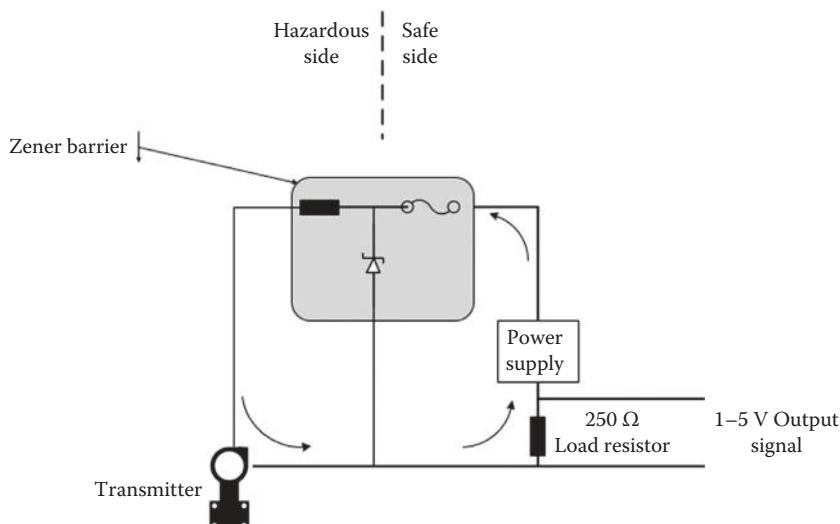

FIGURE 7.13 A 4–20 mA loop with a Zener barrier.

## 7.5 In Closing

---

The simplicity of the HART protocol contributes to its popularity and to the low cost of HART compatible equipment. This section demonstrates the power, the value, and the wide range of HART capabilities and applications. Growth of HART capabilities and applications is certain to continue for many more years.

Use this information to understand the capabilities of HART and to evaluate the field devices and host systems you encounter.

### 8.1 Introduction

---

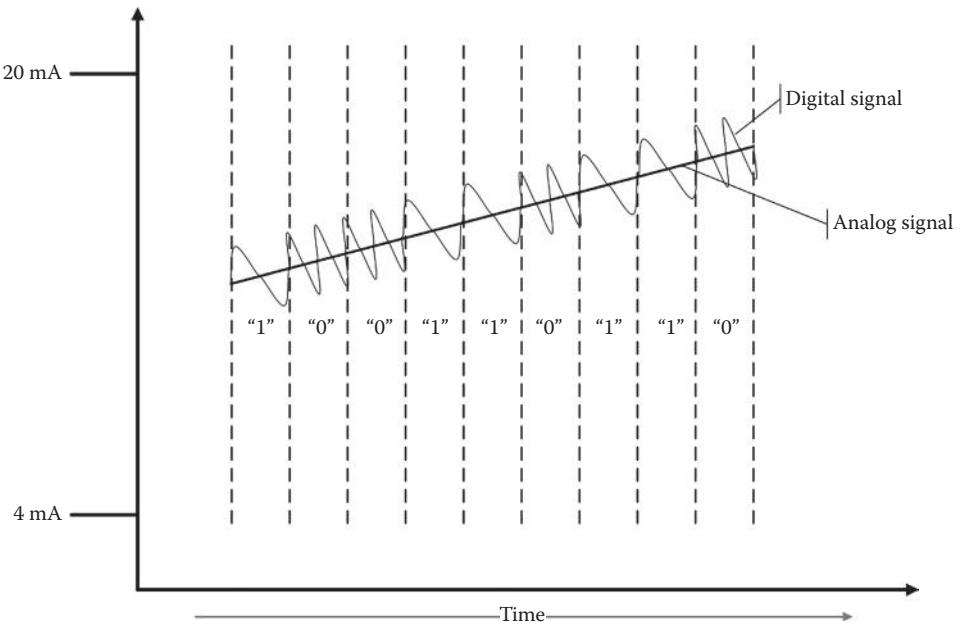

#### 8.1.1 History

The HART™ (Highway Addressable Remote Transducer) fieldbus standard has been in existence since the late 1980s. It is a bidirectional communication protocol that provides data access between intelligent field instruments and host systems. It is administrated by the HART Communication Foundation (HCF), located in Austin, Texas [6]. In its initial release, the HART field communication protocol was superimposed on a 4–20 mA signal providing two-way digital communications with smart field instruments without compromising the integrity of the measured data. As shown in Figure 8.1, the HART protocol has evolved from a 4 to 20-mA-based protocol to the current wired and wireless-based technology with extensive features supporting security, unsolicited data transfers, event notifications, block mode transfers, and advanced diagnostics. Diagnostics now include information about the device, the equipment the device is attached to, and in some cases the actual process being monitored.

The earliest HART communication protocol was based on the Bell 202 telephone communication standard and operated using the frequency shift keying (FSK) principle. The digital signal is made up of two frequencies: 1200 and 2200 Hz representing bits 1 and 0, respectively. As shown in Figure 8.2, sine waves of these two frequencies are superimposed on the analog signal cables to provide simultaneous analog and digital communications. Because the average value of the FSK signal is always zero, the 4–20 mA analog signal is not affected. The digital communication signal has a response time of approximately 2–3 data updates/s without interrupting the 4–20 mA analog signal. A minimum loop

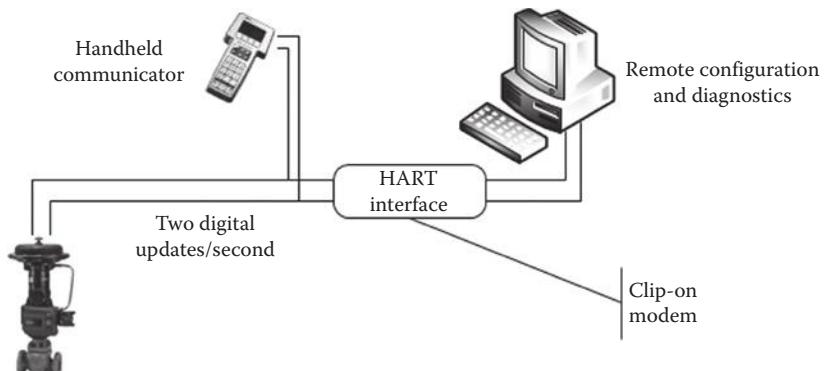

**FIGURE 8.1** Evolution of HART.

**FIGURE 8.2** Wired HART simultaneous analog and digital communication. [7][8]

impedance of  $230 \Omega$  is required for communication. Phase shift keying (PSK), a later variation of the physical layer, is also supported. PSK supports the higher speed of 9600 Bd. PSK is not widely used.

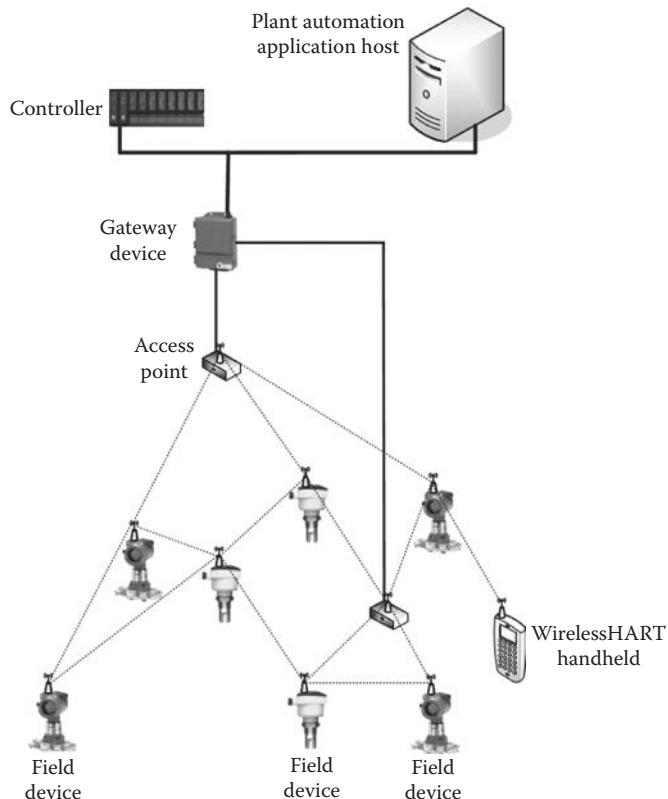

Figure 8.3 shows a wired HART system setup. In this setup, only one device is connected to the HART interface. It is also possible to support more than one device using a multidrop setup. In a multidrop deployment, as shown in Figure 8.7, more than one slave device may be connected to the master device on the same HART network. In HART, unlike simpler protocols like Modbus, data are encapsulated together so that key variables always remain in proper context. For example, measured

**FIGURE 8.3** HART system.

variable, units of measure, and status are always communicated together in the same data packet so that they remain synchronized and in proper relation to each other.

The latest protocol addition to the HART standard is WirelessHART™ [1]. WirelessHART is a secure networking technology operating in the 2.4 GHz ISM radio band. WirelessHART utilizes IEEE 802.15.4-compatible DSSS radios with channel hopping on a packet by packet basis. WirelessHART communication is arbitrated using the WirelessHART network manager to schedule link activity. A given communication link may be dedicated to communication between a network pair or a link may be shared. WirelessHART is shown in Figure 8.4.

**FIGURE 8.4** WirelessHART system.

Applications utilizing HART devices include traditional monitoring and process control, safety applications, asset management, and equipment health monitoring applications. Measurements include temperature, pressure, flow, pH, conductivity, gas detection, discretes, level, vibration, mass flow, energy usage, and valve position. HART devices are also referred to as smart devices. Smart devices include advanced diagnostics that can diagnose the health of the device and, in many cases, the health of the process to which the device is connected. It is not uncommon for smart devices to include diagnostics that can detect plugged lines, burner flame instability, agitator loss, wet gas, orifice wear, leaks, flow cavitation, and excessive vibration. HART smart devices communicate information about the process they are monitoring, information about the overall network, plus information about the process equipment and when they need maintenance.

As the latest addition to the HART family, WirelessHART brings more to the portfolio. Its key factors are security, robustness, availability, and ease of use. To ensure security, all devices joining WirelessHART networks are authenticated and all communications secured. To maintain robustness and high availability, the wireless network employs several redundancy features and is able to adapt to changes in the environment. Ease-of-use includes features such as status on measured values, time stamps, event latching and confirmation, and large data transfer mechanisms. Security, measurement, control, and diagnostics are fully integrated.

### 8.1.2 Improved Plant Operations

Improved operations include the control systems and the operator's ability to view and adjust the process, interact with equipment, and respond to process conditions. Consider the following scenario in which the pH of a tank is controlled and the pH measurement is oscillating about a setpoint. As a first step in investigating this problem, the operator would likely put the valve target, the actual valve position, and the pH reading and its setpoint on a trend. After reviewing the trended oscillations, the operator may decide to adjust the controller gain. The operator notes that the oscillations remain the same regardless of whether they increase or decrease the controller gain. The operator also notes that the read-back value of actual valve position indicates that the minimum change in valve position is 0.5% and notes that a step in an actual valve position change always precedes the pH change. The operator suspects that the oscillation is being caused by the resolution (stick-slip) of the control valve. To follow-through on this, the operator requests a valve signature from the smart valve and compares what is seen with the actual process.

HART supports this scenario through an integrated set of features. The primary signal, in this case pH, is communicated through the HART 4–20 mA signal. The 4–20 mA signal is fast enough to capture and communicate oscillations as described in this scenario. With HART, digital values are utilized to communicate actual valve position as well as auxiliary measurements. Request/response communications are used to manually adjust the valve output. Block data transfer is used to communicate the valve signature. Periodic and burst data reporting are used to make the most efficient use of communication resources. Event reporting may also be used. Event reporting is used to communicate device alerts and other information included by the manufacturer. Both device status and signal status are included as part of Command 9 and utilized by the control system.

### 8.1.3 Reduced Configuration, Installation, and Checkout

HART devices are designed to work in a wide number of applications. As such, the actual process that a specific device is inserted into requires the device to be configured. As part of this configuration, each device is given a tag, a scale (instrument scaling includes high-scale value, low-scale value, engineering units, and decimal places), and a set of signal conditioning parameters (in the case of a valve, it is important to know which direction the valve goes when the signal valve is increased). The set of parameters

that a device supports and the methods available to the device are described in device description language (DDL). Users often make use of standard parameter value templates for different types of devices and use these templates to customize devices for use in their plants (tools such as an AMS 475 field communicator use DDL files to calibrate and configure field devices). In this way, devices can be completely configured off-line at the factory, in the shop, or prior to start-up by downloading the specific configuration into the device as part of the control system setup.

Configuring the control system requires a different set of information: measurements that the device supports and the signal information that is to be associated with those measurements. Signal information includes signal tag (since devices can be multivariable, they can have multiple signal tags associated with them), scaling information, alarm information, linearization, and description. Control system configuration may be downloaded into the control system at various points in the control system development. The HART protocol provides an extensive set of features to support the overall configuration, installation, and checkout procedure. All HART and WirelessHART devices are required to have a maintenance port.

### 8.1.4 Monitoring, Control, and Safety

Table 8.1 provides a classification for monitor and control applications. As shown in Table 8.1, there are six different classes of sensor and control applications ranging from critical safety (class 0) to condition monitoring and regulatory compliance (classes 4 and 5). HART devices and technology have been deployed for all of these classifications.

To better understand these classifications, it is important to consider the question, *How are measurements being used?* In many cases, the measurements are used by operators to monitor tank levels, emission levels, water quality, equipment health, and a wide range of other things. These measurements are often used to generate reports for the US Food and Drug Administration, US Environmental Protection Agency, and other agencies. These measurements are used by plant personnel to make decisions about the operation of the process, plan maintenance activities, and schedule production runs. These measurements are often directly or indirectly used to validate that the quality requirements of the finished product have been met. These measurements are also often directly or indirectly tied into feedforward and feedback control strategies.

On the control side of the discussion, there are many kinds of final control elements including valves, agitators, blowers, and conveyors. These control elements take a value and perform some action. In the case of an on-off valve, the valve attempts to open or close. In the case of a regulating valve, the read-back of the actual valve position is important in order to determine if there are problems with the final control element itself that may be impacting control performance. In the case of an agitator, it is important to know if the agitator is moving.

**TABLE 8.1** Usage Classes

Safety	Class 0: Emergency action	Always critical	
Control	Class 1: Closed-loop regulatory control	Often critical	
	Class 2: Closed-loop supervisory control	Usually noncritical	
	Class 3: Open-loop control	Human in the loop	
Monitoring	Class 4: Alerting	Short-term operational consequence (e.g., event-based maintenance)	Importance of message timeliness increases
	Class 5: Logging and downloading/uploading	No immediate operational consequence (e.g., history collection, sequence-of-events, preventive maintenance)	

Devices that take measurements or take final actions based on the controller outputs are generally smart HART devices. HART devices are the most commonly deployed fieldbus devices in the world.

### 8.1.5 WirelessHART

Protocols such as Foundation Fieldbus, Profibus, and HART are well established in the industrial process control space. Although the cost of installing and maintaining the wiring for these networks is often quite significant, they continue to dominate installations. Many years of experience with wired technologies and procedures for using them are well established. As such, the need to replace these networks with something completely new is relatively low. However, there is also a continued need to improve productivity and safety while at the same time reducing costs. In general, this means more measurements. In many cases, the most effective way to add these measurements is with wireless technology. This has created an opening for WirelessHART, which has emerged as a very significant technology in many plants.

The technology behind WirelessHART includes a combination of device improvements, network technology, and network management. Network management is the key to the operation of the wireless network in that it is used to manage network resources efficiently, schedule communications to meet the requirements of the application, and establish routing to meet reliability and performance goals. Network health reports are used to adapt the network to changing conditions. Network resources are dynamically allocated to cover changes in throughput. Security, reliability, ease of use, long battery life, and support for large numbers of devices are key requirements that can be met by a network manager.

WirelessHART devices can be line-powered or powered by either batteries or energy harvesters. Non-line-powered wireless devices (i.e., battery-powered devices) offer the most flexibility for deployment, but low energy consumption is required to make them practical. While these devices may transmit messages at an interval of every second, more typically, the average will be in increments of 8 s or longer. In general, periodic data updates from these devices will include only a few tens of bytes of data per message. Additionally, some devices may transmit stored files or time-series data on a daily basis that could be tens of kilobytes of data. In all of these cases, the on-off ratio is key to lowering the power required by the non-line-powered device.

### 8.1.6 Security

While remaining backward compatible, HART evolves continuously to keep up with the latest developments and requirements from the industry. At current release version 7, HART introduced WirelessHART as the first industrial wireless mesh network standard and Discretes for controlling discrete devices. Significantly, WirelessHART has addressed one of the biggest challenges in the process industry these days: plant security. The success gained with WirelessHART provides the guidance for the next generation of secured process plants.

WirelessHART employs robust security measures to protect the network and secure the data at all times. These measures include the latest security technologies to provide the highest levels of protection available. It uses industry standard 128 bit AES encryption algorithm at multiple tiers. The secret network key is used at the data link layer to authenticate each data transmission. At the network layer, each session has a different key to encrypt and authenticate peer-to-peer communication. A different join key is used for each device to encrypt and authenticate during the device join process. In addition, the network manager periodically changes all the keys during the lifetime of the network. WirelessHART also supports access control list (white list) through the quarantine state as part of the joining process.

## 8.2 HART Architecture

### 8.2.1 Theory of Operation

HART is a communication protocol. Its purpose is to enable digital data exchange between the field device and the host computer. The host is often represented by a master device or a gateway in the wireless case. Just like with any other network protocol, the HART host first needs to talk to the device, to find out what the device provides, and then makes use of what the device provides. In this section, how HART identifies a device, how HART describes a device's capability, what data are exchanged, and how people could develop products around HART are described.

#### 8.2.1.1 Device Identification

Each HART device has a 38-bit address that consists of the manufacturer ID code, device type code, and device-unique identifier. A unique address is encoded in each device at the time of manufacture. A HART master, for example, the AMS 475, must know the address of a field device in order to communicate successfully with it. A master can learn the address of a slave device by issuing one of two commands that cause the slave device to respond with its address:

1. Command 0, Read Unique Identifier—Command 0 is the preferred method for initiating communication with a slave device because it enables a master to learn the address of each slave device without user interaction. Each polling address (0–15) is probed to learn the unique address for each device.
2. Command 11, Read Unique Identifier by Tag—Command 11 is useful if there are more than 15 devices in the network or if the network devices were not configured with unique polling addresses (multidropping more than 15 devices is possible when the devices are individually powered and isolated.). Command 11 requires the user to specify the tag numbers to be polled.

A WirelessHART device uses this identifier to form its unique long address defined in the wireless network.

#### 8.2.1.2 Electronic Device Description Language

Electronic DDL (EDDL) [2] is a machine-readable language used to describe devices in a common and consistent way. The description describes the device, methods provided by the device, measurement and device parameters that the device supports, configuration information, and, to some extent, the interactions that the users can perform with that device. The description file for a device is called the DD of the device. A DD file provides a picture of all parameters and functions of a device in a standardized language.

HART DDL is used to write the DD that combines all of the information needed by the host application into a single structured file. The DD file identifies which common practice commands are supported as well as the format and structure of all device-specific commands. A device description is shown in Figures 8.14 and 8.15.

DD source files for HART devices resemble files written in the C programming language. DD files are submitted to the HCF for registration in the HCF DD Library. Quality checks are performed on each DD file submitted to ensure specification compliance, to verify that there are no conflicts with DDs already registered, and to verify operation with standard HART hosts. The HCF DD Library is the central location for management and distribution of all HART DDs to facilitate use in host applications such as PCs and handheld terminals.

A DD for a HART field device is roughly equivalent to a printer driver for a computer. DDs eliminate the need for host suppliers to develop and support custom interfaces and drivers. A DD-enabled host application could read and write data according to each device's procedures.

After having identified the device, the host uses the information in the unique identifier to locate the correct DD. The DD is either preloaded into the host, or retrieved from the HCF, or even read out from the device directly. Once the DD is known, meaningful communication may start between the host and the device.

### 8.2.1.3 Accessing Data

There is considerable variation between device types with regard to what data are available from it. The most common data types are the process variable, a percent of range, and a digital reflection of the analog mA signal or device status. These values are often mapped to the HART protocol primary variable (PV), secondary variable (SV), tertiary variable (TV), and fourth variable (FV). For example, a mass flow meter has derived values that would normally be obtained using standard analog instruments. The PV would be the mass flow value, the SV could be the static pressure, the TV could be the temperature, and the FV could be the digital mA signal reflection. These mappings are device dependent and user selectable. Valves have position and cycle information allowing applications to determine if the valve is functioning properly and when it is time to perform a maintenance cycle.

### 8.2.1.4 Writing Parameters and Commanding Devices

HART also describes how to write data back to the instrument. For example, the offset and span calibration data may be written. HART also supports commands that may be used to calibrate instruments. For wired devices, all of the communications are carried out over 4–20 mA wiring using the superimposed HART digital signal. For wireless devices, these communications are sent over-the-air using the IEEE 802.15.4 radios.

### 8.2.1.5 Design Approach

The HCF provides HART specifications that can be used by suppliers to design and build devices, tools, and applications. These HART specifications utilize several design approaches:

- The device description (DD described with DDL).
- HART communicates via HART messages. Using this approach, devices are able to communicate without needing to know specific details about each other.
- Service or protocol structure. The HART specifications include protocol descriptions that describe how to configure, allocate, de-allocate, limit, manage, and diagnose overall device and system resources and behaviors.
- The content of HART messages are HART commands. HART commands are defined in the application layer of the HART protocol.

DDL enables universal host applications. In one place, DDL brings together all the information a host application needs to interoperate with field devices. These applications can access all data and properties of each device, thereby simplifying maintenance, support, and operation of HART-compliant devices. It works well with small handheld hosts and large integrated maintenance systems. It works with embedded applications and applications running on commercial operating systems. DDL's power and portability save costs for host and device vendors alike.

The HART protocol supports message-oriented communication [9]. With message-oriented communications, all communication between applications is based on messages that use well-known descriptions. In the case of HART, these descriptions are HART commands. With this communication pattern, it is not necessary for applications to know internal details about each other. Interaction between applications is accomplished by passing HART commands over a common messaging medium.

HART commands are classified as universal, common practice, and device specific. Universal commands are understood and used by all field devices operating with the HART protocol (device designation, firmware number, etc.). Common practice commands are usually supported by many, but not necessarily all, HART field devices (read variable, set parameter, etc.). Device-specific commands

support functions that are unique to each device. Device-specific commands provide access to data about the type and construction of a device as well as information on the maintenance state and start-up. Most field devices support commands of all three classes.

Using messages and commands has several advantages. First, applications can be run in different environments (e.g., one side of the application may be running on a Windows-based host and the other end in an embedded device such as a Rosemount 3051 pressure transmitter). Second, not all devices need to support all commands and services. Third, services allow higher-level applications to be implemented independently of the actual protocol.

### 8.2.2 Communication Modes

HART was first conceived as a master–slave communication protocol, which means that during normal operation, each slave (field device) communication is initiated by a master communication device. Two masters can connect to each HART loop. The primary master is generally a distributed control system (DCS), programmable logic controller (PLC), or a personal computer (PC). The secondary master can be a handheld terminal or another PC. Slave devices include transmitters, actuators, and controllers that respond to commands from the primary or secondary master.

Most communications between the master and the slave are via request/response communications methods. The master initiates a request and the slave responds. The HART transport layer manages outstanding requests. The content of messages is one or more HART commands.

Later releases of HART added burst mode communications, events and event notifications, and block data transfer. Each of these communication methods is described in the following sections.

#### 8.2.2.1 Request/Response

The HART communication protocol uses request/response messages to access and change parameter values, invoke device methods, configure devices, and, in the case of WirelessHART, manage the wireless network and network devices. As an example, a request/response message pair for reading the PV is shown in Tables 8.2 and 8.3. Command-specific response codes are shown in Table 8.4.

This command is used to read the PV from the device. The HART 4–20 mA loop also transmits a single dynamic variable value using an analog signal. The PV is always associated with the first analog channel of a device. Since the analog signal on the 4–20 mA cable could only convey a single dynamic value, common practice commands are used to define the relationship between the analog signal and the digital PV.

There are many HART commands. The classification and usages of these commands are described later in this chapter.

#### 8.2.2.2 Burst Mode

Burst mode allows the master to instruct the slave device to continuously broadcast a standard HART reply message (e.g., the response of the primary process variable as shown in Table 8.3). The master

**TABLE 8.2** Command 1 Read Primary Variable Request

Byte	Format	Description
None		

**TABLE 8.3** Command 1 Read Primary Variable Response

Byte	Format	Description
0	Enum	Primary variable units
1–4	Float	Primary variable

**TABLE 8.4** Command 1 Read Primary Variable Command-Specific Codes

Code	Class	Description
0	Success	No command-specific errors
6	Error	Device-specific command error
8	Warning	Update failure
16	Error	Access restricted

receives the message at the burst rate until it instructs the slave to stop bursting. Wired devices optionally support burst mode. WirelessHART devices must support burst mode.

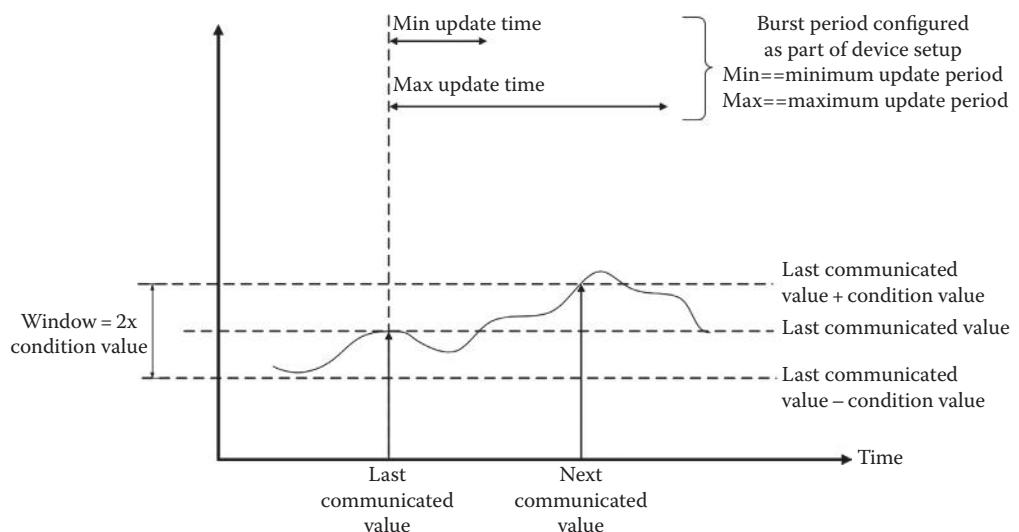

There are several supported burst modes. These are summarized in Table 8.5.

The most common burst mode supported is continuous mode. In some versions of WirelessHART devices where higher reporting rates are required, window mode is supported. Window mode is shown in Figure 8.5.

In some applications, particularly when the control strategy must control the process against a narrow constraint, rising and falling modes may be used to adjust reporting rates. On-change is used to trigger a communication when a value changes. On-change is supported by discrete devices.

**TABLE 8.5** HART Burst Modes

Burst Code	Mode	Description
0	Continuous	The <i>Burst Message</i> is published continuously at (worst case) the minimum update period
1	Window	The <i>Burst Message</i> is triggered when the source value deviates more than the specified trigger value
2	Rising	The <i>Burst Message</i> is triggered when source value <i>Rises Above</i> the specified trigger value
3	Falling	The <i>Burst Message</i> is triggered when the source value <i>Falls Below</i> the specified trigger value
4	On-change	The burst message is triggered when any value in the message changes

**FIGURE 8.5** Window burst mode.

The commands used to setup and manage burst communications are summarized later:

- Command 103: Write burst period
- Command 104: Write burst trigger
- Command 105: Read burst mode configuration
- Command 107: Write burst device variables
- Command 108: Write burst mode command number
- Command 109: Burst mode control

Multiple burst messages may be used if there is a need to communicate many values at different reporting rates.

### 8.2.2.3 Events and Event Notifications

Event notification publishes changes in the device's status independently from data publishing supported in other burst mode commands. For events, the status included in the device status byte, extended device status byte, and Command 48 may be used. It is possible to specify a limited set of bits that will trigger event notification. To prevent spurious event notifications, a de-bounce interval is configured. This defines the amount of time that a condition must persist before the event notification is timestamped and sent out. Once an event has been latched, it is transmitted repeatedly at the rate indicated by the retry period until the event has been acknowledged. Event notifications have a low priority but require a time stamp in order to indicate the first time when a notification occurred. Event notification requires and is built upon burst mode operation.

The HART protocol offers two distinct methods to display events: the device status and the Common Practice Command 48. The following commands are used to set up and manage event notification operation:

- Command 115 is used to determine the configuration of the event notification
- Command 116 selects the bits that can trigger an event notification
- Command 117 controls the timing of event notifications
- Command 118 is used to enable or disable event notification
- Command 119 is used to acknowledge the event notification

The latest values for device status, the configuration change counter, and the Command 48 response bytes are always included in Command 119. Command 116 is used to identify the bits that may trigger the event notification. Command 119 returns the status byte received only when the event mask was established using Command 116. The bytes returned in Command 119 reflect the current device status, and Command 48 data are sent regardless of which bits are masked. The time stamp remains the same until an acknowledge is received. If an acknowledge is received, the time stamp is set to the time when the acknowledge was performed.

### 8.2.2.4 Block Data Transfer

Block data transfer allows devices such as valves, vibration monitors, and analyzers to transfer blocks of information. The block data transfer mechanism is best classified as a transport layer service. The data transfer mechanism is like a pipeline. It establishes a *connection* between the host and the slave device and guarantees the transfer of a stream of data. The mechanism is designed to maximize the utilization of the HART communication bandwidth while performing the transfer.

To access this capability in a field device, the host establishes a connection to a specific *port* in the slave using Command 111. A host opens a port (Command 111), creating a pipeline to the device, and transfers data to or from the field device (Command 112).

The HART protocol includes robust error checking, and the data link layer ensures that a given command will be delivered to the slave device. A master receives a status word indicating whether the command was successful or not. Masters then perform retries to deliver commands when communication errors occur.

**TABLE 8.6** Data Transfer Features

Index	Requirement	Feature
1	Maximize data throughput	The maximum number of bytes to be transferred in a transaction is negotiated when the <i>Port</i> is opened. The more data transferred in each transaction, the more efficient the block transfer becomes.
2	Slaves and masters have differing communication buffer space	Data are transferred in blocks as large as both the master and the slave support.
3	Transfer must be reliable. No data may be duplicated or lost.	Byte counters are used to track the data transferred. Acknowledgment indicates which byte count is next expected by the recipient.
4	Must be flexible to support differing application needs	Transfer is based on a virtual connection to a <i>Port</i> . Different <i>Ports</i> support different, well-defined functions. A block of ports are allocated for device-specific requirements.
5	Transfer must be synchronous	Function codes are used to open, close, or reset a port. The port is not closed until the master and the slave both agree the transfer is complete.

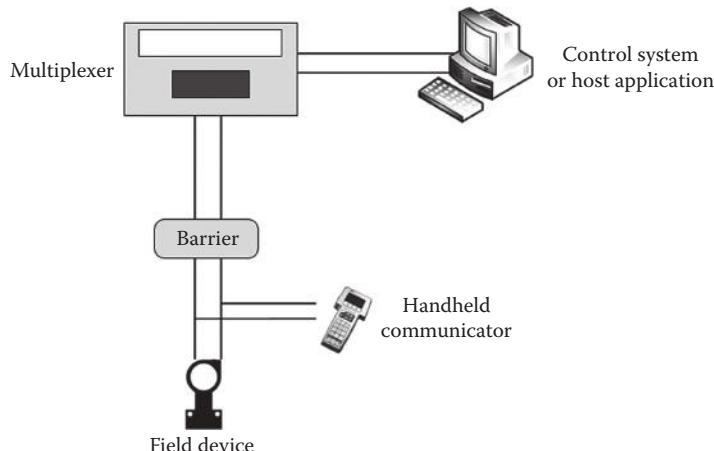

Since HART commands are normally stand-alone, implementing the retry mechanism is relatively simple. However, when transferring a block of data, retries become more complex. Since the data are transferred as a stream, the progress of the data transfer must be tracked. Table 8.6 lists features for block data transfer.

### 8.2.3 HART Network Topologies

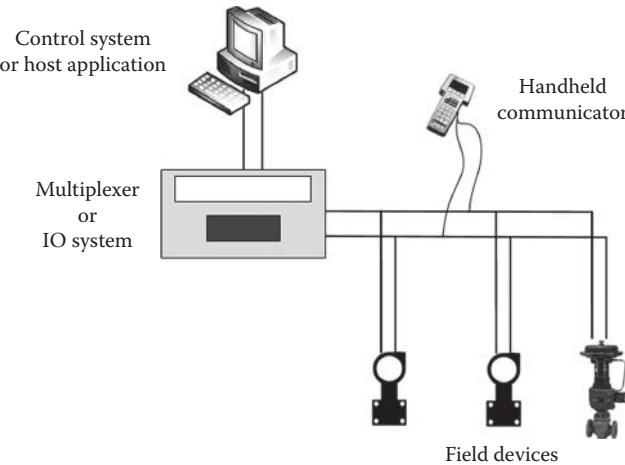

Several topologies are supported by the HART specifications. Each of these is described in the following sections.

#### 8.2.3.1 Point-to-Point

In point-to-point mode, the traditional 4–20 mA analog signal is used to communicate one process variable, while additional process variables, configuration parameters, and other device data are transferred digitally using the HART protocol as shown in Figure 8.6. The 4–20 mA analog signal is not affected by

**FIGURE 8.6** Point-to-point mode of operation. *Note:* Instrument power is provided by an interface or external power source that is not shown.

**FIGURE 8.7** Multidrop mode of operation. *Note:* Instrument power is provided by an interface or external power source that is not shown.

the HART signal and can be used for control in the standard way. The HART digital signal gives access to SVs and other data that can be used for operations, commissioning, maintenance, and diagnostic purposes.

Point-to-point communications is the most common mode of operation. Most DCS suppliers provide IO with integrated HART capabilities. In these configurations, the 4–20 mA device signal is directly connected to an IO channel as part of the DCS system.

### 8.2.3.2 Multidrop

The multidrop mode of operation requires only a single pair of wires and, if applicable, safety barriers and an auxiliary power supply for up to 15 field devices (Figure 8.7). All process values are transmitted digitally. In multidrop mode, all field device polling addresses are >0, and the current through each device is fixed to a minimum value (typically 4 mA).

### 8.2.3.3 WirelessMesh

WirelessHART extends the application of HART communications by enhancing the HART technology. The topology for WirelessHART is shown in Figure 8.4. It is a mesh network. WirelessHART builds on the wired HART universal, common practice, and device-specific commands. Since the technology is fundamentally HART, existing, previously installed host applications can, using a HART wireless gateway, access wireless-enabled HART field devices and new wireless-only HART field devices.

## 8.2.4 HART Commands

At the application layer, HART uses commands for data exchanges. The HART command set provides uniform and consistent communication for all field devices. In addition to the full set of commands for process automation, a set of new commands are defined to manage the WirelessHART network. Recently, HCF defined another set of commands to better deal with discrete devices in HART.

**TABLE 8.7** HART Universal, Common Practice, and Device-Specific Commands

Universal	Common Practice	Device Specific
Read manufacturer and device type	Read selection of up to four dynamic variables	Read or write low-flow cut-off
Read primary variable (PV) and units	Write damping time constant	Start, stop, or clear totalizer
Read current output and percent of range	Write device range values	Read or write density calibration factor
Read up to four predefined dynamic variables	Calibrate (set zero, set span)	Choose PV (mass, flow, or density)
Read or write 8-character tag, 16-character descriptor, date	Set fixed output current	Read or write materials or construction information
Read or write 32-character message	Perform self-test	Trim sensor calibration
Read device range values, units, and damping time constant	Perform master reset	PID enable
Read or write final assembly number	Trim PV zero	Write PID setpoint
Write polling address	Write PV unit	Valve characterization
	Trim DAC zero and gain	Valve setpoint
	Write transfer function (square root/ linear)	Travel limits
	Write sensor serial number	User units
	Read or write dynamic variable assignments	Local display information

#### 8.2.4.1 HART Commands for Process Automation

As shown in Table 8.7, the basic command set includes three classes: universal, common practice, and device specific. Host applications may implement any of the necessary commands for a particular application.

All devices using the HART protocol must recognize and support the universal commands. Universal commands provide access to information useful in normal operations (e.g., read PV and units).

Common practice commands provide functions implemented by many, but not necessarily all, HART communication devices.

Device-specific commands represent functions that are unique to each field device. These commands access setup and calibration information, as well as information about the construction of the device. Information on device-specific commands is available from device manufacturers.

#### 8.2.4.2 WirelessHART Commands

WirelessHART commands build on the same patterns used for device communications. These additional commands are used for gateway communications, network manager communication, and adapter communications. Each of these is summarized in Table 8.8.

#### 8.2.4.3 Discrete Device Commands

The HCF specifications provide support for discrete applications. This support includes

- Discrete field devices supporting, for example, pressure, level, or temperature switches, proximity and limit switches, solenoid valves, motor starters, and simple motion/position control
- Hybrid field devices like level transmitters that include redundant (backup) level switches or positioners with limit switches providing full-open or full-closed valve position
- Discrete adapters that communicate with a connected PLC and allow mini/micro PLCs to be incorporated into HART networks

**TABLE 8.8** WirelessHART Commands

Gateway	Network Manager	Devices
Writing networking IDs	Joining	Read wireless device capabilities
Writing network tags	Health reports	Reporting health
Managing device list entries	Report	Supporting networking resources
Managing blacklists and white lists	Path, route, and transport failures	Reporting path, route, and transport failures
Caching published data from devices	Timetable management	Supporting timetables
Managing network constraints	CCA mode management	Supporting routes
Managing stale data settings	Network flow control	Supporting superframes
Supporting host applications	Managing superframes	Supporting links
Supporting active advertising	Managing links	Supporting graphs
Maintaining device lists	Managing graphs	Supporting security keys
Flushing cached device information	Writing security keys	Supporting routes
Time source for network	Monitoring and grooming the network	
Managing device scheduling flags	Managing routes	

Discrete devices communicate process variables and discrete variables using the same communication techniques as used by traditional HART devices. Discrete variables include packed-Boolean and state variables. Discrete values must include the value along with status. In both process variables and discrete variables, the *variables* are really a collection of real-time data and the properties associated with that real-time data. For example, all discrete variables may include a fault behavior in addition to the discrete values. Commands for configuring and communicating discrete devices were added as part of HART 7.4.

## 8.3 HART Communication Stack

### 8.3.1 Overview

The HART communication standard has been in existence since the late 1980s. In its initial release, the HART field communication protocol was superimposed on a 4–20 mA signal providing two-way communications with field instruments without compromising the integrity of the analog output. The HART protocol has evolved from the initial 4–20 mA based signal to the current wired and wireless-based technology with extensive features supporting security, unsolicited data transfers, event notifications, block mode transfers, and advanced diagnostics. Figure 8.8 illustrates the architecture of the HART protocol stack according to the OSI seven-layer communication model [4].

The following sections describe the wired and wireless communication layers.

### 8.3.2 Wired Protocol

HART protocol stack includes four layers: physical layer, data link layer, transport layer, and application layer. As shown in Figure 8.9, the HART protocol allows two masters (primary and secondary) to communicate with slave devices and provide additional operational flexibility. A permanently connected host system may be used simultaneously, while a handheld terminal or PC controller is communicating with a field device.

The HART protocol ensures interoperability among devices through universal commands that enable hosts to easily access and communicate the most common parameters used in field devices. The HART DDL extends interoperability to include information that may be specific to a particular device. DDL enables a single handheld configurator or PC host application to configure and maintain

OSI layer	Function	HART
Application	Provides the user with network capable application	Command-oriented predefined data types and application procedures
Presentation	Converts application data between network and local machine format	
Session	Connection management services for applications	
Transport	Provide network independent transport message transfer	Auto-segmented transfer of large data sets, reliable stream transport, negotiated segment sizes
Network	End-to-end routing of packets and resolving network addresses	Power-optimized, redundant path, self-healing wireless mesh network
Data link	Establishes data packet structure, framing, error detection, bus arbitration	Mechanical electrical connection transmit raw data bits Secure, reliable, time-synched, TDMA/CSMA, frequency agile with ARQ
Physical	Mechanical and electrical connection and transfers raw bits	Simultaneous analog and digital signaling, 4–20 mA instrument wiring 2.4 GHz wireless, 802.15.4 based radios, 10dBm Tx power

FIGURE 8.8 HART communication layers.

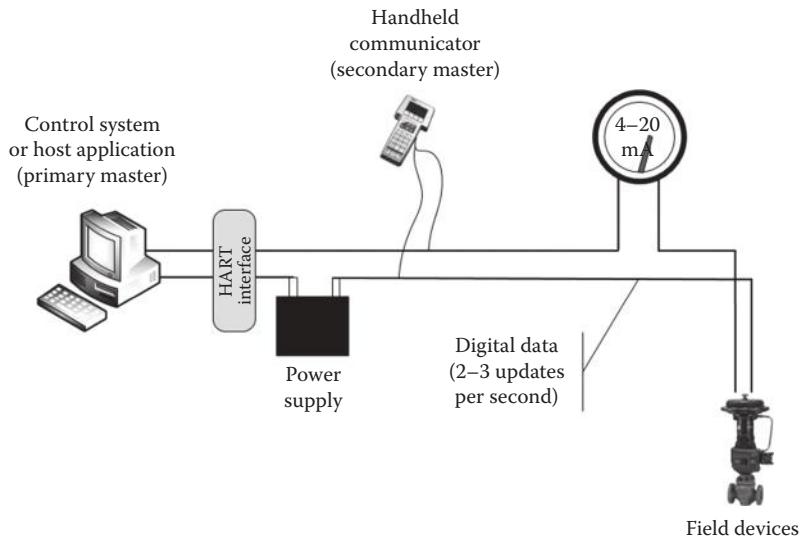

FIGURE 8.9 Multimaster setup.

HART-communicating devices from any manufacturer. The use of common tools for products of different vendors minimizes the amount of equipment and training needed to maintain a plant. The following sections provide additional details on the HART communications stack.

### 8.3.2.1 Physical Layer

Data transmission between masters and field devices is physically realized by superimposing an encoded digital signal on the 4–20 mA current loop. Since the coding has no mean values, an analog signal transmission taking place at the same time is not affected. This enables the HART protocol to include the

existing simplex channel transmitting the current analog signal and an additional half-duplex channel for digital communication in both directions. This is illustrated in Figures 8.2 and 8.3.

The physical layer defines an asynchronous half-duplex interface that operates on the analog current signal line. To encode the bits, the FSK method, based on the Bell 202 communication standard, is used. Digital value 0 is assigned frequency 2200 Hz, and digital value 1 is assigned frequency 1200 Hz. Each individual byte of the layer-2 message is transmitted as 11-bit UART character at a data rate of 1200 bits/s.

The HART specification defines that master devices send voltage signals, while the field devices (slaves) convey their messages using load-independent currents. The current signals are converted to voltage signals at the internal resistance of the receiver (at its load). To ensure a reliable signal reception, the HART protocol specifies the total load of the current loop including the cable resistance to be between 230 and 1100  $\Omega$ . Usually, the upper limit is determined by the power output of the power supply unit.

As shown in Figure 8.3, the HART masters are connected in parallel to the field devices. Connecting this way allows handhelds to be connected and disconnected during operation without disrupting the current loop.

HART wiring in the field usually consists of twisted pair cables. If very thin and/or long cables are used, the cable resistance increases and, hence, the total load. As a result, the signal attenuation and distortion increases, while the critical frequency of the transmission network decreases.

If interference signals are a problem, then the wiring must be shielded. The signal loop and the cable shield should be grounded at one common point only. According to the specification, the following configurations work reliably:

- For short distances, simple unshielded 0.2 mm two-wire lines are sufficient.
- For distances of up to 1500 m, individually twisted 0.2 mm two-wire pairs with a common shield over the cable should be used.
- For distances of up to 3000 m, individually twisted 0.5 mm two-wire lines shielded in pairs are required.

HART communication between two or more devices can function properly only when all communication participants are able to interpret the HART signals correctly. To ensure this, both the cables and devices in the current loop that are not part of the HART communication must also fulfill the requirements. Those devices can impede or even prevent the transmission of the data. The reason is that the inputs and outputs of these devices are specified only for the 4–20 mA technology. Since the input and output resistances change with the signal frequency, such devices are likely to short-circuit the higher-frequency HART signals (1200–2200 Hz). To prevent this, the internal resistance must be increased using an additional circuit. An RC low-pass circuit (250 W, 1 mF) performs this function.

### 8.3.2.2 Data Link Layer

The data link layer provides a reliable, transaction-oriented communication path to and from field devices for digital data transfer. Communications are over twisted pair wire that may be simultaneously carrying the 4–20 mA signals. The data link layer corrects for errors due to noise or other disturbances on the communication links by using error detecting information and an automatic repeat request protocol to request the retransmission of data blocks that may be corrupted.

HART is a master-slave protocol and is loosely organized around the ISO/OSI seven-layer model for communications protocols. The data link layer supports the application layer above it and requires services from the physical layer below it. Furthermore, the data link layer can be divided into two sublayers: the logical link control responsible for addressing, framing, and error detection; and the medium access control that controls the transmission of messages across the physical link.

The data link layer supports long (5 byte) *unique* and short (1 byte) *poll* addresses. Polling addresses may be used only with Command 0. This allows the HART protocol to support both point-to-point and multidropped communication with field devices. If poll (short form) addresses are used, up to 64 slave

devices may be multidropped on a single communication link. If unique (long-form) addresses are used, the number of multidropped devices is essentially unlimited and is determined based on the application's required rate of scan of the devices on the communication link.

The data link layer arbitrates access to the field device between a single secondary master device such as a handheld terminal and a single primary master device such as a control or data acquisition system. The data link layer gives equal access to the communication channel to both kinds of masters when they are being simultaneously used. The data link layer does not arbitrate between two secondary or two primary masters that are trying to talk on the same link.

To support the regular transfer of information from field device to master device, the data link layer supports a mode of operation in which field devices periodically broadcast information onto the communication link. A slave device is said to be in *burst mode* when it is providing a synchronous cyclic broadcasting of data, without continuous polling by a master device. No matter how many field devices are on a communication link, only one may be in burst mode.

Information transfer between devices on the communication link is through a defined message format. The entire message is protected by a single parity check product code. Message framing is through a combination of a start of frame delimiter and a message length field.

HART devices supporting burst communication mode send packets with short 75 ms breaks, which can alternately be read by the primary as well as the secondary master. While usually only two transactions per second are possible, the field device can send up to four messages using this method.

The structure of a HART message is shown in Figure 8.10. Each individual byte is sent as an 11-bit UART character equipped with a start, a parity, and a stop bit. In revision 5 and later, the HART protocol provides two message formats, which use different forms of addressing. In addition to the short frame slave address format containing 4 bits, a long frame address format has been introduced as an alternative. This allows more participants to be integrated, while achieving more safety in case of incorrect addressing during transmission failures.

The elements of the HART frame are summarized as follows:

- The *delimiter* is the first field in a HART message. It is used for message framing by indicating the position of the byte count. It also indicates the frame type, which is used for bus arbitration. Three frame types are supported by the HART data link layer:
  - An STX (0x02) indicates a master to field device (i.e., a slave or burst mode device) frame. An STX is the start of a transaction and is normally followed by an ACK.
  - An ACK (0x06) is the slave's or burst mode device's response to an STX.
  - A BACK (0x01) is a burst acknowledge frame periodically transmitted by a burst-mode device. These frames are transmitted without a corresponding STX.

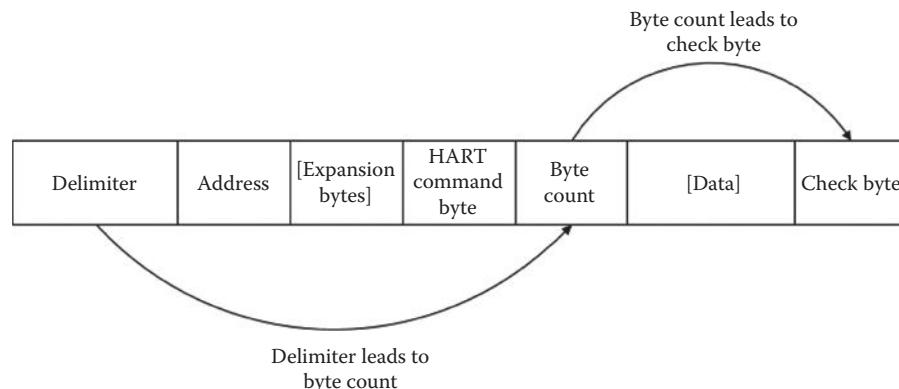

FIGURE 8.10 HART frame structure.

- The *address* field can be short or long. The protocol supports both five (5) byte *unique* addresses and one (1) byte polling addresses. The length of the address field (1 or 5 bytes) is indicated by the delimiter. The address field always includes the master address, the slave address, and (for ACK and BACK frames) whether the slave is in burst mode. The short and long address formats are as follows:
  - The address field of the short frame format contains 1 byte with 1 bit serving to distinguish the two masters and 1 bit to indicate burst-mode messages. For the addressing of the field devices, 4 bits are used (addresses 0–15).
  - The address field of the long frame format contains 5 bytes; hence, the field device is identified using 38 bits.
- The *expansion* bytes are optional. This field is 0–3 bytes long and its length is indicated in the delimiter. The definition of the expansion bytes is controlled by the HCF. If a field device does not know the meaning of all expansion bytes contained in the frame, then the field device must not answer.
- The *command* byte encodes the master commands of the three categories: universal, common practice, and device-specific commands. The significance of these commands depends on the definitions in the application layer.
- The *byte count* character indicates the message length, which is necessary since the number of data bytes per message can vary from 0 to 25. This is the only way to enable the recipient to clearly identify the message and the checksum. The number of bytes depends on the sum of the status and the data bytes.
- The *data* field is optional and consists of an integral number of bytes of application layer data. The data field contains subfields as defined in the command summary specification and contains the information transferred between the host application and the field device. The data can be transmitted as unsigned integers, floating-point numbers, or ASCII-coded character strings. The data format to be used is determined by the command byte. However, not all commands or responses contain data.
- The response message includes two status bytes at the beginning of the data portion of the message. The two status bytes indicate whether the received message was correct and the operational state of the field device. When the field device operates properly, both status bytes are set to logical zero.
- This *check byte* field is 1 byte long. The check byte value is determined by a bitwise exclusive OR of all bytes of a message including the leading delimiter.

The time required to transmit a message results from the bit data rate (1200 Hz) and the number of bits per message. The length of the message varies depending on the message length of 0–25 bytes and the message format. For a payload of 25 bytes, a total of 35 bytes must be transmitted. Since each byte is transmitted as UART character, the following data are obtained:

Bytes per Message	35 (25 Payload Characters + 10 Control Characters)	
Message size	35 characters × 11 bits	385 bits
Usable data rate	25 × 8 bits/385 bits	52%
Time per bit	1/1200 bits/s	0.83 ms
Transaction time	385 × 0.83 ms	0.32 s

### 8.3.2.3 Transport Layer

Traditionally, the wired HART protocol is considered to support only three layers of the ISO/OSI seven-layer model for communication protocols. The reality is that these are also elements of the transport layer found in the protocol specifications such as block data transfer. The block data transfer mechanism, as is described in Section 8.2.2.4, is best classified as a transport layer service.

The HART transport layer is fully described in HART 7 and is utilized as part of the WirelessHART specifications.

### 8.3.2.4 Application Layer

The communication routines of HART master devices and operating programs are based on HART commands that are defined in the application layer of the HART protocol. Predefined commands enable the master device to give instructions to a field device or send messages/data. So setpoints, actual values, and parameters can be transmitted and various services for start-up and diagnostics performed. The field devices immediately respond to a request by sending an acknowledgment that can contain requested status reports and/or the data of the field device.

An example command is Command 33. This HART command enables the master to read four transmitter variables of the field device and the corresponding units of measurement with only one command.

HART commands are classified by universal, common practice, and device specific. These classifications were described in Section 8.2.4.

## 8.3.3 Wireless Protocol

The WirelessHART protocol stack includes five layers: physical layer, data link layer, network layer, transport layer, and application layer. In addition, a centralized network manager is responsible for overall network routing communication scheduling [10][11].

### 8.3.3.1 Physical Layer

The WirelessHART physical layer is based on the IEEE 802.15.4-2006 2.4 GHz DSSS physical layer, which includes 15 of 16 possible RF channels. WirelessHART fully conforms to IEEE 802.15.4-2006 [13]. Additional physical layers can be easily added in the future as radio technology evolves.

### 8.3.3.2 Data Link Layer

The WirelessHART data link layer (DLL) is based on a fully compliant IEEE 802.15.4-2006 MAC. The WirelessHART DLL extends the functionality of the MAC by defining a fixed 10 ms timeslot, synchronized frequency hopping, and time division multiple access to provide collision-free and deterministic communications. To manage timeslots, the concept of a *superframe* is introduced that groups a sequence of consecutive timeslots. A superframe is periodic, with the total length of the member slots as the period. All superframes in a WirelessHART network start from the ASN (absolute slot number) 0, the time when the network is first created. Each superframe then repeats itself based on its period. In WirelessHART, a transaction in a timeslot is described by a vector: {frame id, index, type, source address, destination address, channel offset} where frame id identifies the specific superframe; index is the index of the slot in the superframe; type indicates the type of the slot (transmit/receive/idle); source address and destination address are the addresses of the source device and destination device, respectively; and channel offset provides the logical channel to be used in the transaction. To fine-tune the channel usage, WirelessHART introduces the idea of channel blacklisting. Channels affected by consistent interferences could be put in the blacklist. In this way, the network administrator can totally disable the use of those channels in the blacklist. To support channel hopping, each device maintains an active channel table. Due to channel blacklisting, the table may have less than 15 entries.

### 8.3.3.3 Network Layer

The network layer is responsible for several functions; the most important of which are routing and security within the mesh network. Whereas the DLL moves packets between devices, hop by hop, the network layer moves packets end-to-end within the wireless network. The network layer also includes other features such as route tables and timetables. Route tables are used to route communications along graphs. Timetables are used to allocate communication bandwidth to specific services such as publishing data and transferring blocks of data. Network layer security provides end-to-end data integrity and privacy across the wireless network.

### 8.3.3.4 Transport Layer

The WirelessHART transport layer provides a reliable, connectionless transport service to the application layer. When selected by the application layer interface, packets sent across the network are acknowledged by the end device so that the originated device can retransmit lost packets.

### 8.3.3.5 Application Layer

The application layer is HART. Because of this, access to WirelessHART is readily available by most host systems, handhelds, and asset management systems.

One key to these network layers is the network manager. Network manager is a special WirelessHART node that manages the mesh network. It sets the different parameters in each network layer in a comprehensive way so that individual nodes in the network work together as a whole.

## 8.4 System Tools

---

We have talked about HART devices, HART hosts, and HART networks. This is not enough. HART technology shines when it is fully integrated with a control system. In this section, we describe ways a control system works with HART. We describe technologies to bridge the gap with legacy control systems. We also introduce system tools that work with HART technology.

### 8.4.1 Host Interfaces

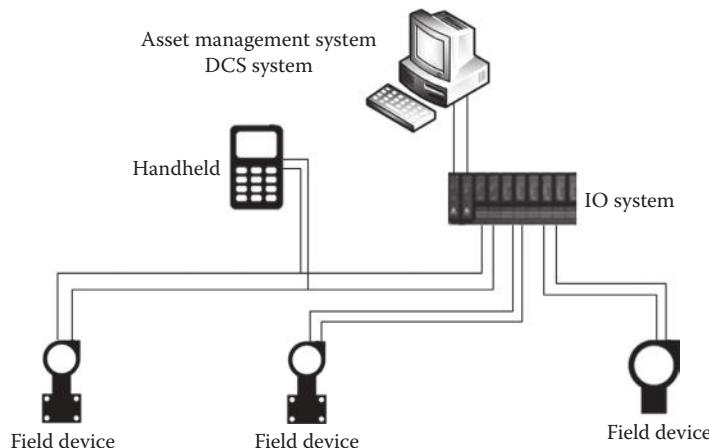

There are many setups that may be used for connecting HART devices to host systems. Several setups are presented in the following sections.

#### 8.4.1.1 HART Point-to-Point Interface

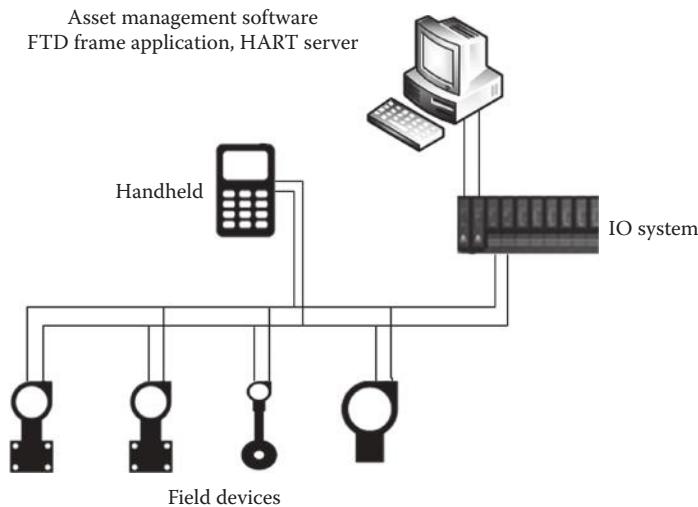

In this scenario, the HART interface is a point-to-point interface. This topology is most often used for control system interfaces. Instrument power may in some cases be provided by the twisted pair connections. In other cases, external power is required. Figure 8.11 shows a point-to-point scenario without external power.

#### 8.4.1.2 HART Multidrop Interface

In this scenario, the HART interface is provided through an IO system. In some cases, this could be as simple as a modem interfaced to a laptop. This topology could be used to support higher-level applications

**FIGURE 8.11** HART point-to-point interface.

**FIGURE 8.12** HART multidrop.

such as an asset management application. The multidrop mode of operation requires only a single pair of wires and, if applicable, safety barriers and an auxiliary power supply for up to 15 field devices. All process values are transmitted digitally. In multidrop mode, all field device polling addresses are >0, and the current through each device is fixed to a minimum value (typically 4 mA). Instrument power is provided by an interface or external power source. This scenario is shown in Figure 8.12 without an external power source.

#### 8.4.1.3 Utilizing an FTA with Legacy Control Systems

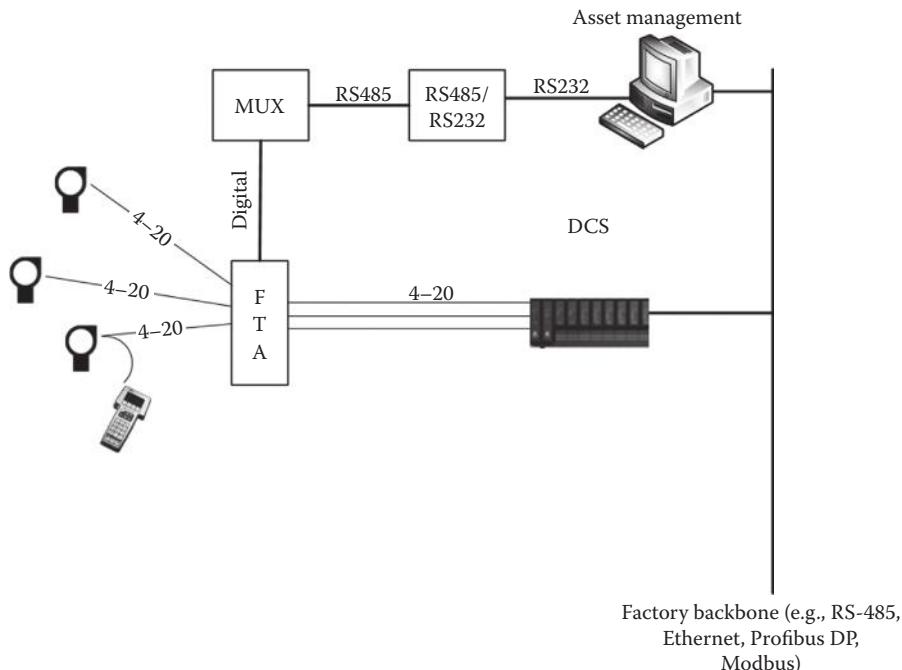

Many legacy control systems may not support the HART signal. In these cases, what may be done is to connect the 4–20 mA signal to a field terminal assembly (FTA) and then wire the FTA to both the control system and a separate system for device management and diagnostics. Figure 8.13 is one example. In other cases, the control system may handle HART but not provide support for an asset management system. In this case, commands such as 0–3, 11, and 13 may be handled by the DCS. Other commands, including configuration and diagnostics, are passed to the asset management system.

#### 8.4.2 Hosts with Limitations on Data Handling

All HART-compatible control systems can read the digital PV from a slave device. However, some system architectures may not be able to accommodate textual data (e.g., tag and descriptor fields). In these cases, the controller is able to read the process variable, but may not have direct access to all other data in the HART device. In this scenario, FTA could also be used to handle the textual data.

#### 8.4.3 Hosts with Pass-Through Messages

Some control systems are integrated with a configuration or instrument management application. In these systems, the control system manages the process, while the management application manages the devices. The control system passes a HART command, issued by the management application, to the field device via its I/O interface. When the control system receives the reply from the field device, it sends the reply to the management application. This function is referred to as a pass-through feature of the control system.

**FIGURE 8.13** Using a field terminal assembly.

#### 8.4.4 Tools Utilizing Device Configuration (DDL)

The HART commands are based on the services of the lower layers and enable an open communication between the master and the field devices. This openness and the interchangeability of the devices, independent of the manufacturer, are available only as long as the field devices operate exclusively with the universal and common practice commands and the user does not need more than the simple HART standard notation for the status and fault messages. In practice, this is not often the case since companies differentiate themselves through measurement technology, diagnostics, and advanced applications that are ideally tuned to work with their devices. The HART standard allows for these innovations through the DDL.

DDL allows the manufacturer to fully describe device-related information and the special properties of a field device. For this reason, DDL is also used in other fieldbus networks such as foundation fieldbus. It is also currently being utilized as a key part of the emerging FDI standard.

The DDL language is a domain-specific language (DSL). A DSL is a programming language that's targeted at a specific problem; other programming languages such as C++ are more general purpose. A DSL contains the syntax and semantics that model concepts at the same level of abstraction that the problem domain offers. In this case, since the domain is devices, the DSL DDL is designed specifically to support all aspects of device description and management.

With DDL, a generic host system could take advantage of the innovations in a device by reading the device's DD, automatically improving plant performance. An example DD is shown in Figure 8.14.

The item declarations for this layout are shown in Figure 8.15.

The actual display for this DD is shown in Figure 8.16.

#### 8.4.5 WirelessHART Tools

WirelessHART shares the application layer with wired HART. As a consequence, all HART tools currently in use could be used with a WirelessHART device. In some cases, the tools are enhanced to support

additional features in WirelessHART. For example, WirelessHART adaptors act as master devices for traditional wired HART devices and present them as subdevices on a WirelessHART network. An enhanced HART tool could interact with these subdevices just like with any other HART devices.

In addition, special new tools are available for WirelessHART. In this section, we describe three such tools. Two are exclusively for WirelessHART: Wi-HTest and Wi-Analys. They are used to help develop, configure, and diagnose WirelessHART devices and networks. The third tool is the WirelessHART handheld device, an extension to wired HART handhelds.

#### 8.4.5.1 Wi-HTest

All HART devices must be registered with the HART Foundation. As part of the registration process, a device is thoroughly tested at each of its network layers. The testing system for the HART device is called HTest. In addition, a WirelessHART device is subjected to Wi-HTest, which checks the wireless conformances. The product name for Wi-HTest is HCF\_KIT-193™.

FIGURE 8.15 HART DDL item declarations.

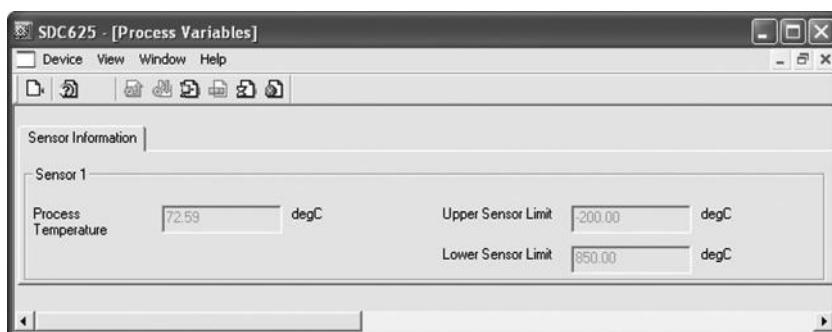

FIGURE 8.16 HART device display built with DDL.

**FIGURE 8.17** Wi-HTest tool.

Figure 8.17 shows the actual Wi-HTest tool. It includes two boxes: the tool itself on the left and the access point with radio on the right. The tool box is an embedded computer. The user plugs a mouse, a keyboard, and a monitor into the tool box.

Wi-HTest works one-on-one with a WirelessHART device. They are also connected by wire via the maintenance port. There is a suite of test script software installed in the tool box. Each test script is independently executed and performs a series of interactions with the device. Depending on the focus and complexity, a script checks the device functionality at the physical, data link network, and application layers, or a combination of the layers. The script is written in CINT, an interpretive version of the C language. There is also support for the user to write new test scripts.

A typical script runs in the following sequence:

- Use the maintenance port to set up the device. Wired HART commands are used.
- Send Force-Join Command 771 to the device via the maintenance port; wait for the device to join wirelessly.
- Once the device has joined, configure the device with wireless commands.
- Perform a series of tests, mostly wirelessly, with the device.
- Disconnect the device and end the test.

The usefulness of Wi-HTest goes beyond the conformance test. Companies could purchase it for different uses. It could help in WirelessHART product development. It could be used to configure a device. When used without the maintenance port connection, Wi-HTest could act as a WirelessHART gateway for a single-device network, in which different scripts could be designed to manipulate the device.

The wireless messages exchanged between the Wi-HTest and the device could be captured by Wi-Analys, the tool we shall describe next.

#### 8.4.5.2 Wi-Analys

Wi-Analys is a wireless sniffer tool that captures all WirelessHART messages on all WirelessHART defined physical channels at the 2.4 GHz frequency band. The product name for Wi-Analys is HCF\_KIT-190™.

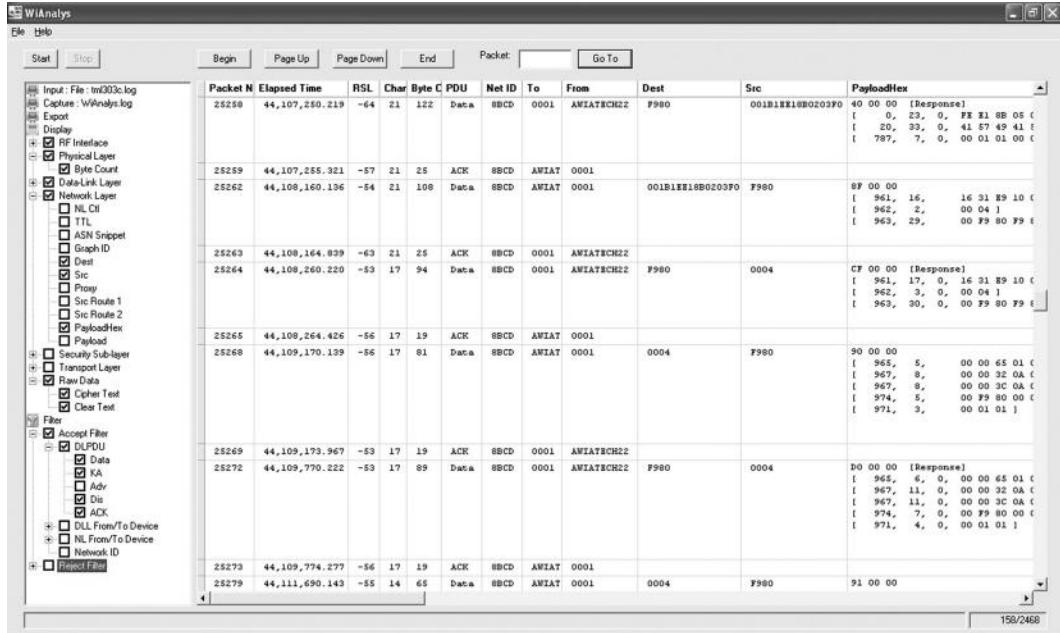

The hardware for Wi-Analys is a single box with an antenna, as shown in Figure 8.18. The box is connected via a USB cable to a Windows PC, on which the software is installed. The software includes a service receiving the streaming messages from the box and a user interface displaying the messages in

**FIGURE 8.18** Wi-Analys tool.

WirelessHART format. The messages are decrypted if the security information is available to the software. The software is intelligent enough to extract some of the keys from the captured messages. Figure 8.19 shows the user interface.

Let's look at the messages displayed in Figure 8.19 column by column. The displayed columns are selected using the check marks in the left-hand pane. The check boxes at the bottom are for message

**FIGURE 8.19** Wi-Analys screen capture.

filtering. The message in the first row is numbered packet 25258. The elapsed time is the time since the Wi-Analys is powered on until the message is captured. The received signal level is -64. The message is transmitted on physical channel 21. There are 122 bytes in the message. This WirelessHART message type is *data*. The message is sent at the data link layer to node 0x0001 from a node named AWIATECH22. At the network layer, the destination node is the network manager 0xF980, and the source node is unique ID 0x001B1EE18B0203F0. The application layer payload contains three commands, Commands 0, 20, and 787. From this information, we know this is a join request message from a new device with that unique ID to the network manager, and the access point 0x0001 is the proxy node interacting with the device.

Wi-Analys is used together with Wi-HTest in conformance testing. Each Wi-HTest execution log includes a Wi-Analys capture to help postanalyze the test result. As a matter of fact, special wireless messages are sent from Wi-HTest to Wi-Analys for coordination and to better manage the captured messages.

Wi-Analys is not limited to conformance testing. It is a complete network sniffer tool for WirelessHART, just like other commercial sniffer tools for wired or wireless networks such as Ethernet and Wi-Fi network. For any use case for a commercial network sniffer, we have a use case for Wi-Analys.

#### 8.4.5.3 Wireless Handheld

WirelessHART handheld is the natural progression of the wired HART handheld. A HART handheld device is shown in earlier figures in this chapter. It connects by wire to the HART network. A wireless handheld connects without wire to the WirelessHART network. Regardless of how it is connected, the wireless handheld has the same functionality as its wired counterpart.

WirelessHART defines two ways a handheld communicates with the network: talking to a targeted field device or joining the network as a regular device. When joining as a regular device, the handheld could only talk to the network manager and the gateway just like other regular devices. This way the handheld could request the diagnostic and health report information, but it could not talk to an individual device directly.

The handheld could talk to an active device in the network via a preconfigured special session between the two. With this connection, the handheld could gather device information, run diagnostics, calibrate, etc. This is similar to the wired handheld; the difference is in how the connection is set up. The special session is set up by the network manager and preconfigured in the device. The handheld acquires the session information and other network information from the network manager. It then listens for the device's advertisement messages from which the initial communication links are extracted. From these links, the session and related communication bandwidth are established. Once the work is done, the handheld terminates the communication, just like you disconnect the wires of the wired handheld.

## 8.5 Planning and Installation

---

### 8.5.1 Wired HART

In general, the installation practice for HART communicating devices is the same as for conventional 4–20 mA instrumentation. Individually shielded twisted pair cable, either in single-pair or multipair varieties, is the recommended wiring practice. Unshielded cables may be used for short distances if ambient noise and cross talk will not affect the communication. The minimum conductor size is 0.51 mm diameter (#24 AWG) for cable runs less than 1524 m (5000 ft) and 0.81 mm diameter (#20 AWG) for longer distances.

**TABLE 8.9** Non-IS Wired HART Cable Lengths

Number of Devices	Cable Capacitance—pf/ft (pf/m)			
	20 pf/ft (65 pf/m)	30 pf/ft (95 pf/m)	50 pf/ft (160 pf/m)	70 pf/ft (225 pf/m)
1	9000 ft (2769 m)	6500 ft (2000 m)	4200 ft (1292 m)	3200 ft (985 m)
5	8000 ft (2462 m)	5900 ft (1815 m)	3700 ft (1138 m)	2900 ft (892 m)
10	7000 ft (2154 m)	5200 ft (1600 m)	3300 ft (1015 m)	2500 ft (769 m)
15	6000 ft (1846 m)	4600 ft (1415 m)	2900 ft (892 m)	2300 ft (708 m)

Allowable cable lengths for 1.02 mm (#18 AWG) shielded twisted pair.

Most installations are well within the 3,000 m (10,000 ft) theoretical limit for HART communication. However, the electrical characteristics of the cable (mostly capacitance) and the combination of connected device scan affect the maximum allowable cable length of a HART network. Table 8.9 shows the effect of cable capacitance and the number of HART devices on the cable. The table is based on typical installations of HART devices in non-IS (intrinsic safe) environments, that is, no miscellaneous series impedance. Detailed information for determining the maximum cable length for any HART network configuration can be found in the HART physical layer specifications.

HART is often used in IS installations. IS is a method of providing safe operation of electronic process control instrumentation in hazardous areas. IS systems keep the available electrical energy in the system low enough to prevent ignition of the hazardous atmosphere. No single field device or wiring is intrinsically safe by itself (except for battery-operated self-contained devices such as a WirelessHART device), but is intrinsically safe only when employed in a properly designed IS system. Most DCS suppliers provide IS-rated IO that is compatible with HART.

### 8.5.2 WirelessHART

In many cases, the WirelessHART network may be configured similarly to a wired HART network. In these cases, the gateway is the remote I/O system connecting wireless devices and adaptors to DCSs, PLCs, and other plant automation systems. And the access points are the I/O modules of the gateway. The gateway has one or more access points that connect wireless devices to the gateway. The WirelessHART network starts with the gateway and access points at one end and the field devices at the other. Access points can be geographically dispersed from the gateway electronics and in general should be located near the devices to which they connect.

A key consideration is the number of devices that may be connected, directly or indirectly, to one access point, which is called the access point loading:

$$\text{NumDevices} = \text{Average update period (AUP)} \times 25$$

For example, with an average reporting rate of once per 1 s, 25 devices may be connected with an access point; with an average reporting rate of once per 10 s, 250 devices can be connected with an access point.

This criterion is similar to that used for any traditional I/O: do not crowd the I/O. When in doubt, use more access points. With little additional cost, this increases the number of alternative network paths and makes the network more robust.

Another formula that may be used to estimate the average bandwidth consumed by a WirelessHART network is as follows:

$$\text{Bandwidth Consumed} = \text{NumDevices} \times \left( 0.0001\% + \left( \frac{0.02\%}{\text{AUP}} \right) \right)$$

where

0.0001% is used for overhead (network health reports and the like)

0.02% is for data publishing and other network traffic

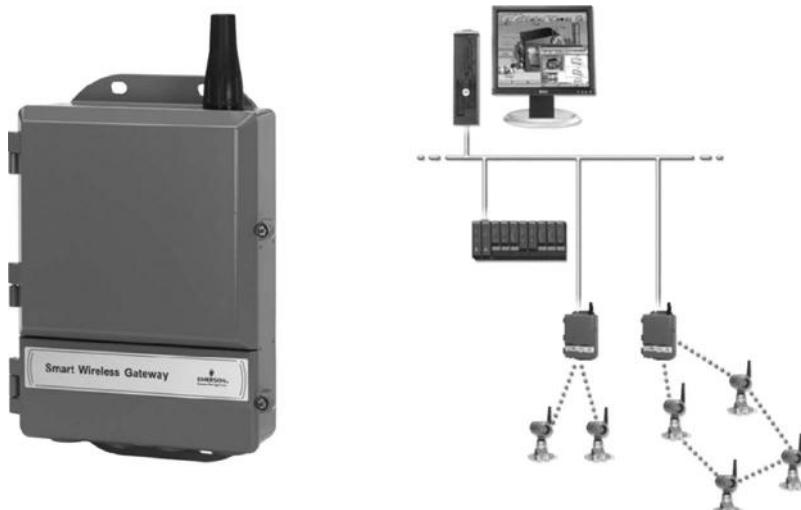

For example, 100 devices at an average update interval of 1 s will consume 2.01% of total bandwidth; 1500 devices at average update interval of 60 s will consume 0.65% of total bandwidth.

These are very conservative estimates that do not account for the size of the area. For large networks, devices farther apart could use the same channel at the same time. And the bandwidth usages in one place will be less than the total network bandwidth due to the distance fading of the radio energy. With this formula, the user could estimate whether the WirelessHART network will coexist well with other 2.4 GHz networks in the same plant area.

A huge benefit of WirelessHART is its adapter. The adapter can be located anywhere along the current loop from the device to the I/O module. This allows existing HART devices to be adapted to wireless. It also frees the designer from having to locate the device in a better reception area instead of where the device physically should belong.

WirelessHART networks are easier and less costly to install than traditional wired HART systems simply because there are no wires to pull through cable trays. You simply locate where the devices should be mounted in the plant and install them, then install the access points and gateway. All WirelessHART devices are default routers, but to fortify the mesh network, routing devices may be added at strategic locations. After the devices have joined the network, simply configure them, and the wireless mesh forms and communications begin. It is as easy as a traditional HART 4–20 mA installation, with the same tools and know-how. An example installation is shown in Figure 8.20.

An example of a gateway is the Rosemount 1420 Wireless Gateway. The 1420 includes both the security manager and the network manager. The 1420, through a web browser, provides an interface for users to set up security, run diagnostics, and configure information about the wireless mesh. The gateway is

**FIGURE 8.20** Connecting WirelessHART to the control system.

also the entry point for host and DCS systems to access wireless device data. The 1420 enables integration with popular communication protocols such as Modbus, OPC, and TCP/IP via Ethernet or serial connections.

In many situations, the gateway connects to the control system through native interfaces and shows up as a part of the overall configuration system. In other cases, industry standard mechanisms such as Modbus and OPC may be used.

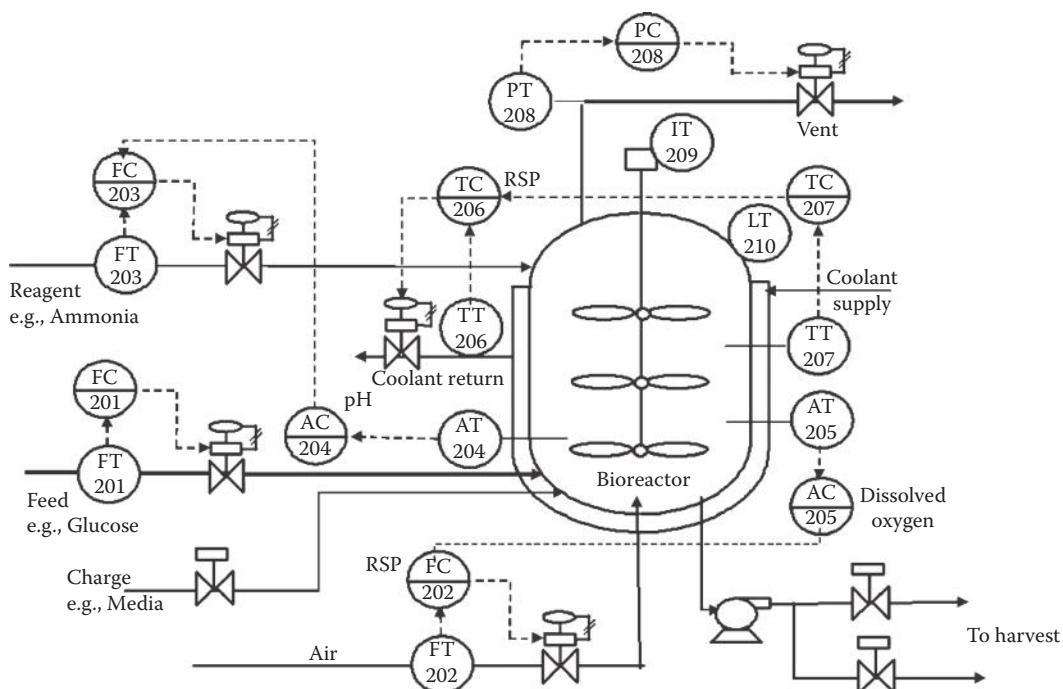

## 8.6 Application Example: Bioreactor

The HART communication protocol enables companies to make sure measurements are as efficient, accurate, and timely as possible. Control and monitoring applications are ideal for a HART point-to-point configuration. The HART network 4–20 mA fast update rates are ideal for pressure and flow measurements. Digital measurements may be used to communicate actual valve position as well as other parameters. Accurate and timely measurement for control of bioreactors is essential in all industries. We use a bioreactor process in Figure 8.21 to show how HART is best suited for such applications.

The measurements, actuators, blocking valves, and scan rates are summarized in Table 8.10.

The primary objective of most field devices will be to provide a process measurement. The frequency at which this information is required by the process automation host is specific to the process equipment and the measurement type (e.g., pressure, temperature, flow, level, and analytical). Thus, as part of the process automation host configuration, the user configures the following information for all network devices that are accessed through the HART host interface:

- Device Tag—which uniquely identifies the device (e.g., HART Tag)
- Measurement value(s) that are to be accessed in the network device
- How often each measurement value is to be communicated to the gateway

**FIGURE 8.21** Bioreactor process.

**TABLE 8.10** Instrument and Valve List for Bioreactor

Category	Device	Measurement	Scan Rates (s)
Measurement	C1	Reactor level (LT210)	16
	C2	Feed flow (liquid—FT201)	1
	C3	Reactor gas pressure (PT208)	1
	C4	Reactor temperature (TT207)	4
	C5	Agitator amps (IT209)	8
	C6	Return water temperature (TT206)	16
	C7	Reagent flow (FT203)	1
	C8	Air flow (FT202)	1
	C9	Dissolved oxygen (AT205)	4
	C10	pH (AT204)	4
Regulating valve	A1	Feed flow (FV201)	1
	A2	Reagent flow (FV203)	1
	A3	Coolant flow (FV206)	1
	A4	Vent flow (FV208)	1
	A5	Air flow (FV202)	1
Blocking valve	B1	Charge flow (FZ211)	1
	B2	Harvest flow (FZ212)	1
	B3	Harvest flow (FZ213)	1

Device configuration settings would typically be configured using a HART handheld or asset management system. The control configuration would typically be configured using the control system connected to the bioreactor.

In this example, we assume that all field devices are HART devices, and they are connected to the host using different HART topologies. Note that we could have WirelessHART devices in the mix.

## 8.7 Future Directions

Wired HART and WirelessHART continue to build on the innovation that was started in the late 1980s. Current advancements follow a well-established foundation in interoperability and design patterns described earlier in this chapter. In this section, we will discuss the following two questions: *What are the business drivers?* and *How will the device infrastructure evolve to support these business drivers?* [11]

Starting with the business drivers, all business performance is based on value that can be generated from its assets. These assets range from people and materials, to intellectual content, to physical properties. Plants are becoming much more integrated with business systems. These plants operate too much tighter requirements, are expected to be able to adjust production schedules in real time to changes in conditions and orders, and are much more regulated. Achieving these objectives requires a much greater understanding of the process, improved understanding of the state of the equipment in the plant, and far better data analysis techniques. The people operating these plants will likely hold degrees and, in many cases, advanced degrees.

This leads to the second question: *How will the device infrastructure evolve to support these business drivers?* The answer to this second question must be considered in several parts. Gaining process insight involves an increased number of measurements, providing more diagnostics on the devices providing the measurements, providing diagnostics on the process that the devices are part of, and moving things online that were in the past done manually. The first release of the WirelessHART standard went a long way toward making it possible both to reach advanced measurements and diagnostics that are already in devices today and to cost effectively measure many things that were difficult to reach in the past. In the first case, many plant infrastructures today are ill equipped to report advanced diagnostics.

Wireless allows these measurements to be communicated on an alternative infrastructure. In other cases, the type of equipment, for example, rotating equipment, made it difficult to take measurements. It is a lot easier to attach devices to this kind of equipment and let the wireless infrastructure take care of the communications. In still other cases where state-of-the-art was manual measurement, wireless makes it cost effective to periodically take these measurements and communicate them. An example of this is equipment health and monitoring. New devices are being designed and built to measure vibration and communicate signal values and diagnostics back to online centralized systems. So what does this mean for HART?

HART today is the workhorse of the industry. There is little evidence to suggest that this will change anytime soon. In this light, the most recent additions such as discrete devices and burst mode enhancements continue to be released for both wired and wireless technologies. Innovation will continue, and both wired and wireless devices will be there to serve users.

### 9.1 Introduction

---

Traditionally, networks used in manufacturing enterprises were optimized for performance in specific applications, most commonly for control, information, and safety. While well suited to the functionality for which they were designed, these networks were not developed with a single, coherent enterprise architecture in mind. Since efficiency, reliability, and, ultimately, profitability are generally dependent on having more than one of these capabilities, manufacturers were forced to implement several different networks, none of which communicated innately with the other. As a result, over the course

of time, most manufacturing enterprise network environments have been characterized by numerous specialized—and generally incompatible—networks existing in one space.

Today, however, corporate expectations for the manufacturing automation network landscape are dramatically different, thanks to the rapid and ubiquitous adoption of Internet technology. Companies of all sizes, all over the world, are trying to find the best ways to connect the entire enterprise. No longer is control of the manufacturing processes enough: The new manufacturing mandate is to enable users throughout the company to access manufacturing data from any location, at any time, and to integrate these data seamlessly with business information systems.

Due to this adoption and expansion of the use of Internet technologies, a rapidly increasing number of users worldwide have looked to *open* systems as a way to connect their disparate enterprise processes. However, the devices, programs, and processes used at the various layers of the seven-layer Open Systems Interconnection (OSI) [64] model have different options, capabilities, and standards (or lack of). In general, integrating these networks requires extra resources and programming, and even then, gaps between the systems often cannot be fully and seamlessly bridged. Consequently, without a way to seamlessly integrate a network, users compromise their investments and rarely achieve all of the productivity and quality benefits promised by open network technology.

Common application layers are the key to advanced communication and true network integration. ODVA's four best-in-class networks—EtherNet/IP™, DeviceNet™, ControlNet™, and CompoNet™—all are linked by one of the industrial automation's most versatile protocols: the Common Industrial Protocol, known as CIP™. CIP encompasses a comprehensive suite of messages and services for the collection of industrial automation applications—control, safety, energy, synchronization and motion, information, and network management. CIP allows users to integrate these applications with enterprise-level Ethernet networks and the Internet. Supported by hundreds of vendors around the world and truly media independent, CIP provides users with a unified communication architecture throughout the industrial enterprise. CIP allows users to benefit today from the many advantages of open networks and protects their existing automation investments, while providing an extensible and upgradable communication architecture.

With media independence comes choice—the ability to choose the CIP Network best suited for an application. As a single, media-independent platform that is shared by a variety of networking technologies, CIP provides the interoperability and interchangeability that is essential to open networks and open systems. Four network adaptations of CIP are available.

### 9.1.1 EtherNet/IP: CIP on Ethernet Technology

EtherNet/IP provides users with the network tools to deploy standard Ethernet technology (IEEE 802.3 [63] combined with the TCP/IP Suite) for industrial automation applications while enabling Internet and enterprise connectivity resulting in data anytime and anywhere. EtherNet/IP offers various topology options including a conventional star with standard Ethernet infrastructure devices or Device Level Ring (DLR) with EtherNet/IP devices so enabled. QuickConnect™ functionality allows devices to be exchanged while the network is running.

### 9.1.2 DeviceNet: CIP on CAN Technology

DeviceNet provides users with a cost-effective network to distribute and manage simple devices throughout their architecture. DeviceNet uses a trunkline/dropline topology and has DC power available on the network cable to simplify installations by providing a single connection point for network communications and device power up to 24 Vdc, 8 A. QuickConnect functionality allows devices to be reconnected quickly while the network is running by using an abbreviated start-up procedure.

### 9.1.3 ControlNet: CIP on Concurrent Time Domain Multiple Access Technology

ControlNet provides users with the tools to achieve deterministic, high-speed transport of time-critical I/O and peer-to-peer interlocks. ControlNet offers a choice of topology options including trunkline/dropline, star, or tree. Hardware options are also offered for applications requiring intrinsically safe hardware. Redundant network communication is also available.

### 9.1.4 CompoNet: CIP on Time Division Multiple Access Technology

CompoNet enables users to maximize network throughput for applications needing to transmit small packets of data quickly between controllers, sensors, and actuators. Its simple network connector and cabling scheme reduces overall system cost and time.

In addition to these network implementations, ODVA has published extensions to CIP for critical applications.

### 9.1.5 Functional Safety

Safety application coverage in CIP provides the ability to mix safety devices and standard devices on the same network or wire for seamless integration and increased flexibility. CIP Safety™ provides fail-safe communication between nodes such as safety I/O blocks, safety interlock switches, safety light curtains, and safety Programmable Logic Controllers (PLCs) in safety applications up to Safety Integrity Level (SIL) 3 according to IEC 61508 standards. CIP Safety has also been adopted by Sercos International. A more detailed description of the CIP Safety extension is given in Section 9.5.2.

### 9.1.6 Synchronization

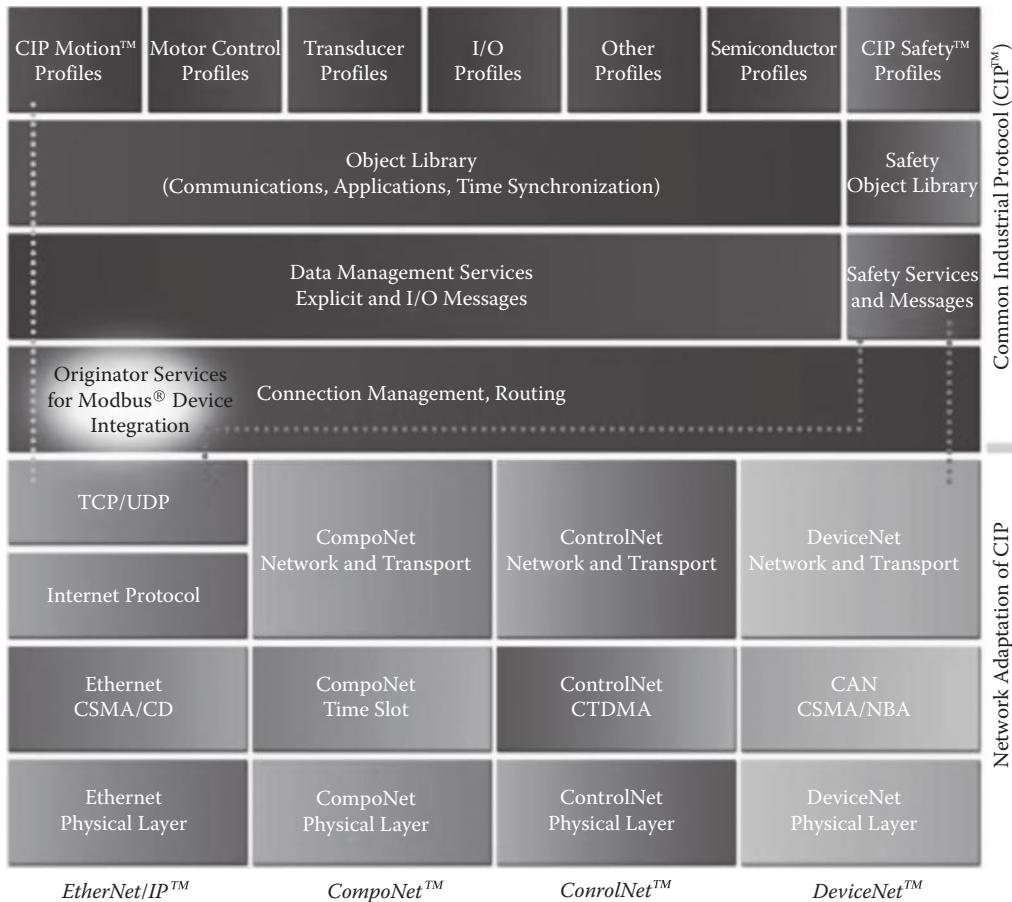

Synchronization services in CIP provide the increased control coordination needed for control applications where absolute time synchronization is vital to achieve real-time synchronization between distributed intelligent devices and systems. CIP Sync™ is compliant with IEEE-1588™ standard and allows synchronization accuracy between two devices of better than 100 ns. Real-time synchronization can be achieved over conventional 100 Mbps Ethernet systems with a switch-based architecture. A more detailed description of the CIP Sync extension is given in Section 9.5.1.

### 9.1.7 Distributed Motion Control

Motion application coverage in CIP eliminates the need for a purpose-built motion-optimized network by allowing high-performance motion control and other devices to be combined on a single EtherNet/IP network. This approach results in a modular and streamlined approach to system design and lowers overall system and training cost. CIP Motion™ achieves real-time deterministic behavior of multiple axes through a common sense of time, allowing for 100 axes to be coordinated with a 1 ms network update to all axes. Clock synchronization between axes of better than 100 ns can be readily achieved, meeting the needs of the most demanding motion control applications.

### 9.1.8 Energy Optimization

Energy application coverage in CIP provides a family of objects and services for the optimization of energy usage (OEU™) and allows scalability of implementation within the device from basic energy awareness to more advanced functions for control of energy, aggregation, and reporting of energy information or dynamic demand-response. Further, the CIP family of energy objects and services will allow systems to monitor energy usage and manage energy for efficient energy consumption through dynamic control of energy state and analysis of energy information. Protocol-neutral energy attributes allow for

**FIGURE 9.1** The Common Industrial Protocol and its network adaptations.

flexibility in the propagation of energy information via multiple protocols to facilitate an e-business model such as capturing energy requirements as a line item on production bills of material or to implement demand-response mechanisms for dynamic energy transactions.

The universal principles of CIP easily lend themselves to possible future implementations on new physical/data link layers. The overall relationship between the four implementations of CIP is shown in Figure 9.1.

## 9.2 Description of the CIP Networks Library

CIP is a very versatile protocol designed with the automation industry in mind. However, due to its open nature, it can be and has been applied to many more areas. The CIP Networks Library contains several volumes:

- Volume 1 deals with the common aspects of CIP that apply to all of the network adaptations. This volume contains the common object library and the device profile library, along with a general description of the communications model, device configuration, and CIP data management. This volume also defines an auxiliary power distribution system that is common to all adaptations of CIP.
- Volume 2 is the EtherNet/IP Adaptation of CIP, which describes how CIP is adapted to the Ethernet TCP/IP and UDP/IP transportation layers. It also contains any extensions to the material in Volume 1 that are necessary for EtherNet/IP, such as the optional industrial physical layer and connectors.

- Volume 3 is the DeviceNet Adaptation of CIP, which describes how CIP is adapted to the CAN data link layer. It also contains any extensions to the material in Volume 1 that are necessary for DeviceNet.
- Volume 4 is the ControlNet Adaptation of CIP, which describes how CIP is adapted to the ControlNet data link layer. It contains a complete description of the ControlNet data link layer and any extensions to the material in Volume 1 that are necessary for ControlNet.
- Volume 5 is CIP Safety. It contains the information necessary to implement the CIP Safety protocol on CIP Networks.
- Volume 6 is the CompoNet Adaptation of CIP, which describes how CIP is adapted to the CompoNet data link layer. It contains a complete description of the CompoNet data link layer and any extensions to the material in Volume 1 that are necessary for CompoNet.
- Volume 7 is the Integration of Modbus Devices into the CIP Architecture. This volume describes a standard for the integration of Modbus devices into the CIP world.

For brevity, this document will use these volume numbers when referencing the different books in the CIP Networks Library.

Specifications for the CIP Networks referenced earlier, and other documents discussing CIP, are available from ODVA at [www.odva.org](http://www.odva.org). It is beyond the scope of this book to fully describe each and every detail of CIP, but key features of the protocol and the auxiliary power distribution system will be discussed, including the following:

- Object modeling
- Services
- Messaging protocol
- Communication objects
- Object library
- Device profiles
- Configuration and electronic data sheets (EDSs)
- Bridging and routing
- Data management
- Auxiliary power distribution system

A few terms used throughout this section are described here to make sure they are well understood; further terms are described in Section 9.9:

- *Client*  
Within a client/server model, the client is the device that sends a request to a server. The client expects a response from the server.
- *Server*  
Within a client/server model, the server is the device that receives a request from a client. The server is expected to give a response to the client.
- *Producer*  
Within the Producer/Consumer model, the producing device places a message on the network for consumption by one or several consumers. Generally, the produced message is not directed to a specific consumer.
- *Consumer*  
Within the Producer/Consumer model, the consumer is one of potentially several consuming devices that picks up a message placed on the network by a producing device.
- *Producer/Consumer Model*  
The Producer/Consumer model is inherently multicast. Nodes on the network determine if they should consume the data in a message based on the connection ID (CID) in the packet. CIP uses the Producer/Consumer model, as opposed to the traditional source/destination message-addressing scheme (see Figure 9.2).

Source/destination			
src	dst	data	crc
Producer/Consumer			
Identifier		data	crc

FIGURE 9.2 Source/destination vs. Producer/Consumer model.

- *Explicit Message*

Explicit Messages contain addressing and service information that directs the receiving device to perform a certain service (action) on a specific part (e.g., an attribute of a given object) of a device.

- *Implicit (I/O) Message*

Implicit messages do not carry address and/or service information; any consuming nodes already know what to do with the data based on the CID that was assigned when the connection was established. Implicit messages are so named because the meaning of the data is *implied* by the CID. In most cases, they are used to transport I/O data.

Let's have a look at the individual elements of CIP.

### 9.2.1 Object Modeling

CIP uses abstract object modeling to describe the following:

- The suite of available communication services
- The externally visible behavior of a CIP node
- A common means by which information within CIP products is accessed and exchanged

Every CIP node is modeled as a collection of objects. An object provides an abstract representation of a particular component within a product. Anything not described in object form is not visible through CIP. CIP objects are structured into classes, instances, and attributes.

A class is a set of objects that all represent the same kind of system component. An object instance is the actual representation of a particular object within a class. Each instance of a class not only has the same attributes but also has its own particular set of attribute values. As Figure 9.3 illustrates, multiple object instances within a particular class can reside within a CIP node.

In addition to the instance attributes, an object class may also have class attributes. These are attributes that describe properties of the whole object class, for example, how many instances of this particular

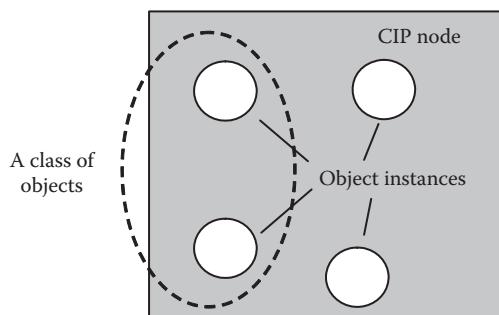

FIGURE 9.3 A class of objects.

object exist. Furthermore, both object instances and the class itself exhibit a certain behavior and allow certain services to be applied to the attributes, instances, or the whole class. All publicly defined objects that are implemented in a device must follow at least the mandatory requirements defined in the various CIP Networks specifications. Vendor-specific objects may also be defined with a set of instances, attributes, and services according to the requirements of the vendor. However, they need to follow certain rules that are also set forth in the specifications.

The objects and their components are addressed by a uniform addressing scheme consisting of the following:

- *Node Address*  
An integer identification value assigned to each node on a CIP Network. On DeviceNet, ControlNet, and CompoNet, this is also called a media access control identifier (MAC ID) and is nothing more than the node number of the device. On EtherNet/IP, the node address is the IP address.
- *Class Identifier (Class ID)*  
An integer identification value assigned to each object class accessible from the network.
- *Instance Identifier (Instance ID)*  
An integer identification value assigned to an object instance that identifies it among all instances of the same class.
- *Attribute Identifier (Attribute ID)*  
An integer identification value assigned to a class or instance attribute.
- *Service Code*  
An integer identification value that denotes an action request that can be directed at a particular object instance or object attribute (see Section 9.2.2).

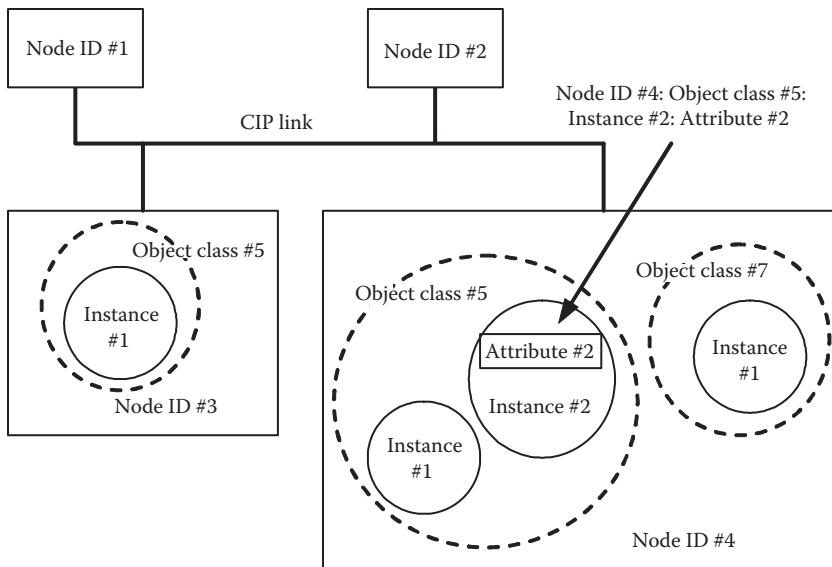

Object class identifiers are divided into two types of objects: publicly defined objects (ranging from 0x0000 to 0x0063 and 0x00F0 to 0x02FF) and vendor-specific objects (ranging from 0x0064 to 0x00C7 and 0x0300 to 0x04FF). All other class identifiers are reserved for future use. In some cases, for example, within the assembly object class, instance identifiers are divided into two types of instances: publicly defined (ranging from 0x0001 to 0x0063 and 0x00C8 to 0x02FF) and vendor-specific (ranging from 0x0064 to 0x00C7 and 0x0300 to 0x04FF). All other instance identifiers are reserved for future use. Attribute identifiers are divided into two types of attributes: publicly defined (ranging from 0x0000 to 0x0063, 0x0100 to 0x02FF, and 0x0500 to 0x08FF) and vendor-specific (ranging from 0x0064 to 0x00C7, 0x0300 to 0x04FF, and 0x0900 to 0x0CFF). All other attribute identifiers are reserved for future use. While vendor-specific objects can be created with a great deal of flexibility, these objects must adhere to certain rules specified for CIP, for example, they can use whatever instance and attribute IDs the developer wishes, but their class attributes must follow guidelines detailed in Volume 1, Chapter 4, of the CIP Networks Library.

Addressing objects and their attributes can be performed with 8-bit, 16-bit, or 32-bit addresses. In most cases, class and instance addresses are 8- or 16-bit wide, and attribute addresses are only 8-bit wide. Thirty-two-bit addresses are currently reserved for instance addressing only.

Figure 9.4 shows an example of this object-addressing scheme.

### 9.2.2 Services

Service codes are used to define the action that is requested to take place when an object or parts of an object are addressed through Explicit Messages using the addressing scheme described in Section 9.2.1. Apart from simple read and write functions, a set of CIP services has been defined. These CIP services are common in nature, meaning they may be used in all CIP Networks and they are useful for a variety of objects. Furthermore, there are object-specific service codes that may have a different meaning for the same code, depending on the class of object. Finally, defining vendor-specific

**FIGURE 9.4** Object addressing example.

services according to the requirements of the product developer is possible. While this provides a lot of flexibility, the disadvantage of vendor-specific services is that they may not be understood universally. Minimally, vendors provide a description of the public information that their customers will need access to in their literature.

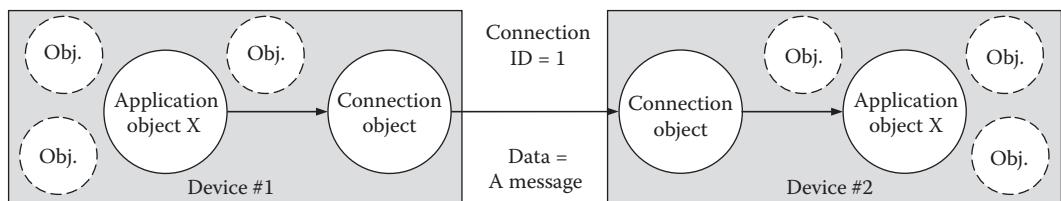

### 9.2.3 Messaging Protocol

CIP is a connection-based protocol. A CIP connection provides a path between multiple application objects. When a connection is established, the transmissions associated with that connection are assigned a CID (see Figure 9.5). If the connection involves a bidirectional exchange, then two CID values are assigned.

The definition and format of the CID is network dependent. For example, the CID for CIP connections over DeviceNet is based on the CAN identifier field.

Since most messaging on a CIP Network is done through connections, a process has been defined to establish such connections between devices that are not yet connected. This is done through the Unconnected Message Manager (UCMM) function, which is responsible for processing unconnected explicit requests and responses.

Establishing a CIP connection is generally accomplished by sending a UCMM Forward\_Open service request message. The Forward\_Open is required for all devices that support connections on ControlNet and EtherNet/IP. CompoNet uses a different method described in Section 9.3.4.12. DeviceNet only uses the simplified methods described in Sections 9.3.1.16 and 9.3.1.17.

**FIGURE 9.5** Connections and Connection IDs.

A Forward\_Open request contains all information required to create a connection between the originator and the target device. The resulting data exchange may be unidirectional or bidirectional. In particular, the Forward\_Open request contains information on the following:

- Timeout information for this connection
- Network CID for the connection from the originator to the target
- Network CID for the connection from the target to the originator
- Information about the identity of the originator (vendor ID and serial number)
- Maximum data sizes of the messages on this connection
- Whether it will be unicast or multicast
- Trigger mechanisms, for example, cyclic, change of state (COS)
- Electronic key so the target node can verify that it is the proper type of node (optional)
- Connection path for the application object data in the node that will be produced and consumed
- Data Segment containing configuration information for the node (optional)
- Routing information if the connection is to span more than one network (optional)

Some networks, like ControlNet, EtherNet/IP, and CompoNet, also make use of Unconnected Explicit Messaging. DeviceNet uses Unconnected Explicit Messaging only to establish connections.

All connections on a CIP Network can be categorized as I/O connections or explicit messaging connections.

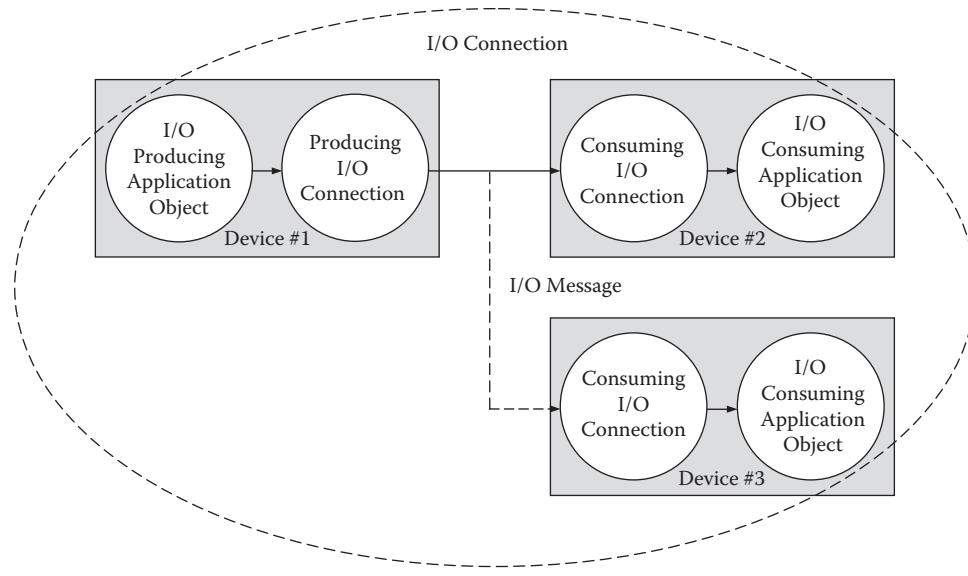

- I/O connections provide dedicated, special-purpose communication paths between a producing application and one or more consuming applications. Application-specific I/O data move through these ports, a process that is often referred to as Implicit Messaging. These messages can be unicast or multicast. These connections are also called *implicit* connections because the meaning of the data is implied by the CID.
- Explicit messaging connections provide generic, multipurpose communication paths between two devices. These connections often are referred to simply as messaging connections. Explicit messages provide typical request/response-oriented network communications. These messages are point to point. They are called *explicit* messages because the data in the request explicitly state what service and object are being requested.

The actual data transmitted in CIP I/O messages are the I/O data in an appropriate format; for example, the data may be prefixed by a Sequence Count Value. This Sequence Count Value can be used to distinguish old data from new, for example, if a message has been resent as a heartbeat in a COS connection. The two states *Run* or *Idle* can be indicated with an I/O message either by prefixing a real-time header, as is primarily used for ControlNet and EtherNet/IP, or by sending I/O data (*Run*) or no I/O data (*Idle*), a process primarily used for DeviceNet. CompoNet uses a bit within the OUT frame or the TRG frame to indicate the states *Run* and *Idle*. *Run* is the normal operational state of a device with the outputs under the control of the controlling application, while the reaction to receiving an *Idle* event is vendor specific and application-specific. Typically, this means bringing all outputs of the device to a predefined safe *Idle* state (which usually means *off*), that is, de-energized.

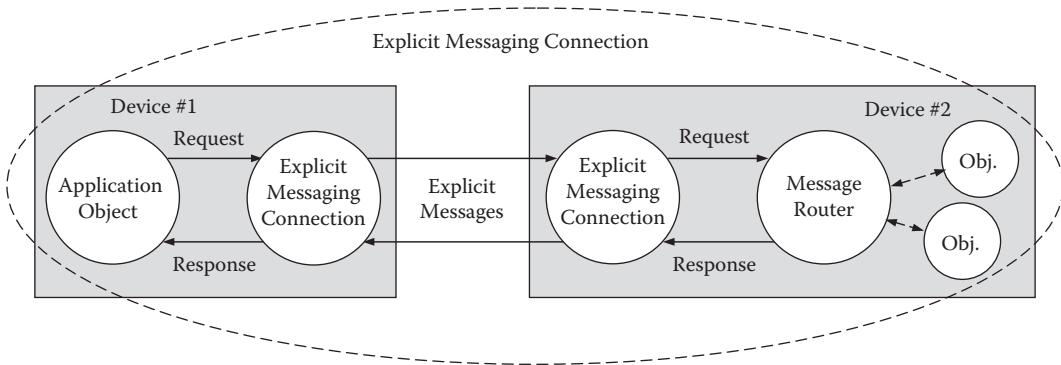

Explicit messaging requests contain a service code with path information to the desired object within the target device followed by data (if any). The associated responses repeat the service code followed by status fields followed by data (if any). DeviceNet and CompoNet use a *condensed* format for Explicit Messages in most cases, while ControlNet and EtherNet/IP only use the *full* format.

#### 9.2.4 Communication Objects

CIP communication objects manage and provide the runtime exchange of messages. Communication objects are unique in that they are the focal points for all CIP communication. It therefore makes sense to look at them in more detail.

**FIGURE 9.6** CIP multicast I/O Connection.

**FIGURE 9.7** CIP Explicit Messaging Connection.

Each communication object contains a link producer part, a link consumer part, or both. I/O connections may be either producing or consuming or producing and consuming, while explicit messaging connections are always producing and consuming.

Figures 9.6 and 9.7 show the typical connection arrangement for CIP I/O messaging and CIP explicit messaging. The attribute values in the connection objects define a set of attributes that describe vital parameters of this connection. Note that Explicit Messages are always directed to the Message Router Object.

The attribute values of a connection object specify whether it is an I/O connection or an explicit messaging connection, the maximum size of the data to be exchanged across this connection, and the source and destination of the data. Further attributes define the state and behavior of the connection. Particularly important behaviors include how messages are triggered (from the application, through COS, that is, when data have changed, through cyclic events or by network events) and the timing of the connections (timeout associated with this connection and predefined action if a timeout occurs). CIP allows multiple connections to coexist in a device, although simple devices—for example, simple DeviceNet or CompoNet slaves—typically will only have one or two live connections at any time (only one connection on CompoNet).

### 9.2.5 Object Library

The CIP family of protocols contains a large collection of commonly defined objects. The overall set of object classes can be subdivided into three types:

1. General-use
2. Application-specific
3. Network-specific

Objects defined in Volume 1 of the CIP Networks Library are available for use on all network adaptations of CIP. Some of these objects may require specific changes or limitations when implemented on some of the network adaptations. These exceptions are noted in the network-specific volume. Therefore, to see a complete picture of a specific network implementation of an object, refer to Chapter 5 in both the Protocol Adaptation Volume and Volume 1.

The following are general use objects (Object IDs in brackets):

---

Assembly (0x04)	Message Router (0x02)
Acknowledge Handler (0x2B)	Originator Connection List (0x45)
Connection (0x05)	Parameter (0x0F)
Connection Configuration (0xF3)	Parameter Group (0x10)
Connection Manager (0x06)	Port (0xF4)
File (0x37)	Register (0x07)
Identity (0x01)	Selection (0x2E)

---

The following group of objects is application-specific (Object IDs in brackets):

---

AC/DC Drive (0x2A)	Position Sensor (0x23)
Analog Group (0x22)	Presence Sensing (0x0E)
Analog Input Group (0x20)	S-Analog Actuator (0x32)
Analog Input Point (0x0A)	S-Analog Sensor (0x31)
Analog Output Group (0x21)	S-Device Supervisor (0x30)
Analog Output Point (0x0B)	S-Gas Calibration (0x34)
Base Energy (0x4E)	S-Partial Pressure (0x38)
Block Sequencer (0x26)	S-Sensor Calibration (0x40)
Command Block (0x27)	S-Single Stage Controller (0x33)
Control Supervisor (0x29)	Safety Analog Input Group (0x4A)
Discrete Group (0x1F)	Safety Analog Input Point (0x49)
Discrete Input Group (0x1D)	Safety Discrete Input Group (0x3E)
Discrete Output Group (0x1E)	Safety Discrete Input Point (0x3D)
Discrete Input Point (0x08)	Safety Discrete Output Group (0x3C)
Discrete Output Point (0x09)	Safety Discrete Output Point (0x3B)
Electrical Energy (0x4F)	Safety Dual Channel Analog Input (0x4B)
Event Log (0x41)	Safety Dual Channel Output (0x3F)
Group (0x12)	Safety Supervisor (0x39)
Motion Device Axis (0x42)	Safety Validator (0x3A)
Motor Data (0x28)	Softstart (0x2D)
Nonelectrical Energy (0x50)	Target Connection List (0x4D)
Overload (0x2C)	Time Sync (0x43)
Position Controller (0x25)	Trip Point (0x35)
Position Controller Supervisor (0x24)	

---

The last group of objects is network-specific (Object IDs in brackets):

---

Base Switch (0x51)
CompoNet Link (0xF7)
CompoNet Repeater (0xF8)
ControlNet (0xF0)
ControlNet Keeper (0xF1)
ControlNet Scheduling (0xF2)
Device Level Ring (DLR) (0x47)
DeviceNet (0x03)
Ethernet Link (0xF6)
Modbus (0x44)
Modbus Serial Link (0x46)
Parallel Redundancy Protocol (0x56)
Power Management (0x53)
PRP Nodes Table (0x57)
SERCOS III Link (0x4C)
SNMP (0x52)
QoS (0x48)
RSTP Bridge (0x54)
RSTP Port (0x55)
TCP/IP Interface (0xF5)

---

The general-use objects can be found in many different devices, while the application-specific objects are typically found only in devices hosting such applications. New objects are added on an ongoing basis by the various ODVA Special Interest Groups (SIGs). As mentioned earlier, there are many vendor-specific objects defined by developers to satisfy needs that may not be met by the existing open objects contained in the published specifications.

Although this looks like a large number of object types, typical devices implement only a subset of these objects. Figure 9.8 shows the object model of such a typical device.

The objects required in a typical device are the following:

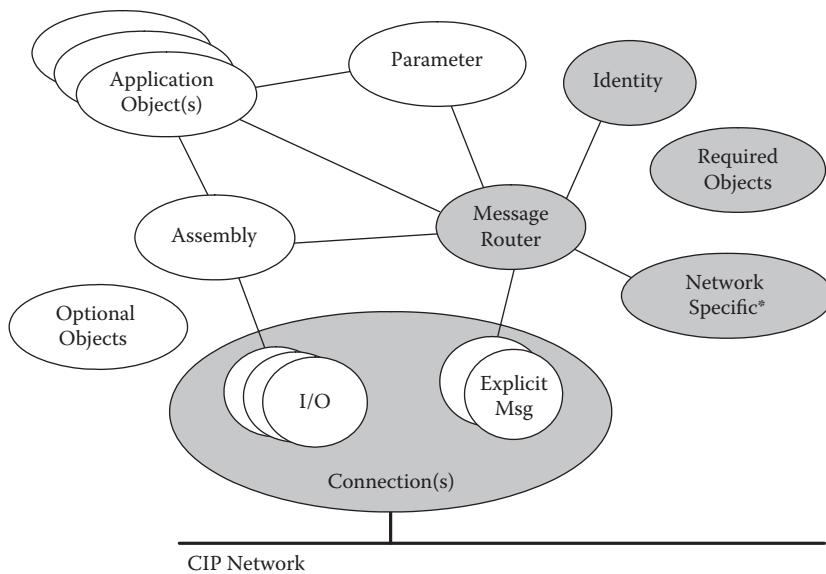

- Either a Connection Object or a Connection Manager Object
- An Identity Object
- One or several network-specific link objects (depends on network)
- A Message Router Object (at least its function)

Further objects are added according to the functionality of the device. This enables scalability for each implementation so that simple devices, such as proximity sensors, are not burdened with unnecessary overhead. Developers not only typically use publicly defined objects (see the list given earlier), but can also create their own objects in the vendor-specific areas, for example, Class ID 100–199. However, they are strongly encouraged to work with the SIGs of ODVA to create common definitions for additional objects instead of inventing private ones.

Out of the general-use objects, several are described in more detail in the following text.

#### 9.2.5.1 Identity Object (Class ID: 0x01)

The Identity Object is described in greater detail because, being a relatively simple object, it can serve to illustrate the general principles of CIP objects. In addition, every device must have an Identity Object.

**FIGURE 9.8** Typical device object model. Note: \* DeviceNet Object, ControlNet Object, TCP/IP Interface Object, Ethernet Link Object, CompoNet Link Object, and CompoNet Repeater Object.

The vast majority of devices support only one instance of the Identity Object. Thus, typically, there are no requirements for any class attributes that describe additional class details, for example, how many instances exist in the device. Only instance attributes are required in most cases. These are as follows:

#### Mandatory Attributes

Vendor ID	Status
Device Type	Serial Number
Product Code	Product Name
Revision	

#### Optional or Conditional Attributes

State
Configuration Consistency Value
Heartbeat Interval
Active Language
Supported Language List
International Product Name
Semaphore
Assigned_Name
Assigned_Description
Geographic_Location
Modbus Identity Info

Let us have a look at these attributes in more detail:

- The *Vendor ID* attribute identifies the vendor that markets the device. This Unsigned Integer (UINT) value (for Data Type descriptions, see Section 9.2.9) is assigned to a specific vendor by ODVA. If a vendor intends to build products for more than one CIP Network, the same Vendor ID will generally be assigned for all networks, but they must be registered independently with ODVA prior to use.
- The *Device Type*, again a UINT value, specifies which profile has been used for this device. It must be one of the Device Types listed in Volume 1, Chapter 6, of the CIP Networks Library or a vendor-specific type (see Section 9.2.6).
- The *Product Code* is a UINT number defined by the vendor of the device. This code is used to distinguish multiple products of the same Device Type from the same vendor. There is generally a loose association between a Catalog Number and a Product Code, but not necessarily.
- The *Revision* is split into two Unsigned Short Integer (USINT) values specifying a Major Revision and a Minor Revision. Any device change(s) that results in modifying the behavior of the device on the network must be reflected in a change to the Minor Revision at minimum. Any changes in the device's logical interface, for example, additional attributes, modified/additional I/O Assemblies, etc., require a change to the Major Revision, and this change must be reflected in a revised EDS (see Section 9.2.7). Vendor ID, Device Type, Product Code, and Major Revision provide an unambiguous identification of an EDS for this device.
- The *Status* attribute provides information on the status of the device, for example, whether it is owned (controlled by another device) or configured (to something different than the out-of-the-box default), and whether any major or minor faults have occurred.
- The *Serial Number* is used to uniquely identify individual devices in conjunction with the Vendor ID, that is, no two CIP devices from one vendor may carry the same Serial Number. The 32 bits of the Serial Number allow ample space for a subdivision into number ranges that can be used by different divisions of larger companies.
- The *Product Name* attribute allows the vendor to give a meaningful ASCII name string (up to 32 characters) to the device.
- The *State* attribute describes the state of a device in a single UINT value. It is less detailed than the Status attribute.
- The *Configuration Consistency Value* allows a distinction between a device that has been configured and one that has not, or between different configurations in a single device. This helps avoid unnecessary configuration downloads.
- The *Heartbeat Interval* enables the Device Heartbeat Message. This is an unconnected change-of-state message that has a settable background cyclic interval between 1 and 255 s. Currently, this option is defined for use only on DeviceNet.
- The *Supported Language List* and *International Product Name* attributes can be used to describe the product in multiple languages, and the *Active Language* attribute then specifies which of the supported languages is in use.
- The *Semaphore* attribute provides a semaphore for client access synchronization to the entire device.
- The *Assigned\_Name*, *Assigned\_Description*, and *Geographical\_Location* attributes can be used to individualize products by the user of the product.
- The *Modbus Identity Info* attribute can provide identity information in Modbus format to the extent the device supports it.

The services supported by the class and instance attributes are either Get\_Attribute\_Single (typically implemented in DeviceNet and CompoNet devices) or Get\_Attributes\_All (typically implemented in ControlNet and EtherNet/IP devices). The only attributes that can be set are as follows: the Heartbeat Interval, the Active Language, the Semaphore, the Assigned\_Name, Assigned\_Description, and Geographical\_Location

attributes. The only other service that typically is supported by the Identity Object is the Reset service. This Reset service comes with three different options that can let the device restart in three different ways.

The behavior of the Identity Object is described through a state transition diagram.

#### 9.2.5.2 Parameter Object (Class ID: 0x0F)

This object is described in some detail since it is referred to in Section 9.2.7, Configuration and Electronic Data Sheets. When used, the Parameter Object comes in two types: a complete object and an abbreviated version (Parameter Object Stub). This abbreviated version is used primarily by DeviceNet and CompoNet devices that have only small amounts of memory available. The Parameter Object Stub, in conjunction with the EDS, has roughly the same functionality as the full object (see Section 9.2.7).

The purpose of the Parameter Object is to provide a general means of allowing access to many attributes of the various objects in the device without requiring a tool (such as a handheld terminal) to have any knowledge about specific objects in the device.

The class attributes of the Parameter Object contain information about how many instances exist in this device and a Class Descriptor, indicating, among other properties, whether a full or a stub version is supported. In addition, class attributes tell whether a Configuration Assembly is used and what language is used in the Parameter Object.

The first six Instance Attributes are required for the Object Stub. These are the following:

Parameter Value	The actual parameter
Link Path Size	These two attributes describe the application object/instance/
Link Path	attribute from which the parameter value was retrieved.
Descriptor	This describes parameter properties, for example, read-only, monitor parameter, etc.
Data Type	This describes the data type (e.g., size and range) using a standard mechanism defined by CIP
Data Size	Data size in bytes

These six attributes allow access, interpretation, and modification of the parameter value, but the remaining attributes make it much easier to understand the meaning of the parameter:

- The next three attributes provide ASCII strings with the name of the parameter, its engineering units, and an associated help text.
- Another three attributes contain the minimum, maximum, and default values of the parameter.
- Four more attributes can link the scaling of the parameter value so that the parameter can be displayed in a more meaningful way, for example, raw value in multiples of 10 mA, scaled value displayed in Amps.
- Another four attributes can link the scaling values to other parameters. This feature allows variable scaling of parameters, for example, percentage scaling to a full range value that is set by another parameter.
- Attribute #21 defines how many decimal places are to be displayed if the parameter value is scaled.
- Finally, the last three attributes are an international language version of the parameter name, its engineering units, and the associated help text.

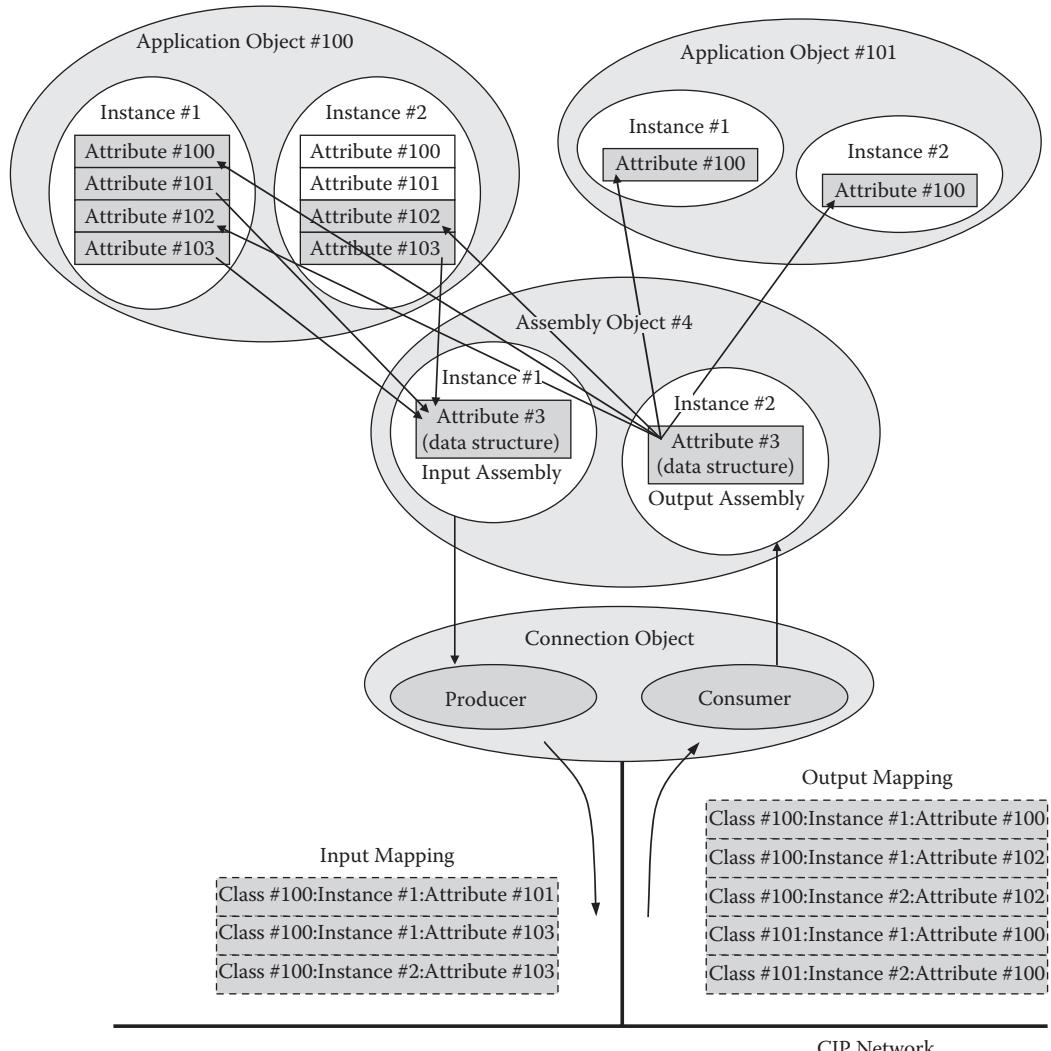

#### 9.2.5.3 Assembly Object (Class ID: 0x04)

Assembly Objects provide the option of mapping data from the attributes of different instances of various classes into one single attribute (#3) of an Assembly Object. This mapping is generally used for I/O Messages to maximize the efficiency of the control data exchange on the network. Assembly mapping makes the I/O data available in one block; thus, there are fewer Connection Object instances

and fewer transmissions on the network. The process data are normally combined from different application objects. An Assembly Object also can be used to configure a device with a single data block, alleviating the need to set individual parameters.

CIP makes a distinction between Input and Output Assemblies. *Input* and *Output* in this context are viewed from the perspective of the controlling element (e.g., a PLC/PAC). An Input Assembly in a device collects data from the input application (e.g., field wiring terminal and proximity sensor) and produces it on the network, where it is consumed by the controlling device and/or operator interface. An Output Assembly in a device consumes data that the controlling element sends to the network and writes that data to the output application (e.g., field wiring terminals and motor speed control). This data mapping is very flexible; even mapping of individual bits is permitted. Assemblies also can be used to transmit a complete set of configurable parameters instead of accessing them individually. These Assemblies are called Configuration Assemblies.

Figure 9.9 shows an example of Assembly mapping. The data from application objects 100 and 101 are mapped in two instances of the Assembly Object. Instance 1 is set up as an Input Assembly for the

**FIGURE 9.9** Example of an Assembly mapping in a typical I/O device.

input data and instance 2 as an Output Assembly for output data. The data block is always accessed via attribute 3 of the relevant Assembly instance. Attributes 1 and 2 contain mapping information.

I/O Assembly mapping is specified for many device profiles in Chapter 6 of Volume 1. Device developers then can choose which Assemblies they support in their products. If none of the publicly defined Assemblies fully represents the functionality of the product, a device vendor may implement additional vendor-specific Assemblies (Instance IDs 100–199).

CIP defines static and dynamic Assembly Objects. Whereas mapping for static Assemblies is permanently programmed in the device (ROM), dynamic Assemblies can be modified and extended through dynamic mapping (RAM). Most simple CIP devices support only static Assembly Objects. Dynamic Assembly Objects may be used in more complex devices, but they are not very common.

### 9.2.6 Device Profiles

It would be possible to design products using only the definitions of communication networks and objects, but this could easily result in similar products having quite different data structures and behavior. To overcome this situation and to make the application of CIP devices much easier, devices of similar functionality have been grouped into Device Types with associated profiles. Such a CIP profile contains the full description of the object structure and behavior. The following Device Types and associated profiles are defined in Volume 1 (profile numbers in parentheses):

AC Drives (0x02)	Limit Switch (0x04)
CIP Modbus Device (0x28)	Managed Ethernet Switch (0x2C)
CIP Modbus Translator (0x29)	Mass Flow Controller (0x1A)
CIP Motion Drive (0x25)	Motor Overload Device (0x03)
Communications Adapter (0x0C)	Motor Starter (0x16)
CompoNet Repeater (0x26)	Photoelectric Sensor (0x06)
Contactor (0x15)	Pneumatic Valve(s) (0x1B)
ControlNet Physical Layer Component (0x32)	Position Controller (0x10)
Programmable Logic Controller (0x0E)	Process Control Valve (0x1D)
DC Drives (0x13)	Residual Gas Analyzer (0x1E)
DC Power Generator (0x1F)	Resolver (0x09)
Encoder (0x22)	RF Power Generator (0x20)
Enhanced Mass Flow Controller (0x27)	Safety Analog I/O Device (0x2A)
Fluid Flow Controller (0x24)	Safety Discrete I/O Device (0x23)
General Purpose Discrete I/O (0x07)	Softstart Starter (0x17)
Generic Device, keyable (0x2B)	Turbomolecular Vacuum Pump (0x21)
Human Machine Interface (HMI) (0x18)	Vacuum/Pressure Gauge (0x1C)
Inductive Proximity Switch (0x05)	

Device developers must use a Device Type ID to uniquely identify their product. Any device that does not fall into the scope of one of the specialized device profiles must use the Generic Device Profile (0x2B) or a vendor-specific profile. What profile is used and which parts of it are implemented must be described in the user's device documentation.

Every profile consists of a set of objects—some required, some optional—and a behavior associated with that particular type of device. Most profiles also define one or more I/O data formats (Assemblies) that define the makeup of the I/O data. In addition to the commonly defined objects and I/O data Assemblies, vendors can add Objects and Assemblies of their own if their devices provide additional functionality. Furthermore, vendors can create profiles within the vendor-specific profile range. They are then free to define whatever behavior and objects are required for their device as long as they adhere to the general rules for profiles outlined in Chapter 6 of Volume 1 of the CIP Networks Library.

Whenever additional functionality is needed by multiple vendors, ODVA encourages coordinating these new features through SIGs, which can then create new profiles or additions to existing profiles for everybody's use and for the benefit of the device users.

All open (ODVA-defined) profiles carry numbers in the 0x00–0x63 or 0x0100–0x02FF ranges, while vendor-specific profiles carry numbers in the 0x64–0xC7 or 0x0300–0x02FF ranges. All other profile numbers are reserved by CIP.

### 9.2.7 Configuration and Electronic Data Sheets

CIP provides several options for configuring devices:

- A printed data sheet
- Parameter Objects and Parameter Object Stubs
- An EDS
- A combination of an EDS and Parameter Object Stubs
- A Configuration Assembly combined with any of the methods provided earlier

When using configuration information collected on a printed data sheet, configuration tools can provide only prompts for service, class, instance, and attribute data and relay this information to a device. While this procedure can do the job, it is the least desirable solution since it does not determine the context, content, or format of the data.

Parameter Objects, on the other hand, provide a full description of all configurable data for a device. Since the device itself provides all the necessary information, a configuration tool can gain access to all parameters and maintain a user-friendly interface. However, this method imposes a burden on a device with full parameter information that may be excessive for a small device with limited internal resources. Therefore, an abbreviated version of the Parameter Object, called a Parameter Object Stub, may be used (see Section 9.2.5.2). This option still allows access to the parameter data, but it does not describe any meaning to the data. Parameter Object Stubs in conjunction with a printed data sheet are usable, but certainly not optimal. On the other hand, an EDS supplies all of the information that a full Parameter Object contains, in addition to I/O Connection information, so the EDS provides the full functionality and ease of use of the Parameter Object without imposing an excessive burden on the individual device. In addition, an EDS provides a means for tools to perform offline configuration and to download configuration data to the device at a later time.

An EDS is a simple ASCII text file that can be generated on any ASCII editor. Since the CIP Specification provides a set of rules for the overall design and syntax of an EDS, specialized EDS editing tools, such as ODVA's EZ-EDS, can simplify the creation of EDS files. The main purpose of the EDS is to give information on several aspects of the device's capabilities, the most important ones being the I/O Connections it supports and what parameters for display or configuration exist within the device. It is highly recommended that an EDS describe all supported I/O Connections, as this makes the application of a device in a control system much easier. When it comes to parameters, EDS files should contain the attributes of application objects so that software can provide user access for monitoring and/or configuration purposes.

Let's look at some details of the EDS. First, an EDS is structured into sections, each of which starts with a section name in square brackets [ ]. The first two sections are mandatory for all EDS files.

- [File]: Describes the contents and revision of the file.
- [Device]: Is equivalent to the Identity Object information and is used to match an EDS to a device.
- [Device Classification]: Describes what network the device can be connected to. This section is optional for DeviceNet, required for ControlNet, EtherNet/IP, and CompoNet.
- [ParamClass]: Describes configuration details in addition to class-level attributes of the Parameter Object.

- [Params]: Identifies all configuration parameters in the device, follows the Parameter Object definition. Further details are given later.
- [Groups]: Identifies all parameter groups in the device and lists group name and parameter numbers.
- [Assembly]: Describes the structure of data items.
- [Connection Manager]: Describes connections supported by the device. Typically used in ControlNet and EtherNet/IP.
- [Connection ManagerN]: Same as the [Connection Manager] section, but only for connection entries that do not apply to all CIP ports of the device.
- [Port]: Describes the various network ports a device may have.
- [Capacity]: Specifies the communication capacity of EtherNet/IP and ControlNet devices.
- [Connection Configuration]: This section defines the characteristics of the Connection Configuration Object implemented in this device, if a Connection Configuration Object implementation exists. It is used for EDS-based I/O Scanner configuration.
- [Event Enumeration]: Associates specific event or status codes within a device with an international string.
- [Symbolic Translation]: This section is used to publicize the translation between a Symbolic Segment or an ANSI Extended Symbol Segment encoded EPATH specification to the equivalent ParamN or AssemN entry keywords.
- [Internationalization]: This section allows the representation of all strings within an EDS in multiple languages.
- [Modular]: Describes modular structures inside a device.
- [IO\_Info]: Describes I/O connection methods and I/O sizes. Allowed for DeviceNet only.
- [Variant\_IO\_Info]: Describes multiple IO\_Info data sets. Allowed for DeviceNet only.
- [EnumPar]: Enumeration list of parameter choices to present to the user. This is an old enumeration method specified for DeviceNet only.
- [ControlNet Physical Layer]: Describes details of the ControlNet physical layer. Allowed for ControlNet only.
- [CompoNet\_Device]: Describes the type of CompoNet device. Allowed for CompoNet only.
- [CompoNet\_IO]: Describes the I/O Connection details of CompoNet slaves. Allowed for CompoNet only.
- [Modbus Mapper]: Used to provide a description of individual Modbus items that correspond to a specific CIP object attribute.
- Object Class sections: These sections—one for every object class—can be used to describe all object details, such as instances, attributes, and supported services.

These sections allow a very detailed device description, although only a few of these details are described here. Further reading is available in Refs. [1,2].

A tool with a collection of EDS files will first use the [Device] section to try to match an EDS with each device it finds on a network. Once this is done and a particular combination of device and EDS is chosen, the tool can then display device properties and parameters and allow their modification if the user so chooses. A tool may also display what I/O Connections a device allows and which of these are already in use. EDS-based tools are mainly used for slave or I/O Adapter devices, as I/O Scanner devices typically are too complex to be configured through EDS constructs alone. For those devices, the EDS is used primarily to identify the device and then guide the tool to call a matching configuration applet.

A particular strength of the EDS approach lies in the methodology of parameter configuration. A configuration tool typically takes all of the information that can be supplied by the Parameter Objects and an EDS and displays it in a user-friendly manner. In many cases, this enables the user to configure a device without needing a detailed manual, as the tool presentation of the parameter information and

the help text enables decision making for a complete device configuration. This assumes the developer of the product and the EDS file has supplied all required information and any optional information with completeness and accuracy.

A complete description of what can be done with EDS files goes well beyond the scope of this book. Available materials on this topic provide greater detail [1,2].

### 9.2.8 CIP Routing

CIP defines mechanisms that allow the transmission of messages across multiple networks, provided that the intermediate devices (CIP routers) between the various networks are equipped with the objects and services used in CIP routing. If this is the case, the message will be forwarded from CIP router to CIP router until it has reached its destination node. Here is how it works:

For Unconnected Explicit Messaging, the actual Explicit Message to be executed on the target device is *wrapped up* inside of another Explicit Message service, the so-called Unconnected\_Send service (Service Code 0x52 of the Connection Manager Object). This service message contains all the information about the transport mechanism, such as the request timeout (which may be modified as the message moves through each CIP router), the message request path information, and the routing path information.

The first CIP router device that receives an Unconnected\_Send message will take its contents and forward it to the next CIP router, as specified within the Route Path section of the message. Before the message is actually sent, the *used* part of the path is removed but is remembered by the CIP router device for the return of the response. The CIP router may subtract some time from the timeout value, thereby reducing the timeout value as it closes in on the destination. This process is executed for every CIP router the message goes through, until the final CIP router is reached. The number of CIP routers an Unconnected\_Send may pass through is theoretically limited by the message length.

Once the Unconnected\_Send message has arrived at the last CIP router, the Unconnected\_Send *wrapper* is removed and the *inner* Explicit Message is sent to the target device, which executes the requested service and generates a response. That response, as received from the target device, is then transported back through all the CIP routers it traversed during its forward journey until it reaches the originating node. It is important to note in this context that the transport mechanism may have been successful in forwarding the message and returning the response, but the response still could contain an indication that the desired service could not be performed successfully in the target network/device. Through this mechanism, the CIP router devices do not need to know anything about the message paths ahead of time so no preconfiguration of the CIP router devices is required. This is often referred to as *seamless routing*.

When a connection (I/O or Explicit) is set up using the Forward\_Open service (see Section 9.3.1.14), it may go to a target device on another network. To enable the appropriate setup process, the Forward\_Open message may contain a field with path information describing a route to the target device. This is very similar to the Unconnected\_Send service described earlier. The routing information is then used to create routed connections within the CIP routing devices between the originator and the target of the message. Once set up, these connections automatically forward any incoming messages for this connection to the proper outgoing port. Again, this is repeated through each CIP router until the message has reached the target node. As with routed Unconnected Explicit Messages, the number of hops is generally limited only by the capabilities of the devices involved. In contrast to routed Unconnected Messages, routed Connected Messages do not carry path information. Since Connected Messages always use the same path for any given connection, the path information that was given to the routing devices during connection setup is held there as long as the connection exists. Again, the CIP routing devices do not have to be preprogrammed; they are self-configured during the connection establishment process.

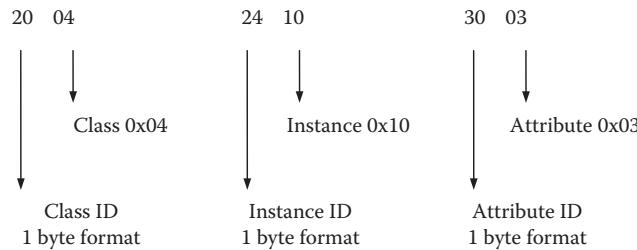

FIGURE 9.10 Logical segment encoding example.

### 9.2.9 Data Management

The data management part of the CIP Specification describes addressing models for CIP entities and the data structures of the entities themselves.

Entity addressing is done by Segments, which allows flexible usage so that many different types of addressing methods can be accommodated. Two uses of this addressing scheme (Logical Segments and Data Types) are looked at in more detail in the following text.

#### 9.2.9.1 Logical Segments

Logical Segments (first byte = 0x20–0x3F) are addressing Segments that can be used to address objects and their attributes within a device. They are typically structured as follows: [Class ID] [Instance ID] [Attribute ID, if required].

Each element of this structure allows various formats (1 byte, 2 bytes, and 4 bytes). Figure 9.10 shows a typical example of this addressing method.

This type of addressing is commonly used to point to Assemblies, Parameters, and other addressable entities within a device. It is used extensively in EDS files, but also within Explicit Messages, to name just a few application areas.

#### 9.2.9.2 Data Types

Types (first byte = 0xA0–0xDF) can be either structured (first byte = 0xA0–0xA3, 0xA8 or 0xB0) or elementary (first and only byte = 0xC1–0xDE). All other values are reserved. Structured Data Types can be arrays of elementary Data Types or a collection of arrays or elementary Data Types. Of particular importance in the context of this book are elementary Data Types, which are used within EDS files to specify the Data Types of parameters and other entities.

Here is a list of commonly used Data Types:

- 1 bit (encoded into 1 byte)
  - Boolean, BOOL, Type Code 0xC1
- 1 byte
  - Bit string, 8 bits, BYTE, Type Code 0xD1
  - Unsigned 8-bit integer, USINT, Type Code 0xC6
  - Signed 8-bit integer, SINT, Type Code 0xC2
- 2 bytes
  - Bit string, 16 bits, WORD, Type Code 0xD2
  - Unsigned 16-bit integer, UINT, Type Code 0xC7
  - Signed 16-bit integer, INT, Type Code 0xC3
- 4 bytes
  - Bit string, 32 bits, DWORD, Type Code 0xD3
  - Unsigned 32-bit integer, UDINT, Type Code 0xC8
  - Signed 32-bit integer, DINT, Type Code 0xC4

The Data Types in CIP follow the requirements of IEC 61131-3 [3,62].

### 9.2.10 Auxiliary Power Distribution System

The CIP application layer can be used on a variety of network technologies. Each CIP Network specification consists of two volumes. The physical layer behavior defined on a particular network is described in the appropriate CIP Network adaptation volume.

Chapter 8 of Volume 1 of the CIP Networks Library defines an optional auxiliary power distribution system that is separate and distinct from the physical layer requirements of any of the CIP Networks.

Auxiliary power may be used to provide application power for such devices as Input/Output modules, Emergency Stop circuitry, and other application-specific needs. The cabling system provides 4-wire, two-circuit wiring that supplies 24 V switched and unswitched power. Depending on the cabling selected by the designer, the maximum current ranges from 7 to 10 A. This standard specifies system topologies, cable and connector requirements, and power supply requirements for auxiliary power distribution.

This system is not intended to provide redundant network power for already powered networks such as DeviceNet or CompoNet.

### 9.2.11 Maintenance and Further Development of the Specifications

ODVA has a set of working groups that maintain the specifications and create protocol extensions, for example, new profiles or functional enhancements such as CIP Sync and CIP Safety. These groups are called Special Interest Groups (SIGs).

The results of these SIGs are written up and presented to the Technical Review Board for approval and then incorporated into the specifications. Only ODVA members can work within the SIGs. These participants have the advantage of advance knowledge of technical changes coming to the specifications. Participation in one or several SIGs is, therefore, highly recommended.

## 9.3 Network Adaptations of CIP

---

Four public derivatives of CIP currently exist. There are currently four public adaptations of CIP, each based on different data link layers and transport mechanisms, which maintain the common upper layers of CIP, as illustrated earlier in Figure 9.1.

### 9.3.1 DeviceNet

#### 9.3.1.1 Introduction

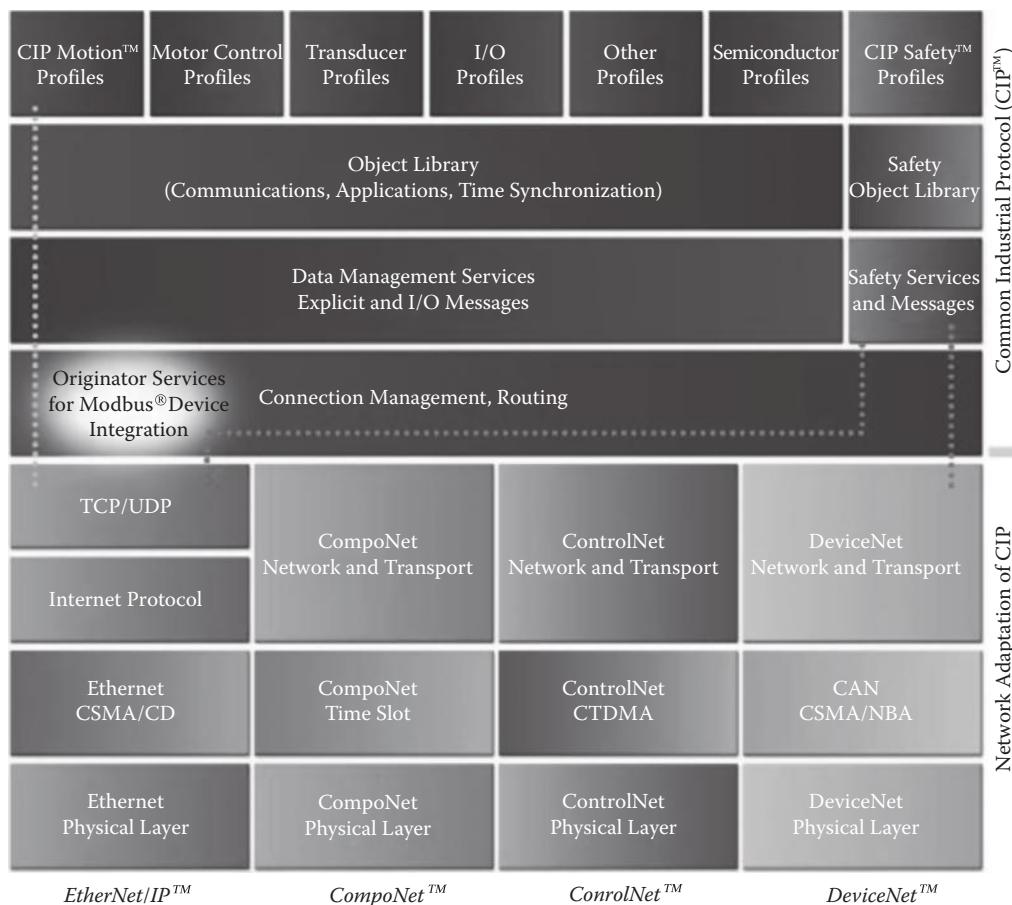

DeviceNet was the first implementation of CIP. As mentioned in Section 9.1, DeviceNet is based on the Controller Area Network (CAN). DeviceNet uses a subset of the CAN protocol (11-bit identifier only, no remote frames). The DeviceNet adaptation of CIP accommodates the 8-byte packet size limitation of the CAN protocol and allows the use of simple devices with minimal processing power. For a more detailed description of the CAN protocol and some of its applications, see Ref. [4].

#### 9.3.1.2 Relationship to Standards

Like other CIP Networks, DeviceNet follows the OSI model, an ISO standard for network communications that is hierarchical in nature. Networks that follow this model define all necessary functions, from physical implementation up to the protocol and methodology to communicate control and information data within and across networks.

Figure 9.11 shows the relationship between CIP and DeviceNet.

The DeviceNet adaptation of CIP is described in Volume 3 of the CIP Networks Library [5]. All other features are based on CIP. For example, DeviceNet is also described in a number of national and international standards [6,7].

**FIGURE 9.11** Relationship between CIP and DeviceNet.

### 9.3.1.3 DeviceNet Features

DeviceNet is a communication system at the low end (sensors and actuators) of the industrial communication spectrum with the following features:

- Trunkline/dropline configuration
- Support for up to 64 nodes
- Node insertion or removal while the network is up and running
- QuickConnect for devices that are frequently removed from and added to the network, for example, robot tools
- Simultaneous support for both network-powered devices, for example, sensors, and separately powered devices, for example, actuators
- Use of sealed or open-style connectors
- Protection from wiring errors
- Selectable data rates of 125, 250, and 500 kBaud
- Adjustable power configuration to meet individual application needs
- High current capability (up to 16 A per supply)
- Operation with off-the-shelf power supplies
- Power taps that allow the connection of several power supplies from multiple vendors that comply with DeviceNet standards

- Built-in overload protection
- Power available along the bus: both signal and power lines contained in the cable
- Several cables that are suitable for a number of different applications

#### 9.3.1.4 DeviceNet Physical Layer and Relationship to CAN

The physical layer of DeviceNet is an extension of the ISO 11898 standard [8]. This extension defines the following additional details:

- Improved transceiver characteristics that allow the support of up to 64 nodes per network
- Additional circuitry for overvoltage and mis-wiring protection
- Several types of cables for a variety of applications
- Several types of connectors for open (IP 20) and sealed (IP 65/67) devices

The cables described in the CIP Networks Library were designed specifically to meet minimum propagation speed requirements to ensure that they can be used up to the maximum system length. Figure 9.12 shows examples of some of the key characteristics that can be achieved with some of the defined cable types in conjunction with suitable transceiver circuits and proper termination resistors ( $121\ \Omega$ ).

ODVA has issued a guideline [9] that gives complete details of how to build the physical layer of a DeviceNet Network; equivalent information can also be found in an IEC standard [10].

Developers of DeviceNet devices can create DeviceNet circuits with or without physical layer isolation (both versions are fully specified). Furthermore, a device may take some or all of its power from the bus, thus avoiding extra power lines for devices that can live on the power supplied through the DeviceNet cable.

All DeviceNet devices must be equipped with one of the connectors described in Volume 3, although hard wiring of a device is allowed, provided the node is removable without severing the trunk.

#### 9.3.1.5 Frame Structure

DeviceNet uses standard CAN frames with an 11-bit identifier; for further details, see [8,11] and Section 9.3.1.15 of this publication.

#### 9.3.1.6 Protocol Adaptations

On the protocol side, there are basically two adaptations of CIP that have been made to better accommodate it to the CAN data frame:

- Shortening CIP Explicit Messages to 8 bytes or less where possible, with the use of message fragmentation for longer messages
- Definition of a Master Slave communications option to minimize the connection establishment overhead (see Section 9.3.1.17).

These two features have been created to allow the use of simple and thus inexpensive microcontrollers. This is particularly important for small, cost-sensitive devices like photoelectric or proximity sensors. As a result of this adaptation, the DeviceNet protocol in its simplest form has been implemented in 8-bit microprocessors with as little as 4 kB of code memory and 175 bytes of RAM.

Data Rate (kBaud)	Trunk Distance			Drop Length	
	Thick Cable (m)	Thin Cable (m)	Flat Cable (m)	Maximum (m)	Cumulative (m)
125	500	100	420	6	156
250	250		200		78
500	100		75		39

FIGURE 9.12 Data Rate vs. Trunk and Drop Length

The message fragmentation mentioned previously comes in two varieties:

1. For I/O Messages, the use of fragmentation is defined by the maximum length of the data to be transmitted through a connection. Any connection that has more than 8 bytes to transmit always uses the fragmentation protocol, even if the actual data to be transmitted is 8 bytes or less, for example, an *Idle* Message.
2. For Explicit Messaging, the use of the fragmentation protocol is indicated in the header of every message, since the actual frame size can vary in length, depending on the content of the Explicit Message. The actual fragmentation protocol is contained in one extra byte within the message that indicates whether the fragment is a start fragment, a middle fragment, or an end fragment. A modulo 64 rolling fragment counter allows very long fragmented messages and is limited in theory only by the maximum Produced or Consumed Connection sizes (65,535 bytes). In reality, the capabilities of the devices limit the message sizes.

### 9.3.1.7 Indicators and Switches

Indicators and switches are optional on DeviceNet. However, certain DeviceNet users not only require indicators and switches; they also specify what type to use. Many factors must be considered before implementing these devices, including packaging, accessibility, and customer expectations.

Indicators allow the user to determine the state of the device and its network connection(s). Since indicators can be very useful when troubleshooting the operation of a device, manufacturers are advised to incorporate some or all of the indicators described in the DeviceNet specification. While devices may incorporate additional indicators with behavior not described in the specification, any indicators labeled per specification must also follow their specified behavior.

Similarly, devices may be built with or without switches or other directly accessible means for configuration of MAC ID and baud rate. If these switches are used, certain rules apply to how these values are used at power-up and during the operation of the device.

### 9.3.1.8 Additional Objects

The DeviceNet Specification defines one additional object, the DeviceNet Object.

#### 9.3.1.8.1 DeviceNet Object (Class ID: 0x03)

A DeviceNet Object is required for every DeviceNet port of the device. The instance attributes of this object contain information on how this device uses the DeviceNet port, including the MAC ID of the device and the (expected) baud rate of the DeviceNet network the device is attached to. Both attributes are always expected to be nonvolatile; that is, after a power interruption, the device is expected to try to go online again with the same values that were stored in these attributes before the power interruption. Devices that set these values through switches typically override any stored values at power-up. The DeviceNet Object may also contain information on further aspects associated with its DeviceNet behavior, such as information related to the Master Slave communications status, QuickConnect support (see Section 9.3.1.17.7), and Active Node Table.

### 9.3.1.9 Network Access

DeviceNet uses the network access mechanisms described in the CAN specification, that is, bitwise arbitration through the CAN Identifier for every frame to be sent. This requires a system design that does not allow multiple uses of any of these identifiers. Since the node number of every device is coded into the CAN Identifier (see Section 9.3.1.15), it is generally sufficient to make sure that none of the node numbers exists more than once on any given network. This is guaranteed through the Network Access algorithm (see Section 9.3.1.10).

### 9.3.1.10 Going Online

Any device that wants to communicate on DeviceNet must go through a Network Access algorithm before any communication is allowed. The main purpose of this process is to avoid duplicate Node IDs on the same network; a secondary purpose is to announce a node's presence on the link for nodes that maintain an Active Node Table. Every device that is ready to go online sends a Duplicate MAC ID Check Message containing its Port Number, Vendor ID, and Serial Number. If another device is already online with this MAC ID or is in the process of going online with this MAC ID, it responds with a Duplicate MAC ID Response Message that directs the checking device to go offline and not communicate any further.

If two or more devices with the same MAC ID happen to transmit the Duplicate MAC ID Check Message at exactly the same time, all of them will win arbitration at the same time and will proceed with their message. However, since this message has different values (Port Number, Vendor ID, and Serial Number) in the data field, the nodes will detect bit errors and will flag error frames that cause all nodes to discard the frame. This reaction triggers a retransmission of the message by the sending node. While this action may eventually result in a Bus-Off condition for the devices involved, a situation with duplicate Node IDs is safely avoided.

### 9.3.1.11 Offline Connection Set

The Offline Connection Set is a set of messages created to communicate with devices that have failed to go online (see Section 9.3.1.10), to allow a new MAC ID to be set. At any given point in time, only one offline device and one tool can use the Offline Connection Set; therefore, the first step in its use is to determine if a tool has ownership of the Offline Connection Set. Once a tool has successfully claimed ownership, it can check whether there are any nodes on the network that are in the offline state. If such nodes exist, the tool can then determine their Vendor ID(s) and Serial Number(s). Using this information, which is unique by definition, the tool can then address a specific device that responds by flashing an indicator. Once this identification is complete and the user is certain that communication is established with the intended device, the tool can then send a new MAC address to the device. The target device then restarts the Duplicate MAC ID algorithm and tries to go online with the new MAC Address. More information on this topic can be found in [4,5].

### 9.3.1.12 DeviceNet Status Indication Messages

There are two optional DeviceNet messages that indicate a status or a status transition of a device. One of them is called *Device Heartbeat* and the other is called *Device Shutdown*. Both messages are transmitted by a UCMM-capable device as an unconnected response message (Message Group 3, Message ID 5) and by a Group 2 Only Server as an unconnected response message (Message Group 2, Message ID 3). These messages are independent of any other communication relationship that may exist with other devices on the network.

The Device Heartbeat Message, sent at a heartbeat interval set in the ID Object, provides a way for a device to indicate its presence on the network and its current *health* condition. The Device Shutdown Message provides a way for a device to indicate that it is in the process of shutting down and going to the offline state.

### 9.3.1.13 Explicit Messaging

All Explicit Messaging in DeviceNet is done via connections and the associated Connection Object instances. However, these objects first must be set up in the device. This can be done by using the Predefined Master Slave Connection Set to activate a static Connection Object already available in the device or by using the UCMM port of a device, to dynamically set up a Connection Object for Explicit Messaging. The only messages sent to the UCMM are *Open* or *Close* requests that set up or tear down an Explicit Messaging Connection, while the only messages that can be sent to the Master Slave equivalent

Byte Offset	Bit Number							
	7	6	5	4	3	2	1	0
0	Frag [0]	XID		MAC ID				Message header
1	R/R [0]		Service Code					Message body
2	Class ID							
3	Instance ID							
4	Service data							
...	...							
7	(optional)							

**FIGURE 9.13** Nonfragmented Explicit Request Message Format

Byte Offset	Bit Number							
	7	6	5	4	3	2	1	0
0	Frag [0]	XID		MAC ID				Message header
1	R/R [1]		Service Code					Message body
2	Service data							
...	...							
7	(optional)							

**FIGURE 9.14** Nonfragmented Explicit Response Message Format

of the UCMM called the Group 2 Only Unconnected Port are the *Allocate* or *Release* service requests (see Section 9.3.1.17). Explicit Messages always pass via the Message Router Object to the object that is being addressed (refer to Figure 9.8).

As mentioned in Section 9.2.3, Explicit Messages on DeviceNet have a very compact structure to make them fit into the 8-byte frame in most cases. Figure 9.13 shows a typical example of a request message using the 8/8 Message Body Format (8/8 means 1 byte for Class ID and 1 byte for Instance ID).

The consumer of this Explicit Message responds using the format shown in Figure 9.14. The consumer sets the R/R (Request/Response) bit and repeats the Service Code of the request message. Any data transferred with the response is entered in the service data field.

Most messages will use the 8/8 format shown in Figure 9.13, since they need to address Class and Instance IDs only up to 255. If there is a need to address any class/instance combinations above 255, then this is negotiated between the two communication partners during the setup of the connection. Should an error occur, the receiver responds with the Error Response Message. The Service Code for an Error Response message is 0x14, and 2 bytes of error code are included in the service data field to convey more information about the nature of the error. See Refs. [4,5] for further details of message encoding, including the use of fragmentation.

### 9.3.1.14 I/O Messaging

Since DeviceNet does not use a Real-Time Header or Sequence Count Value like ControlNet and EtherNet/IP do, I/O Messages in DeviceNet have a very compact structure. For I/O data transfers up to 8 bytes long, the data are sent in a nonfragmented message, which uses the entire CAN data field for I/O data. For I/O data transfers longer than 8 bytes, a fragmentation protocol spreads the data over multiple frames. This fragmentation protocol uses 1 byte of the CAN data field to control the fragmentation of the data. See Figure 9.15 and 9.16 for examples of fragmented and nonfragmented I/O messages. I/O Messages without data (i.e., with zero-length data) indicate the *Idle* state of the producing application. Any producing device can do this—master, slave, or peer.

Byte Offset	Bit Number							
	7	6	5	4	3	2	1	0
0								Process data
...								
7								(0-8 bytes)

FIGURE 9.15 Nonfragmented I/O Message Format

Byte Offset	Bit Number							
	7	6	5	4	3	2	1	0
0								Fragmentation protocol
1								Process data
...								
7								(0-7 bytes)

FIGURE 9.16 Fragmented I/O Message Format

As mentioned, I/O Messages are used to exchange high-priority application and process data via the network, and this communication is based on the Producer/Consumer model. The associated I/O data are always transferred from one producing application object to one or more consuming application objects. This is accomplished using I/O Messages via I/O Messaging Connection Objects (Figure 9.17 shows two consuming applications) that have been preset in the device. This can be done in one of two ways by using

- The Predefined Master Slave Connection Set to activate a static I/O Connection Object already available in the device
- An Explicit Messaging Connection Object already available in the device to dynamically create and set up an appropriate I/O Connection Object

I/O Messages usually pass directly to the data of the assigned application object. The Assembly Object is the most common application object used with I/O Connections. Also refer to Figure 9.8.

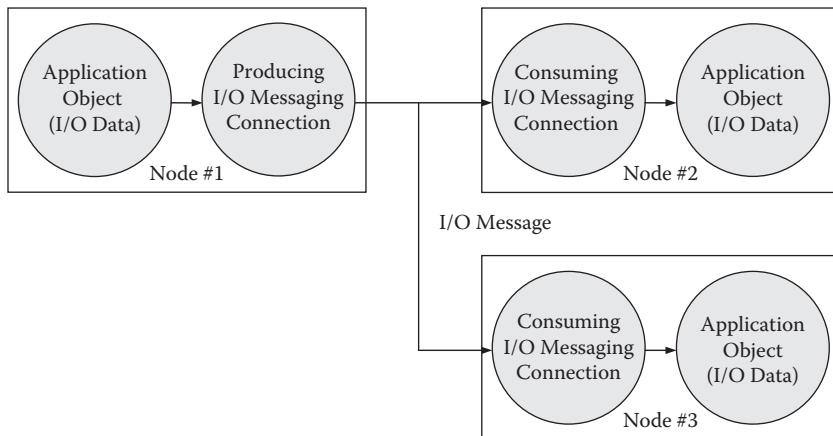

FIGURE 9.17 I/O messaging connections.

### 9.3.1.15 Using the CAN Identifier

DeviceNet is based on the standard CAN protocol and therefore uses an 11-bit message identifier. A distinction therefore can be made between  $2^{11} = 2048$  messages. The 6-bit MAC ID field is sufficient to identify a device because a DeviceNet Network is limited to a maximum of 64 participants.

The overall CAN Identifier range is divided into four Message Groups of varying sizes, as shown in Figure 9.18.

The bitwise arbitration mechanism of CAN determines the priority of messages on DeviceNet. When two nodes transmit simultaneously, the numerically lower CAN Identifier value will win arbitration. The arbitration mechanism is explained in the CAN specification [11]. A detailed description is beyond the scope of this document, but in short, transmitted bits are shifted onto the wire most significant bit first, so a zero in the upper bit positions will take precedence over a one. As is shown in Figure 9.18, Message Group 1 has a zero in bit 10, so it is the highest-priority group. Group 2 is the second highest-priority group because of the zero in bit 9. Group 3 is the next highest priority group, because the CAN IDs contain a one in bits 9 and 10. All valid Group 3 Message IDs are lower numerically than the corresponding bits (8–6) in Group 4 and therefore Group 4 is the lowest priority of all.

In DeviceNet, the CAN Identifier is the CID. This comprises the Message Group ID, the Message ID within this group, and the device's MAC ID, which can be the source or destination address. The definition depends on the Message Group and the Message ID. The significance of the message within the system is defined by the Message Group and Message ID.

The four Message Groups are used as follows:

*Message Group 1* is assigned 1024 CAN Identifiers (0x0000–0x03FF), which is 50% of all identifiers available. Up to 16 different Message IDs are available per device (node) within this group. The priority of a message within this group is primarily determined by the Message ID (the significance of the message) and only after that by the source MAC ID (the producing device). If two devices transmit a Message Group 1 message at the same time, then the device with the lower Message ID will always win the arbitration. However, if two devices transmit the same Message ID at the same time on the CAN bus, then the device with the lower MAC ID will win. The messages of Group 1 are, therefore, well suited for the exchange of high-priority process data.

*Message Group 2* is assigned 512 identifiers (0x0400–0x05FF). Most of the Message IDs in this group are optionally defined for what is commonly referred to as the Predefined Master Slave Connection Set (see Section 9.3.1.17). One Message ID is reserved for the Duplicate Node ID Check (see Section 9.3.1.10). Priority within Message Group 2 is determined primarily by the MAC ID and, only after that, by the Message ID. This message group was designed so that a CAN controller with an 8-bit mask is able to filter out its Group 2 Messages based on MAC ID. This makes it possible for very low-cost, low-functionality microcontrollers with integral CAN controllers to be suitable for use on DeviceNet.

Connection ID = CAN Identifier (Bits 10:0)											Used For
10	9	8	7	6	5	4	3	2	1	0	Used For
0	Message ID				Source MAC ID				Message Group 1		
1	0	MAC ID				Message ID				Message Group 2	
1	1	Message ID				Source MAC ID				Message Group 3	
1	1	1	1	1	Message ID				Message Group 4		
1	1	1	1	1	1	1	x	x	x	x	Invalid CAN Identifiers

FIGURE 9.18 Definition of the Message Groups.

*Message Group 3*, with 448 CAN Identifiers (0x0600–0x07BF), has a similar structure to Message Group 1; however, it is mainly used for low-priority process data exchange due to the relative priority difference between Groups 1 and 3. In addition, the main use of this group is setting up dynamic Explicit Connections. Seven Message IDs per device are possible, and two of these are reserved for what is commonly referred to as the UCMM port (see Section 9.3.1.16).

*Message Group 4*, with 48 CAN Identifiers (0x07C0–0x07EF), does not include any MAC IDs, only Message IDs. The messages in this group are used only for network management. Four Message IDs are currently assigned for services of the Offline Connection Set.

The remaining 16 CAN Identifiers (0x07F0–0x07FF) are invalid CAN IDs and thus are not permitted for use in DeviceNet systems.

With this allocation of CAN Identifiers, the unused CAN Identifiers cannot be used by other devices. Therefore, each device has exactly 16 Message IDs in Group 1, 8 Message IDs in Group 2, and 7 Message IDs in Group 3. One advantage of this system is that the CAN Identifiers used in the network can always be clearly assigned to a device. Devices are responsible for managing their own identifiers. This simplifies the design, troubleshooting, and diagnosis of DeviceNet systems, as a central tool that keeps a record of all CAN ID assignments on the network is not needed.

### 9.3.1.16 Connection Establishment

As described in Sections 9.3.1.12 and 9.3.1.14, messages on DeviceNet are always exchanged in a connection-based manner. Communication objects must be set up for this purpose. These are not initially available when a device is powered on; they first have to be created. There are two ports by which a DeviceNet device can be addressed when first powered on, the UCMM port or the Group 2 Only Unconnected Explicit Request port, which is defined by the Predefined Master Slave Connection Set. Picture these ports as doors to the device. Only one key will unlock each door. The appropriate key for each lock is the CID—that is, the CAN Identifier—of the selected port. Other doors in the device can be opened only if and when the appropriate key is available, and other instances of Connection Objects are set up.

The setting up of communication relationships (i.e., connections) via the UCMM port represents a general procedure that should be adhered to with all DeviceNet devices. Devices that feature the Predefined Master Slave Connection Set and are UCMM Capable are called Group 2 Servers. A Group 2 Server can be addressed by one or more connections from one or more clients.

Since UCMM-capable devices need a good amount of processing power to service multiple communication requests, a simplified communication establishment and I/O data exchange method has been created for low-end devices. This is called the Predefined Master Slave Connection Set (see Section 9.3.1.17). This covers as many as five predefined connections that can be activated (assigned) when accessing the device. The Predefined Master Slave Connection Set represents a subset of the general connection establishment method, and it is limited to pure Master Slave relations. Slave devices that are not UCMM Capable and support only this subset are called Group 2 Only Servers. Only the master that allocates it can address a Group 2 Only Server. All messages received by this device are defined in Message Group 2.

For more details of the connection establishment using UCMM and the Master Slave Connection Set, refer to Refs. [4,5].

### 9.3.1.17 Predefined Master Slave Connection Set

Establishing a connection via the UCMM port requires a relatively large number of steps that must be completed to allow data exchange via DeviceNet, and the devices must provide resources to administer the dynamic connections. Because every device can set up a connection with every other device and the source MAC ID of the devices is contained in the CID, the CAN Identifier (CID) may have to be filtered via software. This depends on how many connections a device supports and on the type and number of screeners (hardware CAN ID filters) of the CAN chip used in the device's implementation.

While this approach maximizes the use of the multicast, peer-to-peer, and Producer/Consumer capabilities of CAN, it requires a higher-performance CPU and more RAM and ROM resources. These requirements eliminate an entire class of low-cost microcontrollers with internal CAN controllers from consideration, raising the cost of implementation to levels that preclude cost-effective solutions for low-end (e.g., low end-user cost) devices. The Predefined Master Slave Connection Set was designed to minimize message processing and to take advantage of the limited screening capabilities of many CAN controllers. The Predefined Master Slave Connection Set is the way that the vast majority of devices communicate on DeviceNet.

The Predefined Master Slave Connection Set defines an alternate way to establish connections called the Group 2 Only Unconnected Explicit Request Port. This method allows a device to limit the messages received to only those in Group 2 with its own MAC ID. This greatly reduces the amount of packets that a node must deal with. A CAN controller with a single mask and match screener (a so-called BasicCAN screener) can be used in this type of device, which makes it possible to use the low-cost microcontrollers and simple CAN controllers mentioned earlier. Devices that operate in this manner are referred to as Group 2 Only Servers, deriving their name from the fact that they are only required to receive messages in Group 2.

The Predefined Master Slave Connection Set is also used in UCMM-capable devices. Such devices are referred to as Group 2 Servers, deriving their name from the fact that they respond to Group 2 messages but are not limited to just Group 2 messages.

Many of the reasons for defining the Predefined Master Slave Connection Set were due to hardware limitations prevalent when the protocol was first developed. Many of the cost considerations have changed as hardware evolved over time. Today, most devices can be implemented with a UCMM port and still be cost effective. This is the preferred type of device to develop today. For reasons that go beyond the scope of this document, devices that are not capable of UCMM place extra burden on other devices and tools. Except in extremely low-cost situations, UCMM should always be a design goal for DeviceNet products.

The Predefined Master Slave Connection Set provides an interface for a set of up to five preconfigured connection types in a node.

The basis of this model is a 1:n communication structure consisting of one control device and decentralized I/O devices. The central portion of such a system is known as the *Master*, and the decentralized devices are known as *Slaves*. Multiple masters are allowed on the network, but a slave can be allocated to only one master at any time.

The predefined Connection Objects occupy instances 1–5 in the Connection Object (Class ID 0x05, see Section 9.2.4):

- Explicit Messaging Connection
  - Group 2 Explicit Request/Response Message (Instance ID 1)
- I/O Messaging Connections
  - Polled I/O Connection (Instance ID 2)
  - Bit-Strobe I/O Connection (Instance ID 3)
  - COS or Cyclic I/O Connection (Instance ID 4)
  - Multicast Polling I/O Connection (Instance ID 5)

The messages to the slave are defined in Message Group 2, and some of the responses from the slave are contained in Message Group 1. The distribution of CIDs for the Predefined Master Slave Connection Set is defined as shown in Figure 9.19.

Because the CAN ID of most of the messages the master produces contains the destination MAC ID of the slave, it is imperative that only one master talks to any given slave. Therefore, before it can use this Predefined Connection Set, the master must first allocate it with the device. The DeviceNet Object manages this important function in the slave device. It allows only one master to allocate its Predefined Connection Set, thereby preventing duplicate CAN IDs from appearing on the wire.

The two services used are called `Allocate_Master_Slave_Connection_Set` (Service Code 0x4B) and `Release_Group_2_Identifier_Set` (Service Code 0x4C). These two services always access instance 1 of the DeviceNet Object (Class ID 0x03) (see Figure 9.20).

Connection ID = CAN Identifier (bits 10:0)											Used For				
10	9	8	7	6	5	4	3	2	1	0	Used For				
0	Group 1 Message ID			Source MAC ID			Group 1 Messages								
0	1	1	0	0	Source MAC ID			Slave's I/O Multicast Poll Response							
0	1	1	0	1	Source MAC ID			Slave's I/O Change of State or Cyclic Message							
0	1	1	1	0	Source MAC ID			Slave's I/O Bit-Strobe Response Message							
0	1	1	1	1	Source MAC ID			Slave's I/O Poll Response or COS/Cyclic Ack Message							
1	0	MAC ID		Group 2 Message ID			Group 2 Messages								
1	0	Source MAC ID		0	0	0	Master's I/O Bit-Strobe Command Message								
1	0	Source MAC ID		0	0	1	Master's I/O Multicast Poll Group ID								
1	0	Destination MAC ID		0	1	0	Master's Change of State or Cyclic Ack Message								
1	0	Source MAC ID		0	1	1	Slave's Explicit/Unconnected Response Messages								
1	0	Destination MAC ID		1	0	0	Master's Explicit Request Messages								
1	0	Destination MAC ID		1	0	1	Master's I/O Poll Command/COS/Cyclic Message								
1	0	Destination MAC ID		1	1	0	Group 2 Only Unconnected Explicit Request Messages								

**FIGURE 9.19** Connection IDs of the Predefined Master Slave Connection Set

Figure 9.20 shows the Allocate Message with 8-bit Class ID and 8-bit Instance ID, a format that is always used when it is sent as a Group 2 Only Unconnected Message. It also may be sent across an existing connection and in a different format if a format other than 8/8 was agreed during the connection establishment.

The Allocation Choice Byte is used to determine which predefined connections are to be allocated (see Figure 9.21).

The associated connections are activated by setting the appropriate bits. COS and Cyclic are mutually exclusive choices. The COS/Cyclic Connection may be configured as not acknowledged using the acknowledge suppression bit. The individual connection types are described in more detail in the following text.

Byte Offset	Bit Number							
	7	6	5	4	3	2	1	0
0	Frag [0]	XID			MAC ID			Message header
1	R/R [0]			Service Code [0x4B]				Message body
	Class ID [0x03]							
	Instance ID [0x01]							
2–5	Allocation Choice							
	0	0			Allocator's MAC ID			

**FIGURE 9.20** Allocate\_Master Slave\_Connect\_Set Request Message

Bit Number								
7	6	5	4	3	2	1	0	
Reserved	Ack suppression	Cyclic	Change of state	Multicast polling	Bit-strobe	Polled	Explicit Message	

**FIGURE 9.21** Format of the Allocation Choice Byte

The allocator's MAC ID contains the address of the node (master) that wants to assign the Predefined Master Slave Connection Set. Byte 0 of this message differs from the allocator's MAC ID if this service has been passed on to a Group 2 Only Server via a Group 2 Only Client (what is commonly referred to as a *proxy function*).

The slave, if not already claimed, responds with a Success Message. The connections are now in the Configuring State. Setting the Expected\_Packet\_Rate EPR (Set\_Attribute\_Single service to attribute 9 in the appropriate Connection Object instance, value in ms) starts the connection's time-monitoring function. The connection then changes into Established State, and I/O Messages begin transferring via this connection.

The allocated connections can be released individually or collectively through the Release\_Master\_Slave\_Connection\_Set service (Service Code 0x4C), using the same format as that in Figure 9.20, except that the last byte (Allocator's MAC ID) is omitted.

The following is an explanation of the four I/O Connection types in the Predefined Master Slave Connection Set.

#### 9.3.1.17.1 Polled I/O Connection

A Polled I/O Connection is used to implement a classic Master Slave relationship between a control unit and a device. In this setup, a master can transfer data to a slave using the Poll Request and receive data from the slave using the Poll Response. Figure 9.22 shows the exchange of data between one master and three slaves in Polled I/O mode.

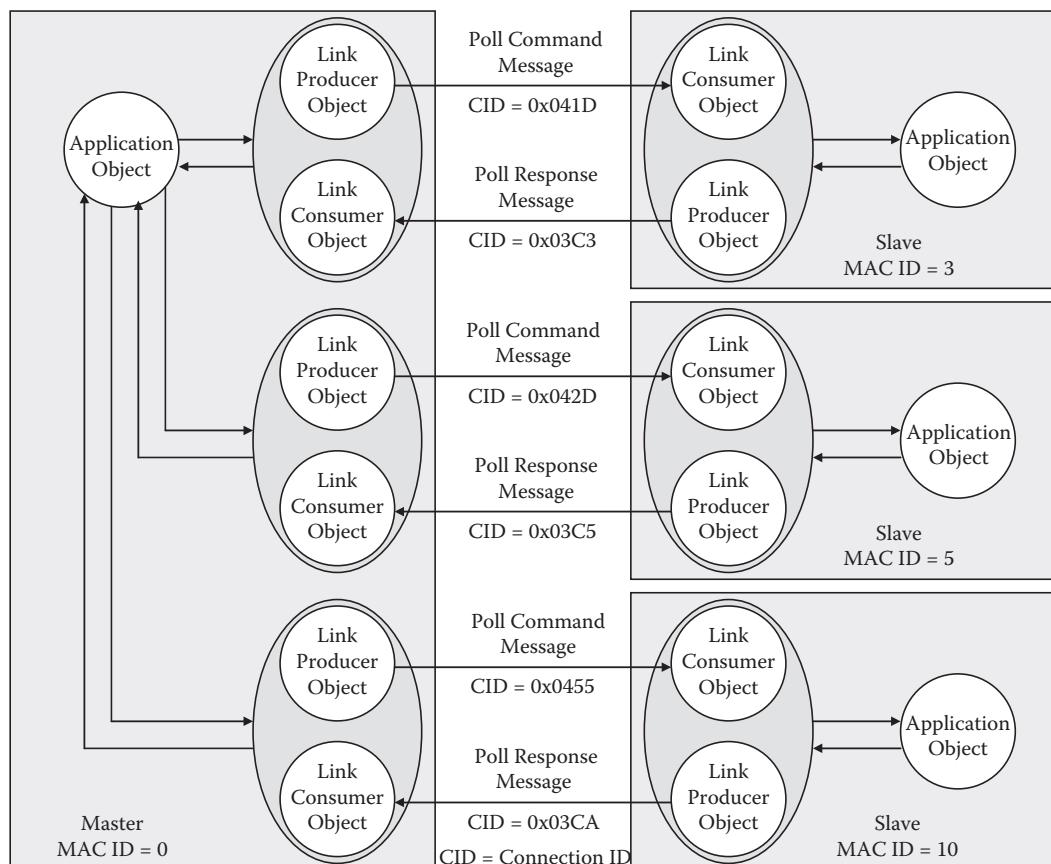

FIGURE 9.22 Polled I/O Connections.

The amount of data transferred in a message between a master and a slave using the Polled I/O Connection can be any length. If the length exceeds 8 bytes, the fragmentation protocol is automatically used. A Polled I/O Connection is always a point-to-point connection between a master and a slave. The slave consumes the Poll Message and sends back an appropriate response (normally, its input data).

The Polled Connection is subject to a time-monitoring function, which can be adjusted, in the device. A Poll Command must have been received within this time ( $4 \times EPR$ ) or else the connection reverts to timeout mode. When a connection times out, the node optionally may go to a preconfigured fault state as set up by the user. A master usually polls all the slaves in a round-robin manner.

A slave's response time to a poll command is not defined in The DeviceNet Specification. While this provides flexibility for slave devices to be tailored to their primary application, it may also exclude the device from use in higher-speed applications.

#### 9.3.1.17.2 Bit-Strobe I/O Connection

The master's transmission on this I/O Connection is the Bit-Strobe Command. Using this command, a master multicasts one message to reach all its slaves allocated for the Bit-Strobe Connection. The frame sent by the master using a Bit-Strobe Command is always 8 bytes or 0 bytes (if Idle). From these 8 bytes, each slave is assigned one bit (see Figure 9.23). Each slave can send back as many as 8 data bytes in its response.

A Bit-Strobe I/O Connection represents a multicast connection between one master and any number of strobe-allocated slaves (see Figure 9.24). Since all devices in a network receive the Bit-Strobe Command at the same time, they can be synchronized by this command. When the Bit-Strobe Command is received, the slave may consume its associated bit and then send a response of up to 8 bytes.

Since this command uses the source MAC ID in the CID (see Figure 9.19), devices that support the Bit-Strobe I/O Connection and have a CAN chip with screening limited to only 8 bits of the CAN ID (11 bits) must perform software screening of the CAN Identifier.

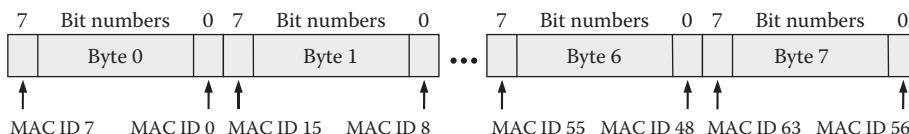

#### 9.3.1.17.3 Change of State/Cyclic I/O Connection

The COS/Cyclic I/O Connection differs from the other types of I/O Connections in that both end points produce their data independently. This can be done in a COS or Cyclic manner. In the former case, the COS I/O Connection recognizes that the application object data indicated by the Produced\_Connection\_Path have changed. In the latter case, a timer of the Cyclic I/O Connection expires and therefore triggers the message transfer of the latest data from the application object.

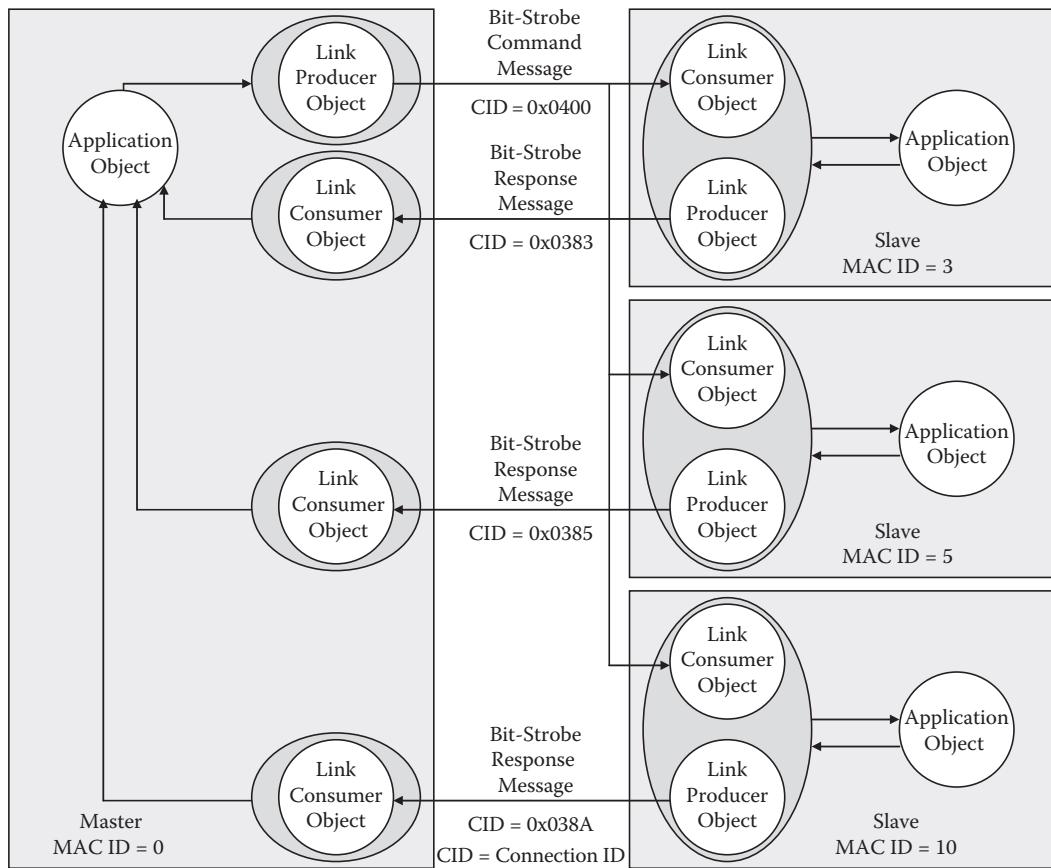

A COS/Cyclic I/O Connection can be set up as acknowledged or unacknowledged. When acknowledged, the consuming side of the connection must define a path to the Acknowledge Handler Object to ensure proper handling of acknowledgments and management of any required retries.

Figure 9.25 shows the various COS/Cyclic I/O Connection possibilities.

A COS/Cyclic I/O Connection can also originate from a master, making it appear to the slave like a Polled I/O Connection. This can be seen in Figure 9.19 since the same CID is used for the master's Polled I/O Message as is used for the master's COS/Cyclic I/O Message. COS Connections have two additional behaviors not present in other connection types. The Expected Packet Rate (EPR) is used as a default production trigger so that, if the connection data have not changed after the EPR timer has expired, it will be resent anyway. This *heartbeat*, as it is sometimes called, is utilized so the consuming node can

**FIGURE 9.23** Data format of the Bit-Strobe I/O Connection.

**FIGURE 9.24** Bit-Strobe I/O Connections.

know the difference between a node that has gone offline and one whose data have not changed. COS Connections also have a Production Inhibit Timer feature that prevents a node from producing data too often and thus using too much network bandwidth. The production inhibit timer determines the amount of time the node must remain quiet after producing data to the network.

#### 9.3.1.17.4 Multicast Polled I/O Connection

This connection is similar to the regular I/O poll except that all of the slaves belonging to a multicast group consume the same output data from the master. Each slave responds with its own reply data. A unique aspect of this connection is that the master picks the CAN ID from one of the slaves in the multicast group and must then set the consumed CAN ID in each of the other slaves to that same value. If, during runtime, that slave's connection times out, the master must either stop producing its multicast poll command or pick another slave in the group and reset the command CAN ID in all the remaining slaves in the group to that value before sending another Multicast Poll Command.

#### 9.3.1.17.5 I/O Data Sharing

Due to the inherent broadcast nature of all CAN frames, applications can be set up to *listen* to the data produced by other applications. Such a *listen-only* mode is not described in the DeviceNet specification, but some vendors have created products that do exactly that, for example, *shared inputs* in Allen-Bradley I/O Scanners.

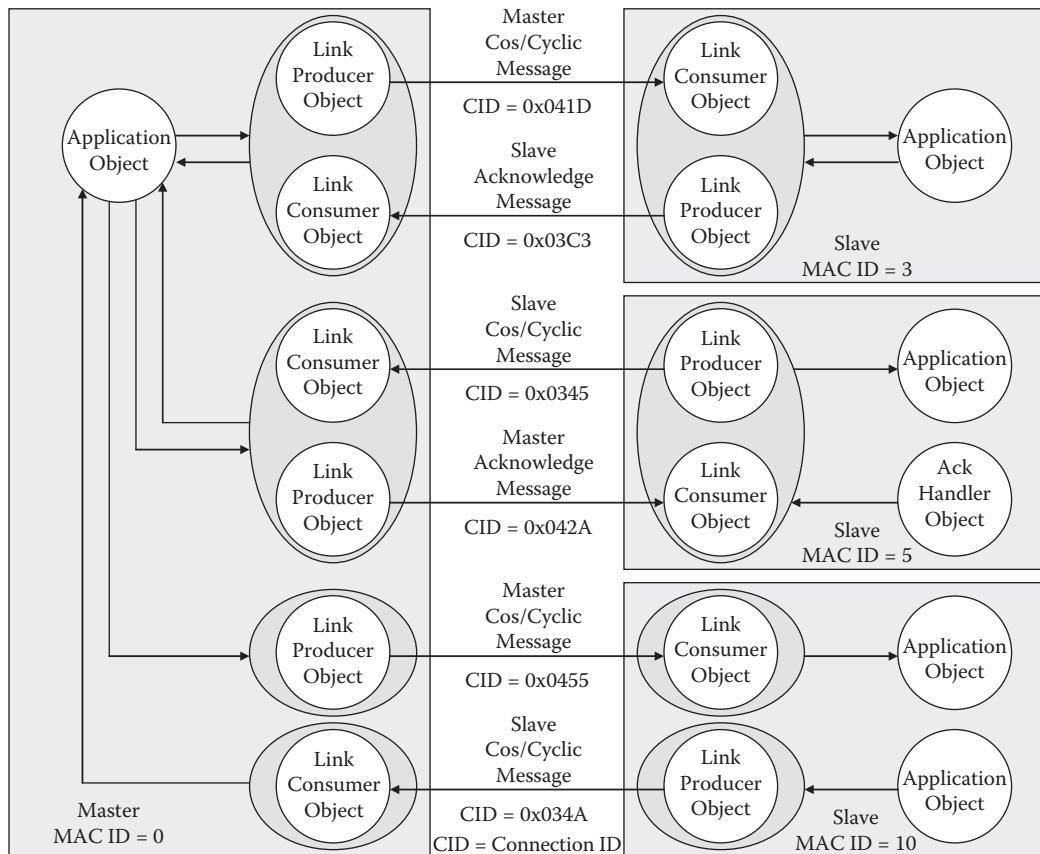

FIGURE 9.25 COS/Cyclic I/O Connections.

#### 9.3.1.17.6 Typical Master Slave Start Sequence

Typically, starting up a DeviceNet Network with an I/O Scanner and a set of slaves is executed as follows:

- All devices run their self-test sequence and then try to go online with the algorithm described in Section 9.3.1.10. Any device that uses an autobaud mechanism to detect the baud rate of a network has to wait with its Duplicate Node ID Message until it has seen enough CAN frames to detect the correct baud rate.
- Once online, slave devices will remain silent, except to defend their MAC ID, until their master allocates them.
- Once online, a master will try to allocate each slave configured into its scan list by running the following sequence of messages:
  - Try to open a connection to the slave using a UCMM Open Message.
  - If successful, the master can then use this connection for further communication with the slave (the device is a Group 2 Server).
  - If not successful, the master will try again after a minimum wait time of 1 s.
  - If unsuccessful again, the master will try to allocate the slave using the Group 2 Only Unconnected Explicit Request Message (at least for Explicit Messaging) after a minimum wait time of 1 s.
  - If successful, the master can then use this connection for further communication with the slave (the device is a Group 2 Only Server).

- If not successful, the master will try again after a minimum wait time of 1 s.
- If unsuccessful again, the master will start over with the UCMM Message after a minimum wait time of 1 s. This process will carry on indefinitely or until the master has allocated the slave.
- Once the master has allocated the slave, it may carry out some identity verification to see whether it is safe to start I/O Messaging with the slave. The master also may apply further configuration to the connections it has established, for example, setting the Explicit Messaging Connection to *Deferred Delete*;
- Setting the EPR value(s) brings the I/O Connection(s) to the Established State so that I/O Messaging can commence.

#### 9.3.1.17.7 QuickConnect Connection Establishment

DeviceNet also allows an optional method of connection establishment known as QuickConnect. This was designed to provide the same level of protection against duplicate MAC IDs, but to do so in a much shorter time period, allowing connections to be established in a fraction of the time they normally take. This method is useful in applications where nodes are added to an operating network and the time required for establishing connections directly impacts productivity. For example, in robotic applications, the end-of-arm electronics are often changed out when a new item enters its workspace. These electronics need to be operational very quickly to avoid cycle time delays.

The QuickConnect process includes all the same steps as the typical start-up process, but most of them are done in parallel rather than in sequence. As a result, the device self-check and Duplicate MAC ID Check processes begin immediately, and the node goes online almost simultaneously. A failure of the device self-test or a duplicate MAC ID indication causes the device to remove itself from the bus.

In order for applications to benefit fully from this method, QuickConnect must be implemented in both the master and the slave. This feature is selectable through an EDS entry and, by default, is disabled in nodes that support it.

#### 9.3.1.17.8 Master Slave Summary

Device manufacturers can easily support the Predefined Master Slave Connection Set by using simple BasicCAN controllers. Software screening of the CAN Identifier generally is not necessary, which enables the use of low-cost 8-bit controllers. This may represent an advantage as far as the devices are concerned but entails some disadvantages for the system design.

Group 2 Only (i.e., UCMM-incapable) devices permit only one Explicit Messaging Connection between client (master) and server (slave), whereas UCMM-capable devices can maintain Explicit Messaging Connections with more than one client at the same time.

If a device wants to communicate with one of the allocated slaves that does not support UCMM, the master recognizes this situation and sets up a communication relationship with the requestor instead. Any communication between the requestor is then automatically routed via the master. This is called the Proxy function. Since this puts an additional burden on the master and on network bandwidth, it is recommended that slave devices support UCMM.

Although not explicitly defined in The DeviceNet Specification, DeviceNet masters can, under certain conditions, automatically configure their scan lists and/or the devices contained in their scan lists. This functionality simply makes use of the explicit messaging capabilities of masters and slaves that allows the master to read from a slave whatever information is required to start an I/O communication and to download any configurable parameters that have been communicated to the master via EDS. This functionality facilitates the replacement of even complex slave devices without the need for a tool, dramatically reducing system downtime.

### 9.3.1.18 Device Profiles

DeviceNet devices may utilize any of the device profiles described in the CIP Networks Library. As of the publication date of this book, no DeviceNet-specific profiles have been defined.

### 9.3.1.19 Configuration

DeviceNet devices typically come with EDSs as described in Section 9.2.7. EDS files for DeviceNet devices can make full use of all EDS features, but they do not necessarily contain all sections. Typical DeviceNet devices contain (apart from the mandatory sections) at least an IO\_Info section.

This section specifies which types of Master Slave connections are supported and which one(s) should be enabled as defaults. It also tells which I/O Connections may be used simultaneously.

An EDS also may contain individual parameters and/or a Configuration Assembly with a complete description of all parameters within this assembly. A full description of what can be done in DeviceNet EDS files would go well beyond the scope of this book. For available materials on this topic that go into more detail, see [1,2].

### 9.3.1.20 Conformance Test

See Chapter 6 of this publication for information on conformance testing.

### 9.3.1.21 Tools

Tools for DeviceNet networks can be divided into three groups:

1. Physical layer tools are tools (hardware and/or software) that verify the integrity and conformance of the physical layer or monitor the quality of the data transmission.
2. Configuration tools are software tools capable of communicating with individual devices for data monitoring and configuration purposes. They can range from very basic software operating on handheld devices to powerful PC-based software packages used to configure complete networks. Most configuration tools are EDS-based; however, more complex devices like I/O Scanners tend to have their own configuration applets that are only partially based on EDS files. Some of these tools support multiple access paths to the network, for example, via Ethernet and suitable routing devices, and thus allow remote access. High-level tools also actively query the devices on the network to identify them and monitor their *health*.
3. Monitoring tools typically are PC-based software packages that can capture and display CAN frames on the network. A raw CAN frame display may be good enough for some experts, but using a tool that allows both raw CAN display and DeviceNet interpretation of the frames is recommended.

For a typical installation, a configuration tool is all that is needed. However, to ensure that the network is operating reliably, verification with a physical layer tool is highly recommended. Experience shows that the overwhelming majority of DeviceNet network problems are caused by inappropriate physical layer installation. Protocol monitoring tools are used primarily to investigate interoperability problems and to assist during the development process. Turn to the CIP supplier directory on the ODVA website to access a list of vendors that provide tools for DeviceNet.

### 9.3.1.22 Advice for Developers

Before starting any DeviceNet product development, the following issues should be considered in detail:

- What functionality does the product require today and in future applications?
  - Slave functionality
  - Group 2 Server vs. Group 2 Only Server.
  - Master functionality
  - Combination of Master and Slave functionality

- What are the physical layer requirements? Is IP 65/67 required, or is IP 20 good enough?
- What type of hardware should be chosen for this product?
- What kind of firmware should be used for this product? Will a commercially available communication stack be used?
- Will the development of hardware and/or software be done internally, or will it be designed by an outside company?
- What are the configuration requirements?
- What design and verification tools should be used?
- What kind of configuration software should be used for this product? Will a commercially available software package be used, that is, is an EDS adequate to describe the device or is custom software needed?
- When and where will the product be tested for conformance and interoperability?
- What is an absolute must before my products can be placed on the market (i.e., own the specification, have the company's own Vendor ID, and have the product conformance tested)?

A full discussion of these issues goes well beyond the scope of this publication; for more information, see [12].

### 9.3.1.23 DeviceNet Summary

Since its introduction in 1994, DeviceNet has been used successfully in tens of millions of nodes in many different applications. It is a de facto standard in many countries, which is reflected in several national and international standards [6,13,7]. Due to its universal communication characteristics, it is one of the most versatile networks for low-end devices. While optimized for devices with small amounts of I/O, it can easily accommodate larger devices as well. Powerful EDS-based configuration tools allow easy commissioning and configuration of even complex devices without the need to consult manuals.

With the introduction of CIP Safety on DeviceNet, many machine-level applications that previously required a set of dedicated networks today can be accommodated on a single DeviceNet network.

Finally, as a member of the CIP family of networks, DeviceNet can be combined into an overall CIP Network structure that allows seamless communication among CIP Networks, as if they were only one network.

## 9.3.2 ControlNet

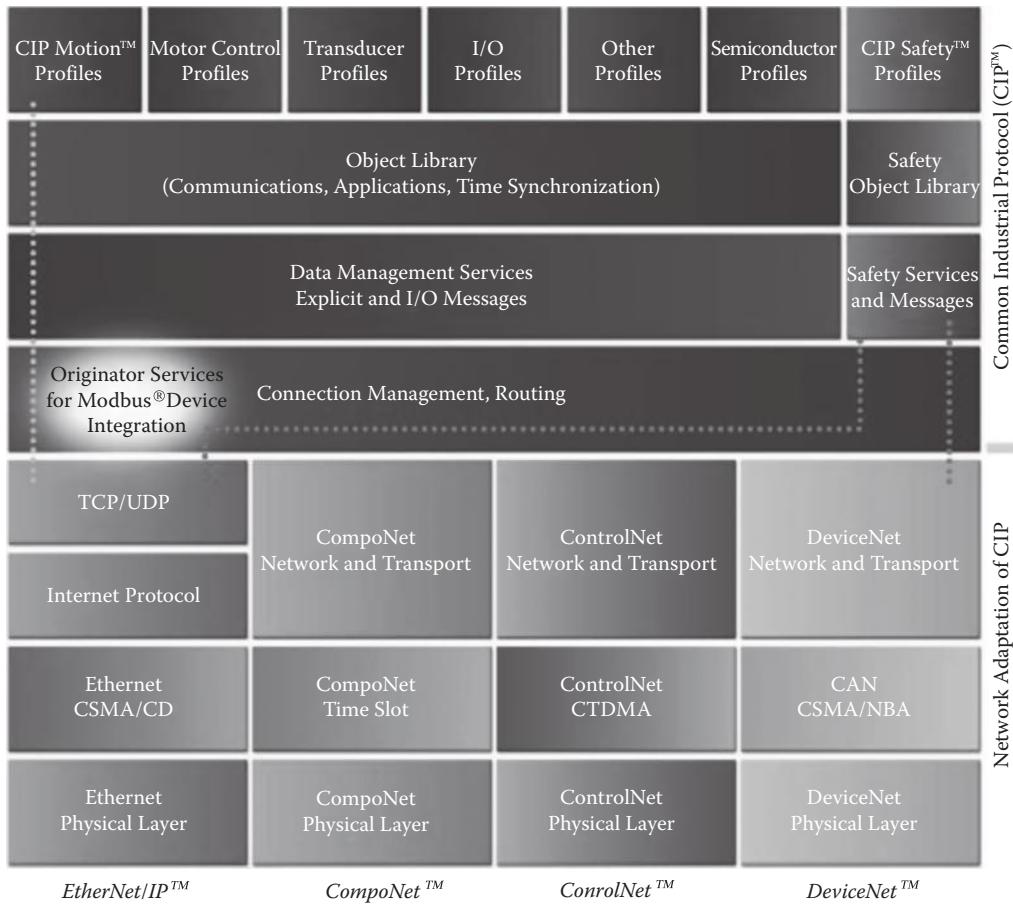

### 9.3.2.1 Introduction

Introduced in 1997, ControlNet is a deterministic digital communications network that provides high-speed transport of time-critical I/O and explicit messaging data—including upload/download of programming and configuration data and peer-to-peer messaging—on a single physical media link. Each device and/or controller is a node on the network.

ControlNet is a Producer/Consumer network that supports multiple communication hierarchies and message prioritization. ControlNet systems offer a single point of connection for configuration and control by supporting both Implicit (I/O) and Explicit Messaging. ControlNet's time-based message scheduling mechanism provides network devices with deterministic and predictable access to the network while preventing network collisions. This scheduling mechanism allows time-critical data, which is required on a periodic, repeatable, and predictable basis, to be produced on a predefined schedule without the loss of efficiency associated with continuously requesting, or *polling*, for the required data.

### 9.3.2.2 Relationship to Standards

Like other CIP Networks, ControlNet follows the OSI model, an ISO standard for network communications that is hierarchical in nature. Networks that follow this model define all necessary functions, from physical implementation up to the protocol and methodology to communicate control and information data within and across networks.

**FIGURE 9.26** Relationship between CIP and ControlNet.

Figure 9.26 shows the relationship between CIP and ControlNet.

The ControlNet adaptation of CIP is described in Volume 4 of the CIP Networks Library [14]. All other features are based on CIP. ControlNet is also described in international standards, for example in [15].

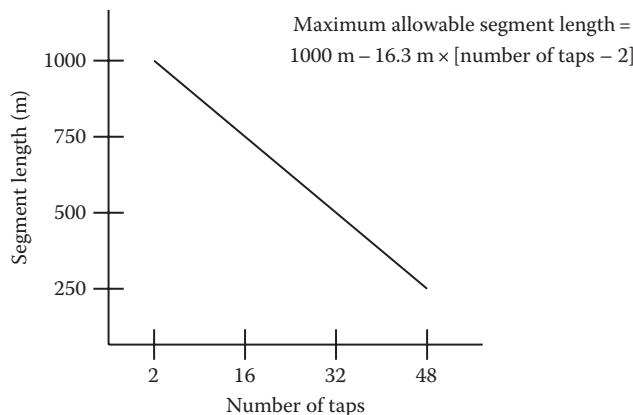

### 9.3.2.3 ControlNet Features

ControlNet is a high-speed deterministic industrial communication system with the following features:

- Trunkline/dropline configuration (copper media), star configuration (optical media)
- Support for media redundancy
- Support for up to 99 nodes
- Node insertion or removal while the network is up and running
- Use of sealed or open-style connectors
- Fixed baud rate (5 Mbaud)

### 9.3.2.4 ControlNet Physical Layer

The physical layer of ControlNet has been designed specifically for this network; it does not reuse any existing open technology. The basis of the physical layer is a  $75 \Omega$  coaxial trunkline (typically of RG-6 type cable) terminated at both ends with  $75 \Omega$  terminating resistors. To reduce impedance mismatch, all ControlNet devices are connected to the network through special taps that consist of a coupling

**FIGURE 9.27** Coax medium topology limits.

network and a specific length of dropline (1 m). There is no minimum distance requirement between taps, but since every tap introduces some signal attenuation, each tap reduces the maximum length of the trunkline by 16.3 m. This results in a full-length trunkline of 1000 m with only two taps at the ends, while a fully populated physical network with 48 taps allows a trunkline length of 250 m (see Figure 9.27).

This physical layer limitation is addressed by including repeaters that can increase the network size without lowering the speed. Therefore, if a network is to be built with a higher number of nodes (up to 99 nodes are possible) or with a topology that goes beyond the single trunkline limitations, repeaters can be used to extend the bus. It is possible to create any type of topology: tree, star, or linear bus. Even a ring topology is possible using a special type of repeater. Repeaters for fiber-optic media can be used either to further increase the system size or to allow isolation of network segments in harsh EMC environments or for high-voltage applications.

The number of repeaters between any two nodes was initially limited to five, but further technology developments now allow up to 20 repeaters in series. However, regardless of the media technology used, the overall length of a ControlNet system (the distance between any two nodes on the network) is still limited by propagation delay. With currently available media, this translates into approximately 20 km.

To better accommodate industry requirements, ControlNet supports redundant media, allowing bumpless transfer from primary to secondary media or vice versa if one of them should fail or deteriorate. Developers are encouraged to support this redundant media feature in their designs. For cost-sensitive applications, less expensive device variants may then be created by populating one channel only.

Another feature often used in the process industry is the capability of running ControlNet systems into areas with an explosion hazard. ControlNet is fully approved to meet worldwide standards for intrinsic safety (explosion protection).

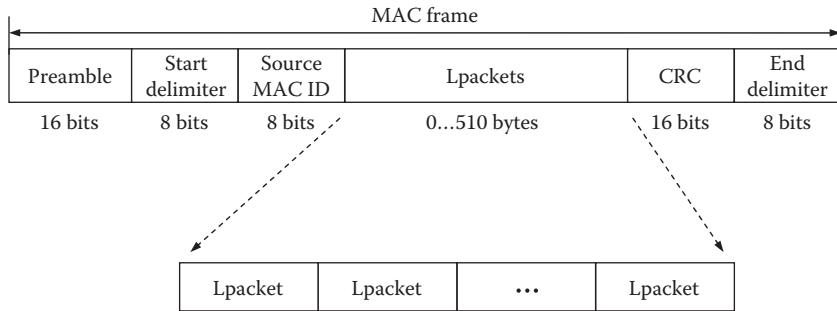

Copper media uses BNC-type connectors for IP 20-type applications and TNC-type connectors for IP 67 protection. Devices also may implement a Network Access Port. This feature takes advantage of the repeater function of the ControlNet ASICs. It uses an additional connector (RJ-45) with RS 422-based signals that provides easy access to any node on the network for configuration devices.

The signal transmitted on the copper media is a 5-Mbps Manchester-encoded signal with an amplitude of up to 9.5 V (pk-pk) at the transmitter that can be attenuated down to 510 mV (pk-pk) at the receiving end. The specification provides reference transmitting and receiving circuits.

### 9.3.2.5 Frame Structure

Every frame transmitted on ControlNet has the format of the MAC frame shown in Figure 9.28.

Within every MAC frame, a field of up to 510 bytes is available for transmitting data or messages. This field may be populated with one or several Lpackets (link packets). These Lpackets carry the individual

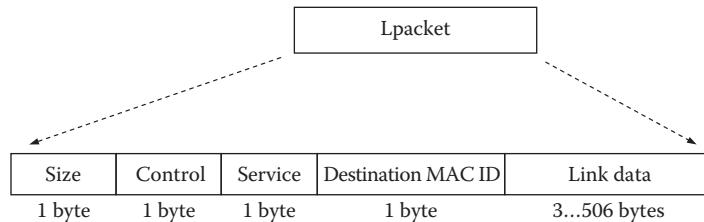

**FIGURE 9.28** MAC Frame Format.

CIP messages (I/O or Explicit). Specialized Lpackets are used for network management. Since all nodes always listen to all MAC frames, they have no problem consuming any of the Lpackets in a frame that is unicast, multicast, or broadcast in nature. This feature allows fine-tuned multicasting of small amounts of data to different sets of consumers without much overhead.

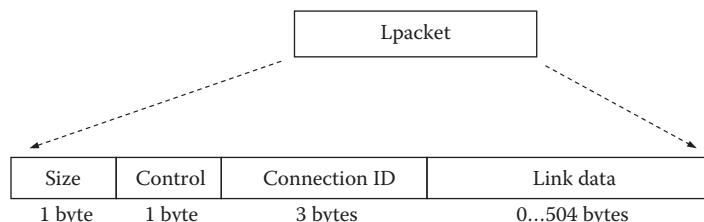

There are two types of Lpacket formats: fixed tag and generic tag. Fixed tag Lpackets are used for Unconnected Messaging and network administration packets, while the generic tag Lpackets are used for all Connected Messaging (I/O and Explicit).

Figure 9.29 shows the format of a fixed tag Lpacket. By including the destination MAC ID, this format reflects the fact that these Lpackets are always directed from the requesting device (sending the MAC frame) to the target device (the destination MAC ID). The service byte within a fixed tag Lpacket does not represent the service of an Explicit Message, but a service type on a different level, since the fixed tag Lpacket format can be used for a variety of actions, such as network administration.

Figure 9.30 shows the format of a generic tag Lpacket. The size byte specifies the number of words within the Lpacket, while the control byte gives information on what type of Lpacket this is. The 3-byte CID specifies which connection this Lpacket belongs to. These three bytes are the three lower bytes of the 4-byte CID specified in the Forward\_Open message; the uppermost byte is always zero. For a device

**FIGURE 9.29** Fixed tag Lpacket format.

**FIGURE 9.30** Generic tag Lpacket format.

that receives the MAC frame, the CID indicates whether to ignore the Lpacket (the device is not part of the connection), to consume the data and forward it to the application (the device is an end point of this connection), or to forward the data to another network (the device acts as a router in a routed connection).

### 9.3.2.6 Protocol Adaptation

ControlNet can use all features of CIP. The ControlNet frame is big enough that fragmentation is rarely required and thus is only provided by application-specific services that might require it. Since ControlNet is not used in very simple devices, no scaling is required.

### 9.3.2.7 Indicators and Switches

ControlNet devices must be built with Device Status and Network Status indicators as described in the specification. Devices may have additional indicators that must not carry any of the names of those described in the specification.

Devices may be built with or without switches or other directly accessible means for configuration. If switches for the MAC ID exist, then certain rules apply regarding how these values must be used at power-up and during the operation of the device.

### 9.3.2.8 Additional Objects

Volume 4 defines three additional objects: the ControlNet Object, the Keeper Object, and the Scheduling Object.

#### 9.3.2.8.1 ControlNet Object (Class ID: 0xF0)

The ControlNet Object contains a host of information about the state of the device's ControlNet interface, among them diagnostic counters, data link and timing parameters, and the MAC ID. A ControlNet Object is required for every physical layer attachment of the device. A redundant channel pair counts as one attachment.

#### 9.3.2.8.2 Keeper Object (Class ID: 0xF1)

The Keeper Object (not required for every device) holds (for the network scheduling software) a copy of the Connection Originator schedule data for all Connection Originator devices using the network. Every ControlNet Network with scheduled I/O traffic must have at least one device with a Keeper Object (typically, a PLC or another Connection Originator). If there are multiple Keeper Objects on a network, they perform negotiations to determine which Keeper is the Master Keeper and which Keeper(s) performs Backup Keeper responsibilities. The Master Keeper is the Keeper actively distributing attributes to the nodes on the network. A Backup Keeper is one that monitors Keeper-related network activity and can transition into the role of Master Keeper should the original Master Keeper become inoperable.

#### 9.3.2.8.3 Scheduling Object (Class ID: 0xF2)

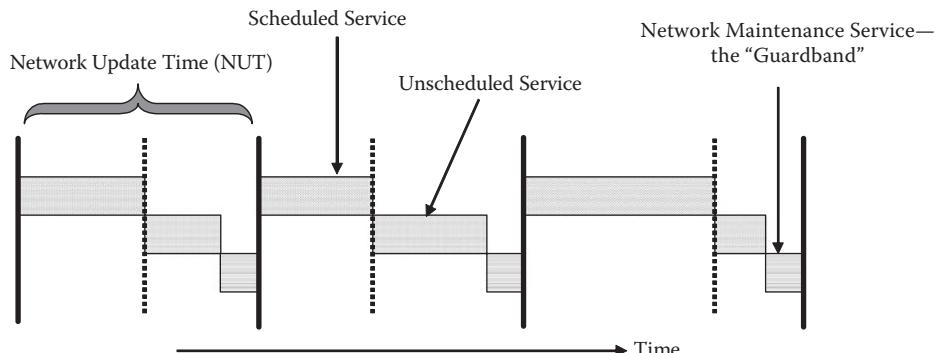

The Scheduling Object is required in every device that can originate an I/O Messaging Connection. Whenever a network scheduling tool accesses a Connection Originator on a ControlNet Network, an instance of the Scheduling Object is created and a set of object-specific services is used to interface with this object. Once the instance is created, the network scheduling tool can then read and write connection data for all connections that originate from this device. After having read the connection data from all Connection Originators, the network scheduling tool can calculate an overall schedule for the ControlNet Network and write these data back to all Connection Originators. The scheduling session is ended by deleting the instance of the Scheduling Object.

### 9.3.2.9 Network Access

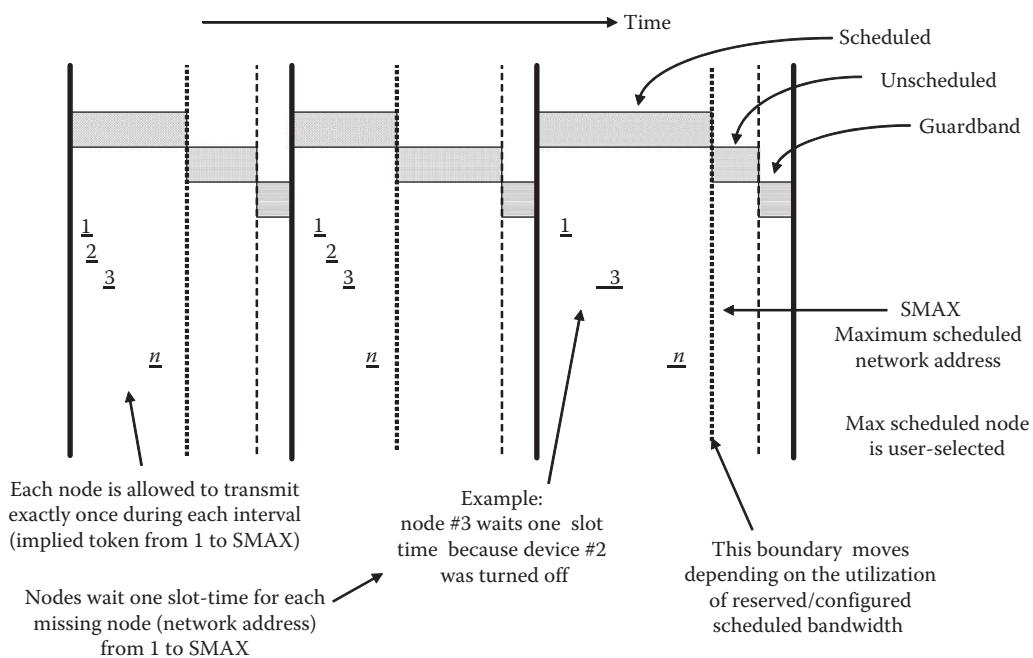

ControlNet's bus access mechanism allows full determinism and repeatability while still maintaining sufficient flexibility for various I/O Message triggers and Explicit Messaging. This bus access mechanism is called Concurrent Time Domain Multiple Access (CTDMA); it is illustrated in Figure 9.31.

The time axis is divided into equal intervals called Network Update Time (NUT). Each NUT is subdivided into the Scheduled Service Time, the Unscheduled Service Time, and the Guardband Time.

Figure 9.32 shows the function of the Scheduled Service. Every node up to, and including, the SMAX node (maximum node number participating in the Scheduled Service) has a chance to send a message within the Scheduled Service. If a particular node has no data to send, it will send a short frame to indicate that it is still alive. If a node fails to send its frame, the next-higher node number will step in after a very short, predetermined waiting time. This process ensures that a node failure will not lead to an interruption of the NUT cycle.

**FIGURE 9.31** Media access through CTDMA (Concurrent Time Domain Multiple Access).

**FIGURE 9.32** Scheduled Service.

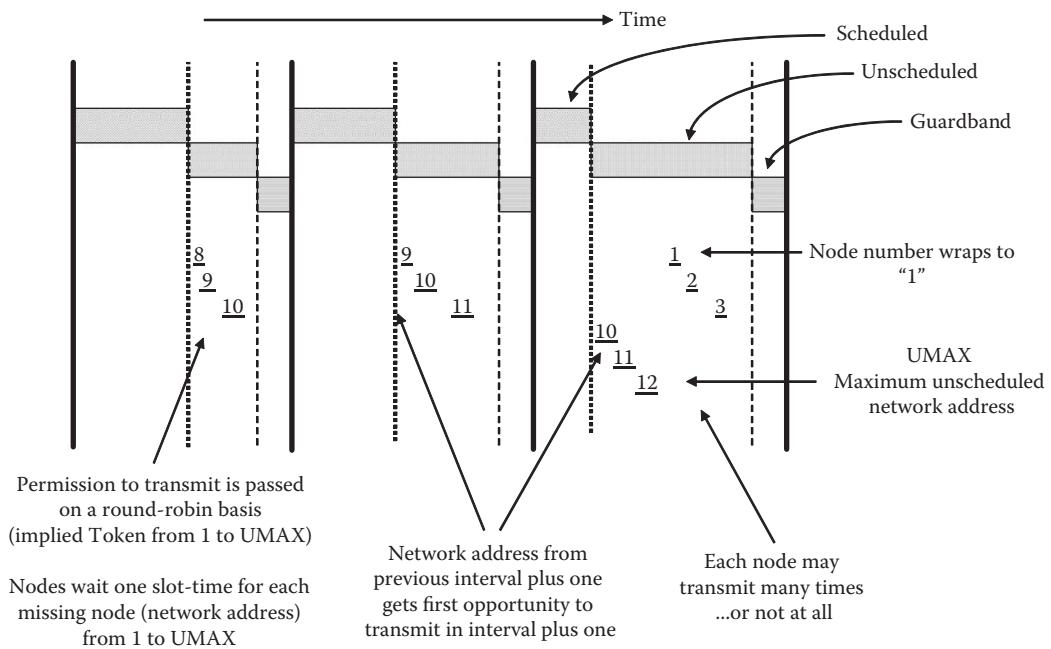

FIGURE 9.33 Unscheduled Service.

Figure 9.33 shows the function of the Unscheduled Service. Since this service is designed for non-time-critical messages, only one node is guaranteed access to the bus during the Unscheduled Service Time. If there is time left, the other nodes (with higher node numbers) will also get a chance to send. As with the Scheduled Service Time, if a node fails to send during its turn, the next node will step in. The node number that is allowed to send first within the Unscheduled Service Time is increased by one in each NUT. This guarantees an equal chance to all nodes. When the node sequencing within a NUT reaches the maximum value, known as UMAX, it wraps around to node 1, and the sequence resumes.

These two service intervals, combined with the Guardband, guarantee determinism and repeatability while still maintaining sufficient freedom to allow for unscheduled message transmissions, for example, for parameterization.

### 9.3.2.10 Network Start-Up

After power-on, every ControlNet device goes through a process of accessing the ControlNet communication network and learning the current NUT and other timing requirements. This is a fairly complex process typically handled by commercially available ControlNet ASICs. It is beyond the scope of this book to describe the details here.

### 9.3.2.11 Explicit Messaging

Explicit Messages on ControlNet, unlike those on DeviceNet, can be sent either connected or unconnected; both are transmitted within the unscheduled part of the NUT. Connected Explicit Messaging requires setting up a connection (see Section 9.3.2.13) before messages are exchanged. This means that all resources required for managing the connection are reserved for this purpose as long as the connection exists, which allows more timely responses to message requests. This is very useful when the application requires periodic explicit requests. Most Explicit Messages also can be sent unconnected, but this mechanism makes use of generally limited resources in nodes that sometimes can be highly utilized. For this reason, Unconnected Explicit Messaging should be used only when the application requires very irregular and infrequent request intervals. Every part of an Explicit Message (request,

response, and acknowledgments) is wrapped into an Lpacket using the fixed tag Lpacket format for Unconnected Explicit Messaging (see Figure 9.29) and the generic tag Lpacket format for Connected Explicit Messaging (see Figure 9.30). The service/class-instance/attribute fields (see Section 9.2.3) of the Explicit Message are contained in the link data field.

### 9.3.2.12 I/O Messaging

ControlNet I/O Messaging is accomplished using connections and always takes place in the scheduled part of the NUT. Only one MAC frame may be transmitted by any device within its time slot, but this MAC frame may contain multiple Lpackets so that data can be sent to multiple nodes in one NUT. The individual Lpackets may be consumed by one node only or by multiple nodes if they are set up to consume the same data.

I/O Messages use the generic tag Lpacket format (see Figure 9.30). The link data field contains the I/O data prefixed with a 16-bit Sequence Count Value for the packet. Run/Idle can be indicated within a pre-fixed Real-Time Header or by sending the data packet (Run) or no data packet (Idle). The method used is indicated in the connection parameters of the Connection Manager section of the EDS. However, only the Real-Time Header method has been used for ControlNet up to now.

### 9.3.2.13 Connection Establishment

All connections on ControlNet are established using a UCMM Forward\_Open message (see Section 9.2.3).

### 9.3.2.14 Device Classes

Four classes of device functionality are built with CIP. While they are not explicitly defined in the specification, they are useful for distinguishing among several classes of devices. The four classes are described here:

1. The minimal device function is that of an Explicit Message Server, which is used for Explicit Messaging applications only and acts as a target for Unconnected and (optionally) Connected Explicit Messages, for example, for program upload/download, data collection, status monitoring, etc.
2. The next device class is an I/O Server, which adds I/O Messaging Support to an Explicit Message Server device and acts as a target for both Explicit and I/O Messages, for example, simple I/O Devices, Pneumatic Valves, and AC Drives. These devices are also called I/O Adapters.
3. Another device class is an Explicit Message Client, which adds client support to Explicit Message Server applications and acts as a target and as an originator for explicit messaging applications, for example, computer interface cards and HMI devices.
4. The most powerful type of device is an I/O Scanner, which adds I/O Message origination support to the functionality of all the other device classes and which acts as a target and as an originator for Explicit and I/O Messages, for example, PLCs and I/O Scanners.

### 9.3.2.15 Device Profiles

ControlNet devices may utilize any device profiles described in the CIP Networks Library. As of the publication date of this book, no ControlNet-specific profiles have been defined.

### 9.3.2.16 Configuration

ControlNet devices typically come with EDSs as described in Section 9.2.6. For EDS-based configuration tools, the EDS should contain a Connection Manager section to describe the details of the connections that can be made into the device. This section basically mirrors the contents of the Forward\_Open message that a Connection Originator would send to the device. Multiple connections can be specified within an EDS, then one or more can be chosen by the configuration tool.

An EDS may also contain individual parameters and/or a Configuration Assembly with a complete description of all parameters within this assembly. In many applications, the Configuration Assembly is transmitted as an attachment to the Forward\_Open message.

### 9.3.2.17 Conformance Test

See Section 9.6 of this publication for information on conformance testing.

### 9.3.2.18 Tools

Tools for ControlNet Networks can be divided into three groups:

1. Physical layer tools are tools (hardware and/or software) that verify the integrity and conformance of the physical layer or monitor the quality of the data transmission.
2. Configuration tools are software tools capable of communicating with individual devices for data monitoring and configuration purposes. Most configuration tools are EDS-based; however, more complex devices like I/O Scanners tend to have their own configuration applets that are only partially based on EDS files. Some of these tools support multiple access paths to the network, for example, via Ethernet and suitable routing devices, and thus allow remote access. High-level tools also actively query the devices on the network to identify them and monitor their health. Configuration tools also may be integrated into other packages like PLC programming software.
3. Monitoring tools typically are PC-based software packages that can capture and display the ControlNet frames on the network. A raw ControlNet frame display may be good enough in some instances, but using a tool that can display both raw ControlNet frames and interpreted frames is recommended.

For a typical installation, a configuration tool is all that is needed. However, to ensure the network is operating reliably, testing with a physical layer tool is highly recommended. Experience shows that the overwhelming majority of ControlNet network problems are caused by inappropriate physical layer installation. Protocol monitoring tools are mainly used to investigate interoperability problems and to assist during the development process.

Turn to the CIP supplier directory on the ODVA website to access a list of vendors that provide tools for ControlNet.

### 9.3.2.19 Advice for Developers

Before any development of a ControlNet product is started, the following issues should be considered in detail:

- What functionality (Device Classes, see Section 9.3.2.14) does the product require today and in future applications?
  - Explicit Messaging server only.
  - I/O Adapter functionality.
  - Explicit Messaging client.
  - I/O Scanner functionality.
- What are the physical layer requirements? Is IP 65/67 required, or is IP 20 good enough?
- Will the development be based on commercially available hardware components and software packages (recommended) or designed from scratch (possible but costly)?
- What are the configuration requirements?
- What design and verification tools should be used?
- When and where will the product be tested for conformance and interoperability?
- What is an absolute must before products can be placed on the market (own the specification, have the company's own Vendor ID, and have the product conformance tested)?

Rockwell Automation has published a comprehensive developer's handbook that assists vendors in developing products, see [16]. ControlNet chipsets and associated software packages are available from Rockwell Automation. Turn to the ODVA website for a list of companies that can support ControlNet developments.

### 9.3.2.20 ControlNet Summary

Since its introduction in 1997, ControlNet has been used successfully in millions of nodes in many different applications. It is the network of choice for many high-speed I/O and PLC interlocking applications. Like DeviceNet, ControlNet has become an international standard [15]. Due to its universal communication characteristics, it is one of the most powerful controller-level networks available.

ControlNet's greatest strengths are its media redundancy and its full determinism and repeatability. These strengths make it ideally suited for many applications that require media redundancy and also for many high-speed applications, in which ControlNet maintains full Explicit Messaging capabilities without compromising its real-time behavior.

Finally, as a member of the CIP family of networks, ControlNet can be combined into an overall CIP Network structure that allows seamless communication among CIP Networks, just as if they were only one network.

## 9.3.3 EtherNet/IP

### 9.3.3.1 Introduction

Introduced in 2000, EtherNet/IP is another member of the CIP family. Using CIP as its upper-layer protocol, EtherNet/IP extends the application of Ethernet TCP/IP to the plant floor. EtherNet/IP can coexist with any other protocol running on top of the standard TCP/UDP Transport Layer and with other CIP Networks. EtherNet/IP—CIP plus Internet and Ethernet standards—provides a pure, unmodified, standards-based Ethernet solution for interoperability among manufacturing enterprise networks, and it enables Internet and enterprise connectivity anywhere, anytime utilizing commonly available switches. The *IP* in EtherNet/IP stands for the *Industrial Protocol* in CIP; this is not to be confused with *IP* in TCP/IP, which stands for *Internet Protocol*.

Due to the length of Ethernet frames and the typical multimaster structure of Ethernet networks, there are no particular limitations in the EtherNet/IP implementation of CIP. Basically, all that is required is a mechanism to encode CIP messages into Ethernet frames.

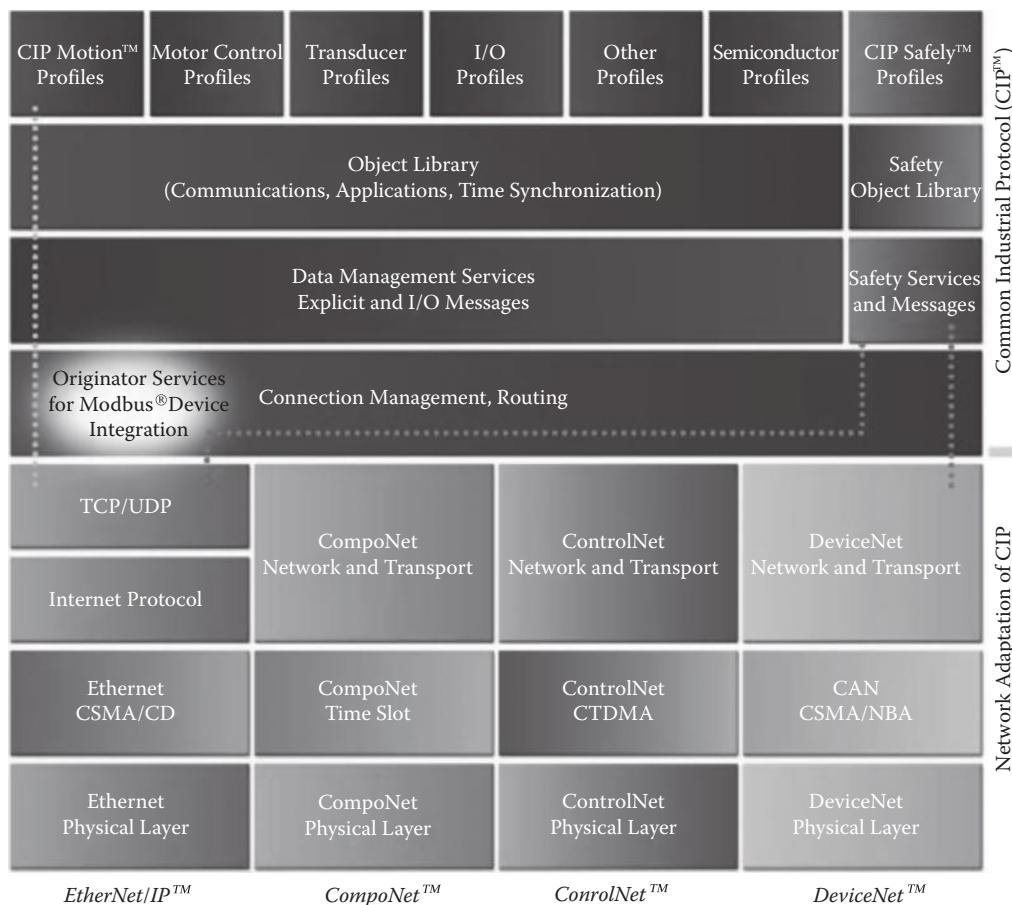

### 9.3.3.2 Relationship to Standards

Like other CIP Networks, EtherNet/IP follows the OSI model, an ISO standard for network communications that is hierarchical in nature. Networks that follow this model define all necessary functions, from physical implementation up to the protocol and methodology to communicate control and information data within and across networks.

Figure 9.34 shows the relationship between CIP and EtherNet/IP.

The EtherNet/IP Adaptation of CIP is described in Volume 2 of the CIP Networks Library. All other features are based on CIP. This volume defines how CIP is adapted for use on Ethernet. An encapsulation mechanism (see Section 9.3.3.11) is defined for EtherNet/IP specifying how I/O and Explicit Messages are carried in Ethernet frames. The well-known TCP/IP protocol is used for encapsulating Explicit Messages, while UDP/IP is used for encapsulating I/O Messages. Since the commonly implemented TCP/IP and UDP/IP protocol stacks are used for encapsulation, many applications will not require extra middleware for this purpose.

Ethernet has its roots in the office computing environment, which is not traditionally concerned with determinism like industrial applications are. However, with the proper selection and configuration of infrastructure devices (see Section 9.3.3.21) using fast data rates with full duplex communications, there

**FIGURE 9.34** Relationship between CIP and EtherNet/IP.

will be no collisions or lost packets, giving Ethernet a level of determinism that is more than adequate for use in industrial control applications. Additionally, extensions to CIP like CIP Sync and CIP Motion (see Section 9.5.1) allow EtherNet/IP to be used in highly synchronous and deterministic applications like coordinated drives and motion control.

EtherNet/IP is also described in international standards, that is, the IEC fieldbus standards, see [10,15].

### 9.3.3.3 EtherNet/IP Features

EtherNet/IP is a communication system built on standard, unmodified Ethernet with the following features:

- Built on and compliant with the relevant Ethernet standards, not just compatible with them
- Fully independent of data rate: 10, 100, 1000 Mbps
- Systems can be built with standard infrastructure
- Virtually unlimited number of nodes in a network
- Networks can be structured into subnets with IP routers
- Full support of communication across subnets since EtherNet/IP uses IP addressing for all communication
- Non-real-time communication and real-time communication can coexist in the same subnet
- Support for coordinated drives and motion control

- Support for DLR that provides single fault tolerance through media redundancy
- QuickConnect for devices that are frequently removed from and added to the network, for example, robot tools
- Coexistence with other upper-layer protocols, such as HTTP, FTP, and VOIP

#### **9.3.3.4 EtherNet/IP Physical Layer**

Since EtherNet/IP takes the Ethernet protocol to the factory floor, recommendations are made in Volume 2 [17] regarding grounding, isolation, and cable and connector construction that are designed to make EtherNet/IP successful in a typical factory automation environment. These changes do not affect the actual signaling or interoperability with standard Ethernet products, but simply make devices more suitable for harsher industrial environments. As a result, two levels of performance criteria are defined:

1. The commercial off-the-shelf (COTS) EtherNet/IP Level provides basic Ethernet connectivity. This level includes the well-known RJ-45-type Ethernet connector but specifies topology constraints (e.g., up to 100 m) and cabling requirements through references to specific IEEE, ANSI/TIA/EIA standards. Such devices are typically suited for IP 20 applications.
2. The industrial EtherNet/IP Level goes beyond the COTS Level by specifying minimum environmental, cabling, and connector requirements that include IEC, ANSI/TIA/EIA standards. Connectors required for the industrial EtherNet/IP Level include an enhanced performance RJ-45 connector, a sealed RJ-45 connector, as well as a more compact D-coded M 12-4 connector. The sealed RJ-45 and M 12 connectors can achieve an IP 67 rating.

Cat 5E or Cat 6 shielded or unshielded cables are recommended for EtherNet/IP. The use of shielded cables is specifically recommended in applications where adjacent material, such as metal cable ducts, may have substantial influence on the characteristics of the cable. In accordance with IEEE 802.3, copper media may be used only for distances up to 100 m. Fiber-optic media is recommended for longer distances. Fiber-optic media may also be advisable for applications with very high electromagnetic disturbances or high-voltage potential differences between devices.

ODVA has published a guideline for the installation of Ethernet media, see [18]. This topic is also covered by the international standard IEC 61784-5-2 [10].

#### **9.3.3.5 Frame Structure**

EtherNet/IP uses standard Ethernet TCP/IP and UDP/IP frames as defined by international standards [19–22]. Therefore, no further frame details are described here.

#### **9.3.3.6 Protocol Adaptation**

EtherNet/IP can use all features of CIP. The Ethernet frame is big enough that fragmentation is rarely required. If it is required, fragmentation is automatically handled by IP fragmentation provided by TCP/IP and UDP/IP. Since EtherNet/IP is not expected to be used in very simple devices, no further scaling is required.

#### **9.3.3.7 Indicators and Switches**

EtherNet/IP devices that need to conform to the industrial EtherNet/IP Level must have the two indicators set forth in the specification: Module Status and Network Status. Devices may have additional indicators that must not carry any of the names of those described in the specification.

Devices may be built with or without switches or other manual means for configuration.

#### **9.3.3.8 Additional Objects**

Volume 2 defines the following 11 additional objects that are found only on EtherNet/IP devices. Most of these objects are required only when the feature they pertain to is implemented. Exceptions to this are noted where appropriate.

### 9.3.3.8.1 TCP/IP Interface Object (Class ID: 0xF5)

The TCP/IP Interface Object provides a mechanism for configuring a device's TCP/IP network interface. Examples of configurable items include the device's IP address, network mask, and gateway address. Every EtherNet/IP must have at least one instance of this class.

### 9.3.3.8.2 Ethernet Link Object (Class ID: 0xF6)

The Ethernet Link Object maintains configuration parameters, various error counters, and status information for the Ethernet IEEE 802.3 communications interface. Each device has exactly one instance of the Ethernet Link Object for each Ethernet IEEE 802.3 communications interface.

### 9.3.3.8.3 Device Level Ring Object (Class ID: 0x47)

The DLR Object manages all data and behavior associated with the DLR functionality of a device. For further details on DLR, see Section 9.3.3.23.2 of this publication.

### 9.3.3.8.4 QoS Object (Class ID: 0x48)

The Quality of Service (QoS) Object manages all data and behavior associated with the QoS functionality of a device. It includes the settings for DSCP in the IP header and the Frame Prioritization settings for the Ethernet header. If the device supports DLR, then this class must be implemented, too.

### 9.3.3.8.5 Base Switch Object (Class ID: 0x51)

The Base Switch Object provides the CIP application-level interface to basic status information for a Managed Ethernet switch device. Devices shall implement no more than one instance of the Base Switch Object.

### 9.3.3.8.6 Simple Network Management Object (Class ID: 0x52)

The SNMP Object provides parameters used to configure aspects of the SNMP Agent in the device.

### 9.3.3.8.7 Power Management Object (Class ID: 0x53)

The Power Management Object defines a Sleeping state and a Paused state. The method to trigger the transition from the Sleeping state to the Paused state is network adaptation specific.

### 9.3.3.8.8 RSTP Bridge Object (Class ID: 0x54)

The RSTP Bridge Object provides the configuration and diagnostic interface for the RSTP protocol at the bridge level. For further details on the use of RSTP, see Section 9.3.3.24 of this publication.

### 9.3.3.8.9 RSTP Port Object (Class ID: 0x55)

The RSTP Port Object provides a configuration and diagnostic interface for the RSTP protocol at the port level. For further details on the use of RSTP, see Section 9.3.3.24 of this publication.

### 9.3.3.8.10 Parallel Redundancy Protocol Object (Class ID: 0x56)

The Parallel Redundancy Protocol (PRP) Object provides a configuration and diagnostic interface for PRP parameters, if implemented in the product.

### 9.3.3.8.11 PRP Nodes Table Object (Class ID: 0x57)

The PRP Node Table Object keeps the record of all PRP-capable nodes that have been detected on the network.

## 9.3.3.9 IP Address Assignment

Since the initial development of TCP/IP, numerous methods for configuring a device's IP address have evolved. Not all of these methods are suitable for industrial control devices. In the office environment,

for example, it is common for a PC to obtain its IP address via Dynamic Host Configuration Protocol (DHCP), meaning that it can potentially acquire a different address each time the PC reboots. This is acceptable because the PC is typically a client device that only makes requests, so there is no impact if its IP address changes.

However, for an industrial control device that is a target of communication requests, the IP address cannot change at each power-up. A PLC, for example, must be at the same address each time it powers up.

In addition, the only interface common to all EtherNet/IP devices is an Ethernet communications port. Some devices may also have a serial port, a user interface display, hardware switches, or other interfaces, but these are not universally shared across all devices. Since Ethernet is the common interface, the initial IP address should at least be configurable over Ethernet.

The EtherNet/IP Specification, via the TCP/IP Interface Object, defines a number of ways to configure a device's IP address. A device may obtain its IP address via Bootstrap Protocol (BOOTP), via DHCP, or via an explicit Set\_Attribute\_Single or Set\_Attributes\_All service. None of these methods is mandated however. As a result, vendors could choose different methods for configuring IP addresses.

From the user's perspective, it is desirable for vendors to support some common mechanism(s) for IP address configuration. The current ODVA recommendations on this subject can be downloaded from the ODVA website [23].

### 9.3.3.10 Address Conflict Detection

Since IP addresses are often assigned by human interaction or as a default private address by the device manufacturer (e.g., 192.168.1.1), it is not uncommon to find multiple devices on the same network with the same IP address. This situation is undesirable; therefore, duplicate IP address detection and the subsequent address conflict resolution have been defined for EtherNet/IP. The Address Conflict Detection (ACD) mechanism deployed in EtherNet/IP conforms to the IETF RFC 5227 [24]. Support for ACD is optional; however, any EtherNet/IP device that supports it must follow the method described in Volume 2, Appendix F, of The EtherNet/IP Specification.

### 9.3.3.11 EtherNet/IP Encapsulation

EtherNet/IP is based entirely on existing TCP/IP and UDP/IP technologies and uses them without any modification. TCP/IP is mainly used for the transmission of Explicit Messages while UDP/IP is used mainly for I/O Messaging.

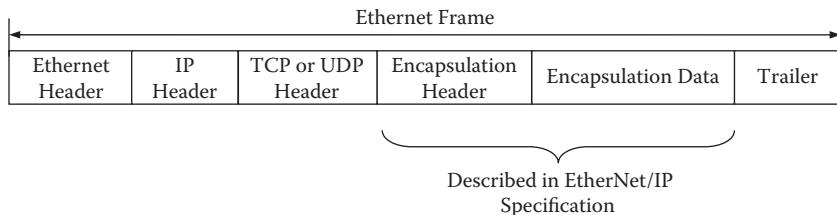

The encapsulation protocol defines two reserved TCP/UDP port numbers. All EtherNet/IP devices accept at least two TCP connections on TCP port number 0xAF12. This port is used for all TCP-based Explicit Messaging, either connected or unconnected. It is also used for the encapsulation protocol commands that are employed when setting up communications between nodes. Some encapsulation commands may also be sent to port 0xAF12 via UDP datagrams.

Port 0x08AE is used by any devices that support EtherNet/IP's I/O messaging over UDP. These messages can be sent either unicast or multicast by taking advantage of the multicast capabilities of IP. Multicast data flow makes more efficient use of the available bandwidth and provides for better data consistency across the system. Being connectionless, UDP is well suited to this purpose as connection management is handled by CIP.

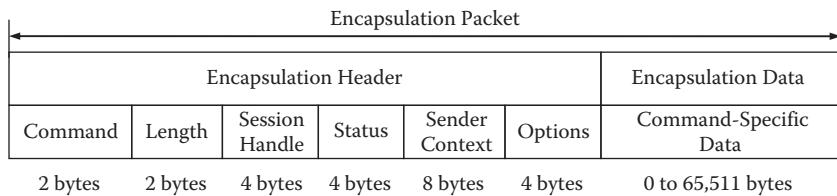

#### 9.3.3.11.1 General Use of the Ethernet Frame

Since EtherNet/IP is completely based on Ethernet with TCP/IP and UDP/IP, all CIP-related messages sent on an EtherNet/IP network are Ethernet frames with an IP header (see Figure 9.35).

The Ethernet header, the IP header, and the TCP or UDP headers are described through international standards (see Section 9.3.3.5); therefore, details of these headers are mentioned only in The EtherNet/IP Specification when it is necessary to understand how they are used to carry CIP.

**FIGURE 9.35** Relationship between CIP and Ethernet frames.

**FIGURE 9.36** Structure of the encapsulation packet.

The encapsulation header contains a command that determines the meaning of the encapsulation data. Many commands specify the use of the so-called Common Packet Format. I/O Messages sent in UDP frames do not use the encapsulation header, but they still follow the Common Packet Format.

#### 9.3.3.11.2 Encapsulation Header and Encapsulation Commands

The overall encapsulation packet has the structure described in Figure 9.36.

While the description of some of the encapsulation header details would go beyond the scope of this book, the command field requires more attention here. However, only those commands that are needed to understand the EtherNet/IP protocol are described, and their description lists only the main features.

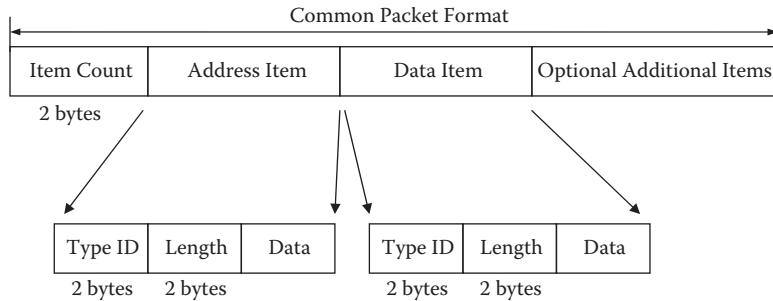

**9.3.3.11.2.1 ListIdentity Command** The ListIdentity command typically is sent as a broadcast UDP message to tell all EtherNet/IP devices to return a data set with identity information. This command is used by software tools to browse a network.

**9.3.3.11.2.2 RegisterSession/UnRegisterSession Commands** These two commands are used to open and close an Encapsulation Session between two devices. Once a session is established, it is used to exchange more messages. Only one session may exist between two devices.

The device receiving the RegisterSession request creates a Session Handle that it returns in the RegisterSession reply. This value is used to identify messages sent between the two devices that use this session.

**9.3.3.11.2.3 SendRRData/SendUnitData Commands** The SendRRData Command is used for Unconnected Explicit Messaging, and the SendUnitData Command is used for Connected Explicit Messaging. The device transmitting the SendRRData request creates a Sender Context value that is returned with the reply. The SendUnitData does not use the Sender Context field.

**9.3.3.11.2.4 Common Packet Format** The Common Packet Format is a construct that provides a way to structure the Encapsulation Data field for those Encapsulation commands that specify Encapsulation data. The Common Packet Format defines Items that represent different types of information to be exchanged between devices. If the command definition requires it, the Common Packet Format allows packing of multiple Items into one encapsulation frame, as shown in Figure 9.37.

**FIGURE 9.37** Example of the Common Packet Format.

### 9.3.3.12 Use of the Encapsulation Data

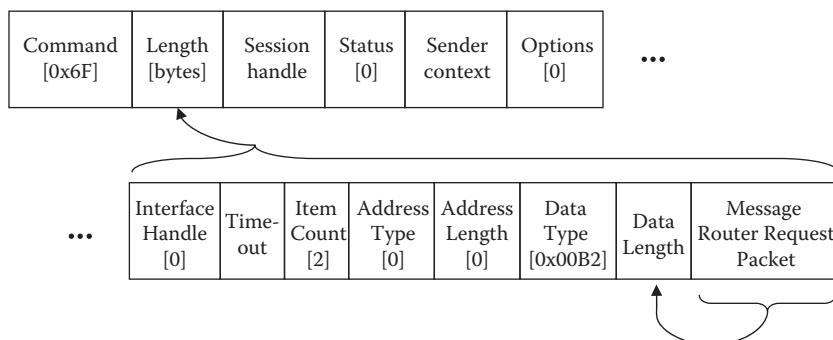

#### 9.3.3.12.1 Explicit Messaging

Explicit Messages on EtherNet/IP can be sent either connected or unconnected. Connected Explicit Messaging requires setting up a connection (see Section 9.3.3.13) before messages are exchanged. This means that all resources required for managing the connection are reserved for this purpose as long as the connection exists, which allows for more timely responses to message requests. This is very useful in applications that require periodic explicit requests. Explicit Messages also can be sent unconnected, but this mechanism makes use of generally limited resources in nodes that sometimes can be highly utilized. For this reason, Unconnected Explicit Messaging should be used only when the application requires very irregular and infrequent request intervals. Explicit Messages on EtherNet/IP are sent with a TCP/IP header and use the SendRRData Encapsulation Command (unconnected) or the SendUnitData Encapsulation Command (connected). As an example, the full encapsulation of a UCMM request is shown in Figure 9.38.

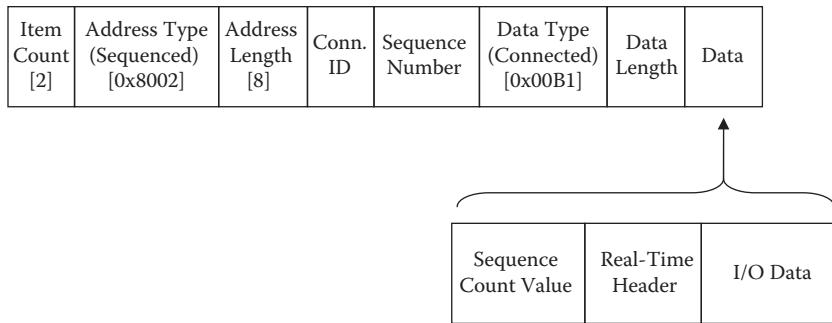

The Message Router Request Packet noted in the figure contains the CIP message request or response. This part of the packet follows the general format of Explicit Messages—the Message Router Request/Response Format—defined in Volume 1, Chapter 2, of the CIP Networks Library.

#### 9.3.3.12.2 I/O Messaging

I/O Messages on EtherNet/IP are sent with a UDP/IP header. No encapsulation header is required, but the message still follows the Common Packet Format. See Figure 9.39 for an example.

**FIGURE 9.38** UCMM request encapsulation.

**FIGURE 9.39** I/O Message encapsulation.

The data field contains the I/O data prefixed with a 16-bit Sequence Count Value for the packet. I/O data transmission without the Sequence Count Value is possible, but it is used only for CIP Safety connections. Run/Idle can be indicated within a Real-Time Header or by sending the packet with I/O data (Run) or without I/O data (Idle). The method used is indicated in the connection parameters of the Connection Manager section of the EDS. The Real-Time Header method is recommended [25] for use on EtherNet/IP for interoperability reasons, and this is what is shown in Figure 9.39.

I/O Messages from the originator to the target are typically sent as UDP unicast frames, while those sent from the target to the originator can be sent as UDP multicast or unicast frames. Multicast frames allow other EtherNet/IP devices to listen to the input data. To avoid having these UDP multicast frames propagating too widely over the network, the use of switches that support (IGMP) Snooping is highly recommended. IGMP (Internet Group Management Protocol) [26] is a protocol that allows the automatic creation of multicast groups. Using this functionality, the switch will automatically create and maintain a multicast group consisting of the devices that need to consume these multicast messages. Once the multicast groups have been established, the switch will direct such messages only to those devices that have subscribed to the multicast group of that message.

### 9.3.3.13 Connection Establishment

All connections on EtherNet/IP are established using a UCMM Forward\_Open message (see Section 9.2.3).

### 9.3.3.14 QuickConnect Connection Establishment

While most applications can wait several seconds until a connection is established, there are certain application scenarios that require a device to be operational with only a very short delay after the application of power. Typically, these are devices sitting on an exchangeable tool that a robot would pick up for certain manufacturing steps. In comparison to DeviceNet, EtherNet/IP devices are more complex and larger, and more complex parts of the communication stack are typically implemented in software, so it will take more time to power up a device. The other additional complexity in EtherNet/IP is the TCP layer with a timeout behavior of its own. Furthermore, active infrastructure (switches) may take a long time to reboot. Under consideration of these conditions, the following method was developed for a fast establishment of I/O connections:

- If more than one EtherNet/IP device is mounted onto the exchangeable tool, embedded infrastructure with defined start-up behavior must be used.
- In preparation of a restart, every connection that participates in the QuickConnect application must be shut down using the Forward\_Close service before disconnecting the device.
- When the device has responded to the Forward\_Close request, it closes the TCP connection with the I/O Scanner.

- At the restart of any QuickConnect device, the I/O Scanner receives notification of power reapplication through a contact in the tool changer.
- The I/O Scanner then waits for a predetermined time (described in the EDS) before a connection is reestablished.

Using this methodology, start-up times of less than 100 ms can be achieved with current technology; the first products are available on the market.

The full description of the QuickConnect functionality can be found in Appendix E of The EtherNet/IP Specification.

### 9.3.3.15 Device Classes

Four classes of device functionality are built with CIP. While they are not explicitly defined in the specification, they are useful for distinguishing among several classes of devices. The four classes are described here:

1. The minimal device function is that of an Explicit Message Server, which is used for Explicit Messaging applications only and acts as a target for Unconnected and (optionally) Connected Explicit Messages, for example, for program upload/download, data collection, and status monitoring.
2. The next device class is an I/O Server, which adds I/O Messaging Support to an Explicit Message Server device and acts as a target for both Explicit and I/O Messages, for example, simple I/O Devices, Pneumatic Valves, and AC Drives. These devices are also called I/O Adapters.
3. Another device class is an Explicit Message Client, which adds client support to Explicit Message Server applications and acts as a target and as an originator for explicit messaging applications, for example, computer interface cards and HMI devices.
4. The most powerful type of device is an I/O Scanner, which adds I/O Message origination support to the functionality of all the other device classes and which acts as a target and as an originator for Explicit and I/O Messages, for example, PLCs and I/O Scanners.

### 9.3.3.16 Device Profiles

EtherNet/IP devices may utilize any of the device profiles described in the CIP Networks Library. As of the publication date of this book, no EtherNet/IP-specific device profiles have been defined.

### 9.3.3.17 Configuration

EtherNet/IP devices typically come with EDSs as described in Section 9.2.7. For EDS-based configuration tools, the EDS should contain a Connection Manager section to describe the details of the connections that can be made into the device. This section basically mirrors what is contained in the Forward\_Open message that a Connection Originator would send to the device. Multiple connections can be specified within an EDS that can then be chosen by the configuration tool.

An EDS also may contain individual parameters and/or a Configuration Assembly with a complete description of all parameters within this assembly. In many applications, the Configuration Assembly is transmitted as an attachment to the Forward\_Open message.

### 9.3.3.18 Conformance Test

See Section 9.6 of this publication for information on conformance testing.

### 9.3.3.19 Requirements for TCP/IP Support

In addition to the various requirements set forth in The EtherNet/IP Specification, all EtherNet/IP hosts are required to have a functional TCP/IP protocol suite and transport mechanism. The minimum host requirements for EtherNet/IP hosts are those covered in RFC 1122 [27], RFC 1123 [28], and RFC 1127 [29] and the subsequent documents that may supersede them. Whenever a feature or protocol is implemented

by an EtherNet/IP host, that feature shall be implemented in accordance with the appropriate RFC (Request for Comment) documents, regardless of whether the feature or protocol is considered required or optional by this specification. The Internet and the RFCs are dynamic. There will be changes to the RFCs and to the requirements included in this section as the Internet and The EtherNet/IP Specifications evolve.

All EtherNet/IP devices shall at a minimum support

- Internet Protocol (IP version 4) (RFC 791 [21])
- User Datagram Protocol (UDP) (RFC 768 [20])
- Transmission Control Protocol (TCP) (RFC 793 [22])
- Address Resolution Protocol (RFC 826 [30])
- Internet Control Messaging Protocol (RFC 792 [31])
- Internet Group Management Protocol (IGMP) (RFC 1112 [32] and 2236 [26])
- IEEE 802.3 (Ethernet) as defined in RFC 894 [33]

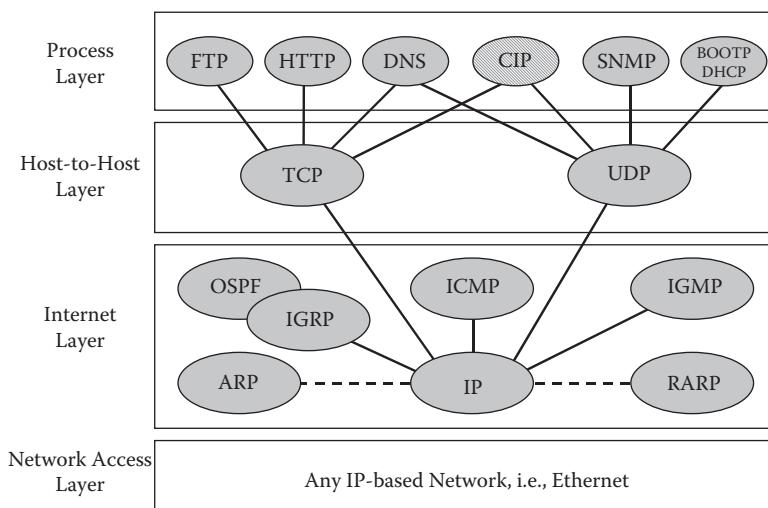

Although the encapsulation protocol is suitable for use on other networks besides Ethernet that support TCP/IP and products may be implemented on these other networks, conformance testing of EtherNet/IP products is limited to those products on Ethernet. Other suitable networks include

- Point-to-Point Protocol (RFC 1171 [34])
- ARCNET (RFC 1201 [35])
- FDDI (RFC 1103 [36])

### 9.3.3.20 Coexistence of EtherNet/IP and Other Ethernet-Based Protocols

EtherNet/IP devices are encouraged, but not required, to support other Ethernet-based protocols and applications not specified in The EtherNet/IP Specification. For example, they may support HTTP, Telnet, FTP, etc. The EtherNet/IP protocol makes no requirements with regard to these protocols and applications.

Figure 9.40 shows the relationship between CIP and other typical Ethernet-based protocol stacks. Since EtherNet/IP, like many other popular protocols, is based on TCP/IP and UDP/IP, coexistence with many other services and protocols is not a problem, and CIP blends nicely into the set of already existing functions. This means that anyone who is already using some or all of these popular Ethernet services can add CIP without undue burden; the existing services like HTTP or FTP may remain as before, and CIP will become another service on the process layer.

**FIGURE 9.40** Relationship of CIP to other typical Ethernet protocols.

### 9.3.3.21 Ethernet Infrastructure

#### 9.3.3.21.1 Traditional Approach

To apply EtherNet/IP successfully to the automation world, the issue of determinism has to be considered. The inherent principle of the Ethernet bus access mechanism, whereby collisions are detected and nodes back off and try again later, cannot guarantee determinism. While Ethernet in its present form cannot be made strictly deterministic, there are ways to improve this situation.

First, the hubs typically used in many office environments must be replaced by more intelligent switches that will forward only those Ethernet frames intended for nodes connected to these switches. By using wire-speed switching fabric and full duplex switch technology, collisions are completely avoided; instead of colliding, multiple messages sent to the same node at the same time are queued up inside the switch and are then delivered one after another.

As already mentioned in Section 9.3.3.12.2, using switches that support IGMP Snooping is highly recommended.

If EtherNet/IP Networks are to be connected to a general company network, this should always be done through a router. The router keeps the UDP multicast messages from propagating into the company network and ensures that the broadcast or multicast office traffic does not congest the control network. Even though the router separates the two worlds, it can be set up to allow the TCP/IP-based Explicit Messages to pass through so that a configuration tool sitting in a PC in the office environment may be capable of monitoring and configuring devices on the control network.

### 9.3.3.22 Devices with Multiple Ethernet Ports

Chapter 6 of Volume 2 of the CIP Specifications describes a number of scenarios for devices with multiple Ethernet ports and how these scenarios are to be mapped in the object structure.

### 9.3.3.23 Ring and Linear Topologies

#### 9.3.3.23.1 Linear Topology

Many end-user applications benefit from connecting devices in a linear or ring topology. With such a topology, end devices typically have two Ethernet ports (with an embedded switch) and are connected in sequence, one device to the next (Figure 9.41).

With linear topology, a failure of one node or a link between two nodes causes nodes on either side of the failure to be unreachable. By using a ring protocol implemented in the end devices, these devices may be configured in a ring topology so that a single-point failure does not prevent communication between the remainder of the functioning devices.

#### 9.3.3.23.2 Ring Topology with Device Level Ring

**9.3.3.23.2.1 DLR Overview** The EtherNet/IP specification includes the DLR protocol, allowing multiport devices to be connected in a ring topology. DLR provides for fast network fault detection and reconfiguration in order to support the most demanding control applications. For example, a ring network of 50 nodes implementing the DLR protocol has a worst-case fault recovery time of less than 3 ms.

The DLR protocol operates at Layer 2 (in the ISO OSI network model). The presence of the ring topology and the operation of the DLR protocol are transparent to higher-layer protocols, such as

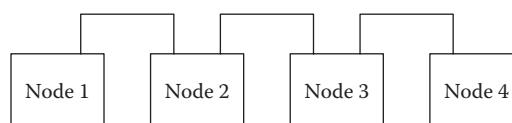

FIGURE 9.41 Linear topology.

TCP/IP and CIP, with the exception of a DLR Object that provides a DLR configuration and diagnostic interface via CIP.

There are several classes of DLR implementation, as described in the following text:

- *Ring Supervisor*

This class of devices is capable of being a ring supervisor. These devices must implement the required ring supervisor behaviors, including the ability to send and process Beacon frames at the default Beacon interval of 400 µs and may be user-configured for as fast as 100 µs Beacon interval. Ring supervisors must also send Announce frames for those devices that rely on the Announce frame mechanism to detect a change in ring status.

- *Ring Node, Beacon-based*

This class of devices implements the DLR protocol, but without the ring supervisor capability. The device must be able to process and act on the Beacon frames sent by the ring supervisor. Beacon-based ring nodes must support Beacon rates from 100 µs to 100 ms.

- *Ring Node, Announce-based*

This class of devices implements the DLR protocol, but without the ring supervisor capability. These devices do not have the capacity to process Beacon frames, so they simply forward Beacon frames received on one port to the other port and instead rely on Announce frames to indicate the ring state. Announce frames are sent at a much slower rate than Beacon frames.

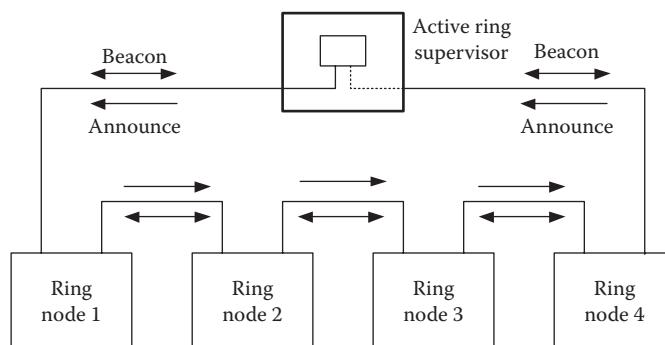

**9.3.3.23.2.2 Normal DLR Operation** A DLR network includes at least one node configured to be a ring supervisor and any number of normal ring nodes. The ring supervisor sends special frames (*Beacon* and *Announce* frames) to detect ring fault and ring restoration.

Figure 9.42 illustrates the normal operation of a DLR network. Each node has two Ethernet ports, has implemented an embedded switch, and supports DLR. When a ring node receives a packet on one of its Ethernet ports, it determines whether the packet needs to be received by the ring node itself (e.g., the packet has this node's MAC address as the destination MAC address) or whether the packet should be sent out the other Ethernet port.

The active ring supervisor blocks traffic on one of its ports with the exception of few special frames and does not forward traffic from one port to other. This configuration avoids a network loop, so only one path exists between any two ring nodes during normal operation.

The active ring supervisor transmits a Beacon frame through both of its Ethernet ports once per Beacon interval (400 µs by default). The active ring supervisor also sends Announce frames once per second. The Beacon and Announce frames serve several purposes:

- The presence of Beacon and Announce frames inform ring nodes to transition from linear topology mode to ring topology mode.

**FIGURE 9.42** Normal DLR operation.

- Loss of Beacon frames at the supervisor enables detection of certain types of ring faults. (Note that normal ring nodes are also able to detect and announce ring faults.)
- The Beacon frames carry a precedence value, allowing selection of an active supervisor when multiple ring supervisors are configured.

**9.3.3.23.2.3 Ring Faults** Ring faults may include common link failures such as device power failure or media disconnection, or higher-level failures where the physical layer is active but the device has failed.

The ring supervisor detects a ring fault directly via a Link Status message from a ring node or indirectly via loss of Beacon frames. When a ring fault is detected, the active ring supervisor reconfigures the network by unblocking traffic on its previously blocked port and flushing its unicast MAC table. The supervisor immediately sends Beacon and Announce frames with the ring state value indicating that the ring is now faulted.

Ring nodes also flush their unicast MAC tables upon detecting loss of the Beacon in one direction or upon receipt of Beacon or Announce frames with the ring state value indicating the ring fault state. Flushing the unicast MAC tables at both supervisor and ring nodes is necessary for network traffic to reach its intended destination after the network reconfiguration.

Figure 9.43 shows the network configuration after a link failure, with the active ring supervisor passing traffic through both of its ports.

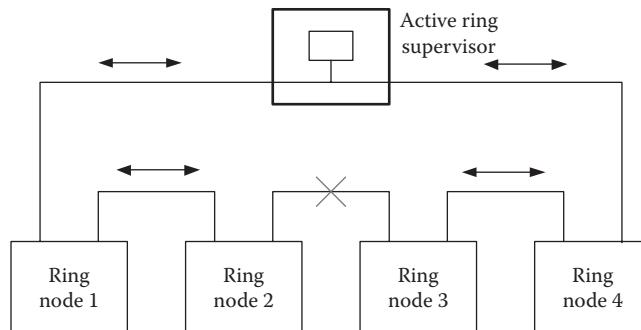

**9.3.3.23.2.4 Further Information for Developers** Further details of the DLR protocol operation, including event tables, state diagrams, and other implementation requirements, are included in Chapter 9 of The EtherNet/IP Specification.

### 9.3.3.24 Use of the Rapid Spanning Tree Protocol

In addition to the DLR protocol, the Rapid Spanning Tree Protocol (RSTP) has also been allowed for use in conjunction with EtherNet/IP.

RSTP was originally designed for networks based on a tree topology where many devices are connected back to an Ethernet switch, which in turn can be connected to other Ethernet switches. RSTP is a mature and widely accepted approach to solve the Ethernet ring recovery issue when one looks at the most current enhancements to the specification. The IEEE Standard 802.1D 2004 edition incorporated RSTP into that part of the standard. Changes were made by the IEEE Standards committee to RSTP, which make it a suitable recovery mechanism for a ring topology for some automation applications.

Chapter 9 of The EtherNet/IP Specification describes the use of RSTP within EtherNet/IP.

**FIGURE 9.43** Network reconfiguration after link failure.

### 9.3.3.25 Tools

Tools for EtherNet/IP Networks can be divided into four groups:

1. *Physical layer tools* are tools (hardware and/or software) that verify the integrity and conformance of the physical layer or monitor the quality of the data transmission.
2. *Commissioning tools*: are tools that set the IP address needed for all EtherNet/IP devices (see Section 9.3.3.9). In these cases, a BOOTP/DHCP server tool, such as the free BOOTP/DHCP routine downloadable from the Rockwell Automation website, is required.
3. *Configuration tools* are software tools capable of communicating with individual devices for data monitoring and configuration purposes. Most configuration tools are EDS-based; however, more complex devices like I/O Scanners tend to have their own configuration applets that are only partially based on EDS files. Some of these tools support multiple access paths to the network, for example, via suitable routing devices. High-level tools also actively query the devices on the network to identify them and monitor their health. Configuration tools also may be integrated into other packages like PLC programming software.
4. *Monitoring tools* typically are PC-based software packages (e.g., traffic analyzers or *sniffers*) that can capture and display the Ethernet frames on the network. A raw Ethernet frame display may be good enough in some instances, but using a tool that can both display raw Ethernet frames and provide multiple levels of frame interpretation (IP, TCP/UDP, and EtherNet/IP header interpretation) is recommended. Due to the popularity of Ethernet, a large number of these tools are available, but not all of them support EtherNet/IP decoding.

In a typical installation, only a commissioning tool and a configuration tool are needed. Protocol monitoring tools are used mainly to investigate interoperability problems and to assist during the development process.

Turn to the CIP supplier directory on the ODVA website to access a list of vendors that provide tools for EtherNet/IP.

### 9.3.3.26 Advice for Developers

Before any development of an EtherNet/IP product is started, the following issues should be considered in detail:

- What functionality (Device Classes, see Section 9.3.2.13) does the product require today and in future applications?
  - Explicit Messaging server only.
  - I/O Adapter functionality.
  - Explicit Messaging client.
  - I/O Scanner functionality.
- What are the physical layer requirements? Is IP 65/67 required, or is IP 20 good enough?
- Will the development be based on commercially available hardware components and software packages (recommended) or designed from scratch (possible but costly)?
- What are the configuration requirements?
- What design and verification tools should be used?
- When and where will the product be tested for conformance and interoperability?
- What is an absolute must before products can be placed on the market (own the specification, have the company's own Vendor ID, and have the product conformance tested)?

Ethernet chipsets and associated base software packages are available from many vendors. For the support of the EtherNet/IP part of development, refer to the ODVA website for a list of companies that can

support EtherNet/IP development. An extended description of the development process is available for download from the ODVA website [37].

To help EtherNet/IP developers in creating their products, ODVA runs a series of so-called Implementor Workshops for EtherNet/IP during which various aspects of EtherNet/IP are discussed. These workshops (with a North American and a European series) have created a number of documents with functionality recommendations for EtherNet/IP devices, see [23,25,38–40]. EtherNet/IP devices are then tested against these recommendations during multivendor testing events, called Plugfests. Visit the ODVA web page to learn more about upcoming EtherNet/IP Implementor Workshops and Plugfests.

### 9.3.3.27 EtherNet/IP Summary

Since its introduction in 2000, EtherNet/IP has shown remarkable growth in many applications that previously used traditional networks. This success (several million nodes installed to date) is largely attributed to the fact that EtherNet/IP uses standard unmodified Ethernet to introduce real-time behavior into the Ethernet domain without sacrificing any of Ethernet's most useful features, such as company-wide access with standard and specialized tools through corporate networks.

A major strength of EtherNet/IP is the fact that it does not require a modified or highly segregated network: standard switches and routers used in the office world can be used for industrial applications without modification. At the same time, all existing transport-level or TCP/UDP/IP-level protocols can continue to be used without any need for special bridging devices. The substantially improved real-time behavior of CIP Sync and the introduction of CIP Safety also allow EtherNet/IP to be used in applications that currently require several dedicated networks.

Finally, as a member of the CIP family of networks, EtherNet/IP Networks can be combined into an overall CIP Network structure that allows seamless communication among CIP Networks, just as if they were only one network.

## 9.3.4 CompoNet

### 9.3.4.1 Introduction

CompoNet is a low-level network that provides high-speed communication between higher-level devices such as controllers and simple industrial devices such as sensors and actuators. IEC has published CompoNet as IEC 62026-7 in 2010 [41].

### 9.3.4.2 Relationship to Standards

Like other CIP Networks, CompoNet follows the OSI model, an ISO standard for network communications that is hierarchical in nature. Networks that follow this model define all necessary functions, from physical implementation up to the protocol and methodology to communicate control and information data within and across networks.

Figure 9.44 shows the relationship between CIP and CompoNet.

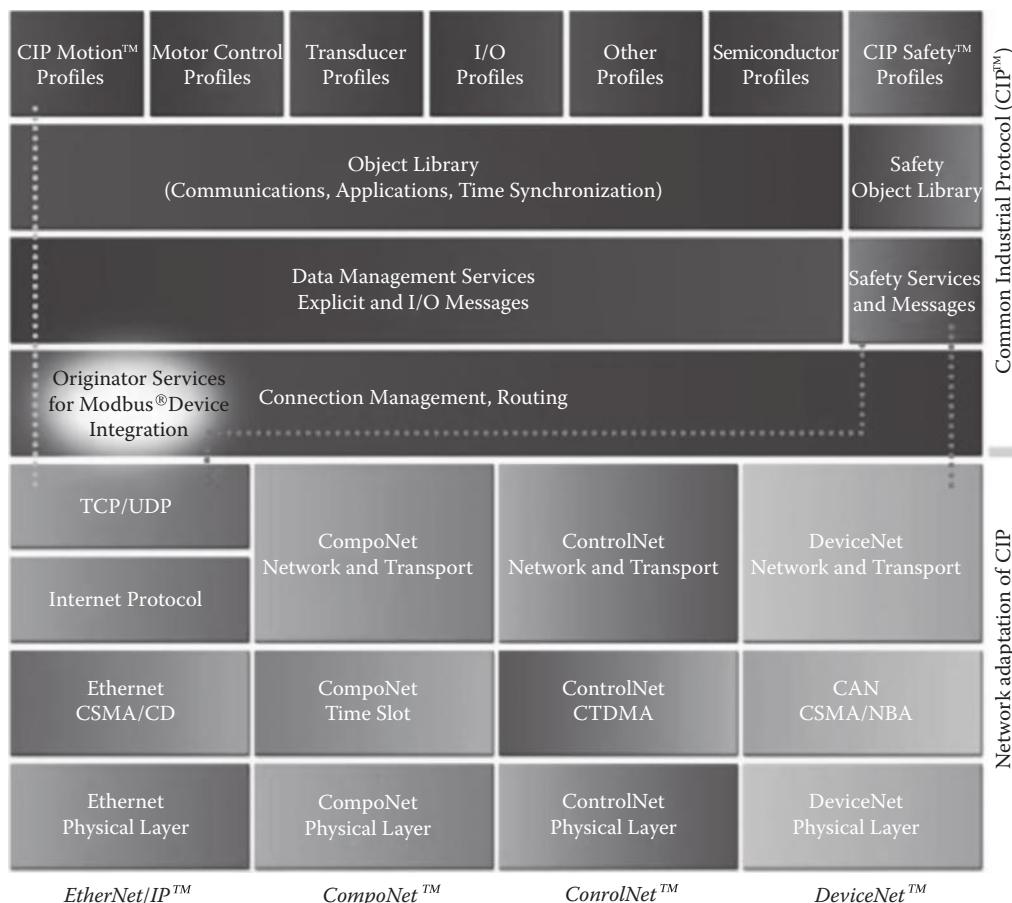

The CompoNet adaptation of CIP is described in Volume 6 of the CIP Networks Library [42]. All other features are based on CIP. CompoNet is also described in an international standard [41].

### 9.3.4.3 CompoNet Features

CompoNet supports both bit-level I/O slaves (BitIN and BitOUT slaves) and byte-level I/O slaves (WordIN and WordOUT slaves) simultaneously in one network. It also supports intelligent repeaters to expand the network flexibly and provide network diagnosis [43].

The main features of CompoNet are as follows:

- Selectable data rates: 4 Mbps/3 Mbps/1.5 Mbps/93.75 kbps.
- Single master network with a large number of slave nodes: 384 slave devices maximum including WordIN: 64; WordOUT: 64; BitIN: 128; BitOUT: 128.

**FIGURE 9.44** Relationship between CIP and CompoNet.

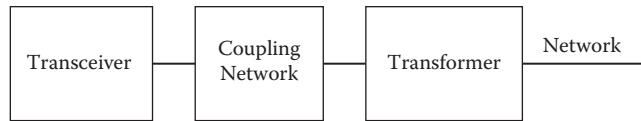

- Up to 64 repeaters per network to expand physical covering area and to adapt different cables.
- Up to 32 nodes (slaves and repeaters) per segment.
- I/O capacity: 1280 input/1280 output points.
- Support for flat 4-wire, round 4-wire, and 2-wire cables in bus and branch topologies.
- Maximum of three segment layers. This means up to two repeaters are allowed between any slave and the master.
- 30/30/100/500 m maximum trunk cable distance with respect to data rates, and 150/150/500/2500 m maximum distance between the most distant slaves with repeaters.
- Trunkline/dropline except for 4 Mbps.
- Efficient communication with multicast polling and Time Division Multiple Access (TDMA).

#### 9.3.4.4 CompoNet Physical Layer

The physical layer of CompoNet has been designed specifically for this network; it does not reuse any existing open technology.

CompoNet uses a transformer-coupled transmission method and a Manchester-encoded signal on the wire; the principal circuit of the physical media attachment is shown in Figure 9.45.

Master ports and slave ports use the same physical media attachment with only minor differences in the coupling network. To help vendors design their CompoNet physical media attachment, ODVA

**FIGURE 9.45** Physical media attachment of CompoNet.

has published recommended circuits for both masters and slaves in Chapter 8 of The CompoNet Specification [42]. Vendors can also design their own circuits.

#### 9.3.4.5 Frame Structure

A typical message frame is composed of the Preamble, Command Code, Command Code-Dependent Block(s), and Cyclic Redundancy Code (CRC), as shown in Figure 9.46.

All frames use the same Preamble. Two types of CRC generator polynomials, CRC8 (8-bit) and CRC16 (16-bit), are used depending on which frame is used.

There are seven types of frames with varying lengths of command codes as shown in Figure 9.47:

1. *OUT Frame*

This is a frame from the Master to the Slaves/Repeaters, which delivers OUT data to OUT slaves, specifies the group of slaves/repeaters that should report their status, and synchronizes the slaves/repeaters to start time domain timers of the CN and IN frames. Data are organized in 16-bit words and transmitted, LSB first, word by word in ascending order.

2. *TRG Frame*

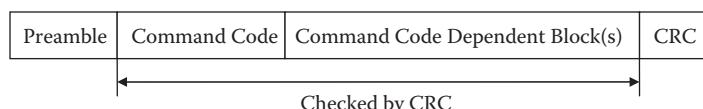

This frame functions like the OUT frame except that it contains no output data; it is a trigger frame sent by the master in place of the OUT frame when it has no outputs to send.

3. *CN Frame*

This frame is used by slaves/repeaters to report their connection status to the master and notify the master of a request to send an event.

4. *IN Frame*

This is a frame from input slaves to the master with input data. Data are transmitted, LSB first, word by word in ascending order, if the size is greater than 16 bits.

**FIGURE 9.46** A general frame.

Command code							Meaning
B0	B1	B2	B3	B4	B5	B6	
0	0	0	1	x	x	x	OUT
0	0	1	1	x	x	x	TRG
0	1	x	x				CN
1	0						IN
1	1	1	x	x	x	\diagup	A_EVENT
1	1	0	x	x	x		B_EVENT
0	0	0	0	1	\diagup		BEACON

**FIGURE 9.47** Command code in frames.

#### 5. A\_EVENT Frame

Any node on the network can send A\_EVENT frames, used for acyclic message communications. Data are in 16-bit words and transmitted, LSB first, word by word in ascending order.

#### 6. B\_EVENT Frame

This frame is always originated by a master who sets data link parameters or reads the information as described in Section 9.3.4.9.2. Also, it is used to grant a slave/repeater permission to send an A\_EVENT request or response.

#### 7. BEACON Frame

This frame specifies the data rate and sends the initial communication parameters to slaves/repeaters.

### 9.3.4.6 Protocol Adaptation

CompoNet uses connection-based I/O Messaging and Unconnected Explicit Messaging. Thus, every device must have the UCMM Function.

### 9.3.4.7 Indicators and Switches

CompoNet does not require a product to have indicators. However, if a product includes indicators with any of the legends in Chapter 9 of The CompoNet Specification, they must follow the behavior specified in that chapter.

Chapter 9 of The CompoNet Specification describes how switches are used to set the MAC address and baud rate. The MAC address may also be set via Explicit Messaging.

### 9.3.4.8 Additional Objects

The CompoNet Specification defines two additional objects: the CompoNet Link Object and the CompoNet Repeater Object.

#### 9.3.4.8.1 CompoNet Link Object (Class ID: 0xF7)

The CompoNet Link Object manages all aspects associated with the CompoNet link, in particular node address and baud rate as well as the switches associated with MAC address and baud rate. Furthermore, this object contains information on the allocation of the I/O communication. Within a master device, this object may also contain information on the slaves that are present on the network.

#### 9.3.4.8.2 CompoNet Repeater Object (Class ID: 0xF8)

Every repeater device on CompoNet must support one instance of the CompoNet Repeater Object. Its main purpose is to monitor the power supply voltage of the subnet it connects to.

### 9.3.4.9 Network Access

#### 9.3.4.9.1 Network Schedule

In a CompoNet network, the master controls bus communications according to its configuration. A master divides a communication cycle into several time domains or time slots.

CompoNet conducts arbitration under strict time supervision managed by the master. The communication cycle is partitioned into time domains as shown in Figure 9.48. Each node obtains the right to send data to the network within a specified time period after the completion of the OUT time domain.

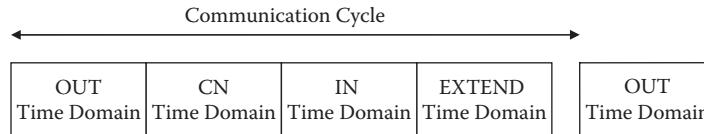

The first domain of each communication cycle is the OUT time domain. Subsequent domains are the CN time domain, the IN time domain, and the EXTEND time domain.

- *OUT Time Domain*

The master sends an OUT frame or a TRG frame in this period.

- *CN Time Domain*

CN frames are sent in this period. The number of CN frames sent in this time domain is determined by the master.

**FIGURE 9.48** Time domains.

- *IN Time Domain*

IN frames are sent in this period consecutively by all input-type devices.

- *EXTEND Time Domain*

The master executes message communications in this period. Event frames, that is, A\_EVENT frames and B\_EVENT frames, can be sent in this period. BEACON frames shall be sent periodically. The master can send a BEACON before every OUT Time Domain starts or in an idle EXTEND Time Domain.

Figure 9.49 shows the sequence of frames in a communication cycle. The master starts the cycle by sending an OUT frame. The OUT frame is a broadcast message used to send output data to all OUT slaves. Each OUT slave consumes its output data (up to 16 bits) from its offset in the OUT frame. The completion of the OUT frame indicates the end of the OUT Time Domain and triggers slaves and repeaters to start the timers that allow them to correctly participate in the CN Time Domain and the IN Time Domain.

In the CN Time Domain, the slaves or repeaters addressed by the *CN Request MAC ID Mask* field in the OUT frame will transmit their CN frames at the predefined time sequence.

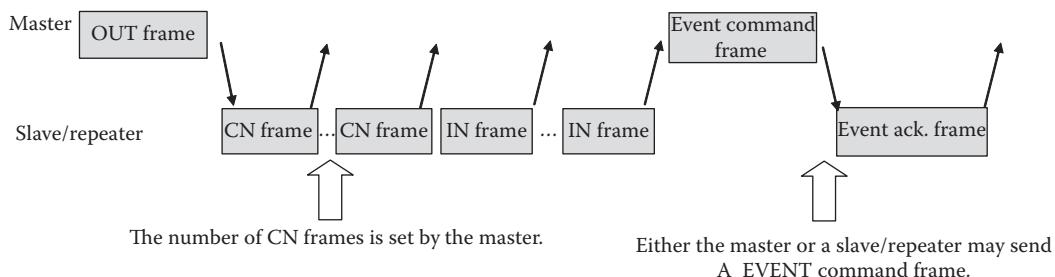

During the IN Time Domain, IN frames are sent by any IN devices that are in the Participated State, at the predefined time sequence (see Figure 9.49). During the IN Time Domain, nodes in the EventOnly Substate do not transmit an IN frame.

During the EXTEND Time Domain, nodes may transmit an event command frame and possibly an immediate acknowledge frame, depending on the event type. These can be sent by the master, slaves, or repeaters. The node designated in the event command frame's Destination MAC ID field will send an event acknowledge frame, if required by the specific event command. CIP explicit messaging is done during this domain.

#### 9.3.4.9.2 Network Access

CompoNet has an algorithm that controls the network access of any of the slaves and repeaters. This is a combination of actions taken by the slave itself and commands from the master using Status Read and Status Write (STW) operation.

Starting from power-up, all devices first need to detect the data rate of the network. Once a device has detected the data rate from the BEACON frames sent by the master, it transitions to the

**FIGURE 9.49** A typical communication cycle.

*Nonparticipated* state. The device will stay in this state as long as it receives valid frames within the timeout period (650 ms for 93.75 kbps, 200 ms for the other data rates) and no other event occurs. When the master has determined that it is OK for the slave to transition to the normal operating mode, that is, no duplicate of the slave's node number has been detected, it sends an STW\_Run command to the slave and the slave then transitions to the *Participated* state, which is the normal operating state. The slave will leave this state and fall back to the *Nonparticipated* state either when it has experienced a network timeout (no OUT or TRG frames within the timeout period) or when it receives an STW\_Standby command from the master.

The detection of duplicate node IDs is also a combination of master and slave actions. The slave will go to the Communication Fault state if told to do so by the master through an STW\_Dup command or when its CN Counter overflows due to communication errors caused by duplicate node IDs.

#### 9.3.4.10 Explicit Messaging

CompoNet uses UCMM for explicit messaging; there is no connection-based Explicit Messaging. Explicit Messages are encapsulated into A\_EVENT frames as shown in Figure 9.50.

The format of an Explicit Message is defined to have two parts as shown in Figure 9.51: Header and Service Data. The Header is the CompoNet-specific part containing information for flow control, fragmentation protocol, and addresses in a word format. The Service Data part consists of the Request/Response Data as defined in the Message Router Request/Response format in Volume 1, Chapter 2, of the CIP Networks Library.

Two types of Explicit Message formats are defined:

- Compact 1 Octet Class ID and Instance ID (required)
- Expanded—CIP EPATH (optional)

A fragmentation protocol is defined optionally for supporting long data transfers in Explicit Messages.

The SID/Extended SID field is used for reply matching. The client sets the value, and the server echoes it back. Values used are specific to whether the master or the slave is the client in the transaction.

Explicit Messaging transactions are subject to timeouts. The default timeout values can be changed by Explicit Messages.

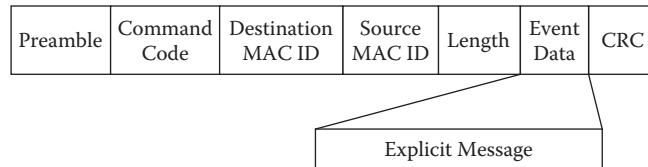

FIGURE 9.50 A\_EVENT frame format.

Word offset	B15	...	B00
0 to n	Header: Control Code, Destination MAC ID, Source MAC ID, SID/Extended SID, Size, Service Code, Class ID, Instance ID		
n + 1 to 21	Service Data		

FIGURE 9.51 CompoNet Explicit Message format.

### 9.3.4.11 I/O Messaging

I/O Messages on CompoNet, like on any other CIP Network, are always exchanged in a connection-based manner. Communication Objects must be set up for this purpose. CompoNet uses a Predefined Allocation service to establish I/O communication between the master and the slaves. Since these I/O connections are not initially available when a device is powered on, they first have to be created. This is done by sending an Allocate Service to the CompoNet Link Object of the slave that is to be allocated. When an I/O Connection is no longer needed, the slave(s) can be released by sending a Release Service to the slave's CompoNet Link Object.

CompoNet uses OUT frames to deliver output data to consuming slaves and to trigger IN frame transmission, IN frames to deliver produced data to the master, and TRG frames to trigger IN frame transmission when the master has no output data to send.

OUT/TRG frames are monitored by I/O slaves to restart a watchdog timer. If an I/O slave has not received any OUT/TRG frames before the watchdog timer expires, it will produce a Timeout event. The timer value of the watchdog is four times the EPR attribute in the I/O connection instance. A watchdog timeout event transitions the connection instance to the *Timeout* state, and the application will be notified.

An OUT frame with I/O-Refresh disabled or a TRG frame indicates *Idle*, and an OUT frame with I/O-Refresh enabled indicates *Run*.

### 9.3.4.12 I/O Connection Establishment

As described in Section 9.3.4.11, I/O Messages on CompoNet are always exchanged in a connection-based manner. Similar to DeviceNet, a CompoNet slave is allocated by the master by sending an Allocate Service to the CompoNet Link Object of the slave that is to be allocated.

When an I/O Connection is no longer needed, a slave can be released by sending a Release Service to the slave's CompoNet Link Object.

In contrast to DeviceNet, which also uses a Predefined Master Slave Connection Set, CompoNet has only one I/O data exchange mechanism (polled). Therefore, only one type of allocation may take place so there is only a single Allocation Choice bit defined in the Allocate service.

### 9.3.4.13 Device Profiles

#### 9.3.4.13.1 Bit Slave or Word Slave

All existing profiles must be realized by using the minimum amount of CompoNet communication. The following rules apply to the adaptation of existing profiles:

- CompoNet frame rules must be observed.
- If an existing profile can be realized by a Bit Slave, it must be a Bit Slave.
- An existing profile must be realized with the minimal data length that is feasible.

#### 9.3.4.13.2 Byte Size Differences

CompoNet uses the same definitions as other CIP Network even though it has specific transmission frames. In order to agree with the data size in bytes as used by CIP, CompoNet needs some rules to align a CompoNet I/O frame (which counts I/O size in bits) with CIP objects (which typically count data length in bytes).

For bit-level slaves, the related I/O size shown in the connection object instance is rounded up to 1 byte. For example, a BitIN slave with 1-bit valid input data uses IN frames with 2 bits of data to deliver data on the wire, but the *produced\_connection\_size* (attribute 7) of its connection instance shall be 1, which means 1 byte in CIP.

For byte-level slaves, the same sizes shall be used as with other CIP Networks. If the CIP byte size does not match the CompoNet frame size, the size is rounded up to the next even number for the

transmission. For example, a device with 3 bytes of application data will have size 3 in its application object (e.g., the Assembly Object) and size of 3 for the *produced\_connection\_size* (attribute 7) of its connection instance, but the IN frames on the wire have 32 bits of valid data.

#### 9.3.4.14 Configuration

CompoNet devices typically come with EDSs as described in Section 9.2.7.

To support EDS-based configuration, several CompoNet-specific EDS keywords have been added. With these new keywords and most CIP EDS keywords, CompoNet masters can be configured by a tool that can decode CompoNet EDS files. As a minimum (apart from the required sections), CompoNet EDSs should contain the CompoNet-specific sections that describe the I/O Connections available in the slave.

An EDS also may contain individual parameters and/or a Configuration Assembly with a complete description of all parameters within this Assembly.

CompoNet can also be configured by FDT/DTM, which is beyond the scope of CIP [44].

#### 9.3.4.15 Advice for Developers

Before starting any CompoNet product development, the following issues should be considered in detail:

- What functionality does the product require today and in future applications?
  - Slave functionality.
  - Master functionality.
- What are the physical layer requirements? Is IP 65/67 required, or is IP 20 good enough?
- What type of hardware should be chosen for this product?
- What kind of firmware should be used for this product? Will a commercially available communication stack be used?
- Will the development of hardware and/or software be done internally, or will it be designed by an outside company?
- What are the configuration requirements?
- What design and verification tools should be used?
- What kind of configuration software should be used for this product? Will a commercially available software package be used, that is, is an EDS adequate to describe the device or is custom software needed?
- When and where will the product be tested for conformance and interoperability?
- What is an absolute must before my products can be placed on the market (i.e., own the specification, have the company's own Vendor ID, and have the product conformance tested)?

A full discussion of these issues goes well beyond the scope of this publication, see [45,46] instead. ODVA provides a developer's toolkit including working source code for CompoNet slaves and repeaters.

#### 9.3.4.16 Conclusions

CompoNet is a well-adapted CIP Network. It complies with the CIP object modeling, object addressing, as well as the CIP communication model and its configuration rules. It is easy to realize CIP network routing and bridging. Combining with its advantages in aspects of data link and physical layer, CompoNet provides unique solutions with existing CIP resources to vendors and users.

All the changes in automation require consideration of the next generations of networking. In view of these trends and in view of technologies similar to those described earlier, it can be seen how much more successful a network can be if it is from the family of CIP Networks in all levels of hierarchy—instead of being patched together as a result of selecting isolated independent networks specific to each level.

## 9.4 Benefits of the CIP Family

---

CIP offers distinct benefits for two groups:

1. Device manufacturers
2. Users of devices and systems

### 9.4.1 Benefits for Device Manufacturers

For device manufacturers, a major benefit of using CIP is the fact that existing knowledge can be reused from one protocol to another, resulting in lower training costs for development, sales, and support personnel. Manufacturers also can reduce development costs, since certain parts (e.g., parameters and profiles) of the embedded firmware that are the same regardless of the network can be reused from one network to the other. As long as these parts are written in a high-level language, the adaptation is simply a matter of running the right compiler for the new system.

Another important advantage for manufacturers is the easy routing of messages from one system to another. Any routing device can be designed very easily since there is no need to invent a *translation* from one system to another; both systems already speak the same language.

Manufacturers also benefit from working with the same organizations for support and conformance testing.

### 9.4.2 Benefits for the Users of Devices and Systems

For users of devices and systems, a major benefit of using CIP is the fact that existing knowledge can be reused from one protocol to another, for example, through device profiles, and device behavior is identical from one system to another, resulting in lower training costs. Technical personnel and users do not have to make great changes to adapt an application from one type of CIP Network to another, and the system integrator can choose the CIP Network that is best suited to his or her application without having to sacrifice functionality.

Another important CIP advantage is the ease of bridging and routing between CIP Networks. Moving information among incompatible networks is always difficult and cumbersome since there is seldom a direct translation of all functionality on one network to another. This is where users can reap the full benefits of CIP. Forwarding data and messages from top to bottom and back again is very easy to implement and uses very little system overhead. There is no need to translate from one data structure to another—they are the same. Services and status codes share the same benefit, as these, too, are identical over all CIP Networks. Finally, creating a message that runs through multiple hops of CIP Networks is simply a matter of inserting the full path from the originating to the target device. Not a single line of code or any other configuration is required in the routing devices, resulting in fast and efficient services that are easy to create and maintain. Even though these networks may be used in different parts of the application, messaging from beginning to end really functions as if there is only one network.

Finally, the Producer/Consumer mechanisms used in all CIP Networks provide highly efficient use of transmission bandwidth, resulting in system performance that often is much higher than that of other networks running at higher raw baud rates. With CIP, only the truly important data are transmitted, rather than old data being repeated over and over again.

Planned and future protocol extension will always be integrated in a manner that allows coexistence of *normal* devices with *enhanced* devices like those supporting CIP Sync and/or CIP Safety. Therefore, no strict segmentation into *Standard*, CIP Sync, and CIP Safety networks is required unless there is a compelling reason, for example, unacceptable high response times due to high bus load.

## 9.5 Application Layer Enhancements

### 9.5.1 CIP Sync and CIP Motion

#### 9.5.1.1 General Considerations

While CIP Networks [5,14,17,42,47] provide real-time behavior that is appropriate for many applications, a growing number of applications require even tighter control of certain real-time parameters. Let us have a look at some of these parameters:

- *Real-Time*

This term is being used with a variety of meanings in various contexts. For further use in this section, the following definition is used: A system exhibits real-time behavior when it can react to an external stimulus within a predetermined time. How short or how long this time is depends on the application. Demanding industrial control applications require reactions in the millisecond range while, in some process control applications, a reaction time of several seconds or more is sufficient.

- *Determinism*

A deterministic system allows for a worst-case scenario (not a prediction or a probability) when deciding on the timing of a specific action. Industrial communication systems may offer determinism to a greater or lesser degree, depending on how they are implemented and used. Networks featuring message transmission at a predetermined point in time, such as ControlNet, Sercos Interface, and Interbus-S, are often said to offer absolute determinism. On the other hand, networks such as Ethernet may become nondeterministic under certain load conditions, specifically, when it is deployed in half-duplex mode with hubs. However, when Ethernet is deployed with full-duplex high-speed switches, it operates in a highly deterministic manner (see Section 9.3.3.21).

- *Reaction Time*

In an industrial control system, the overall system reaction time is what determines real-time behavior. The communication system is only one of several factors contributing to the overall reaction time. In general, reaction time is the time from an input stimulus to a related output action.

- *Jitter*

This term defines the time deviation of a certain event from its average occurrence. Some communication systems rely on very little message jitter, while most applications require only that a certain jitter is not exceeded for actions at the borders of the system, such as input sampling jitter and output action jitter.

- *Synchronicity*

Distributed systems often require certain actions to occur in a coordinated fashion, that is, the actions must take place at a predetermined moment in time, independent of where the action is to take place. A typical application is coordinated motion or electronic gearing. Some of these applications require synchronicity in the microsecond range.

- *Data Throughput*

This is a system's capability to process a certain amount of data within a specific time span. In communication systems, protocol efficiency, the communication model (e.g., Producer/Consumer), and end-point processing power are most important, while the wire speed sets only the limit of how much raw data can be transmitted across the physical media.

CIP Sync is a communication principle that enables synchronous low-jitter system reactions without the need for low-jitter data transmission. This is of great importance in systems that do not provide absolute deterministic data transmission or where it is desirable for a variety of higher-layer protocols to run in parallel with the application system protocol. The latter situation is characteristic of Ethernet.

Most users of TCP/IP-based Ethernet want to keep using it as before without the need to resort to a highly segregated network segment to run the real-time protocol. The CIP Sync communication principle meets these requirements.

### 9.5.1.2 Using IEEE 1588 Clock Synchronization

The published IEEE standard 1588—Standard for a Precision Clock Synchronization Protocol for Networked Measurement and Control Systems [48]—lays the foundation for a precise synchronization of real-time clocks in a distributed system.

An IEEE 1588 system consists of a Time Master that distributes its system time to Time Slaves in a tree-like structure. The Time Master may be synchronized with another real-time clock further up in the hierarchy while the Time Slaves may be Time Masters for other devices *below* them. A Time Slave that is Time Master to another set of devices (typically, in another part of the system) is also called a Boundary Clock. The time distribution is done by multicasting a message with the actual time of the master clock. This message originates in a relatively high layer of the communication stack, and, therefore, the actual transmission takes place at a slightly later point in time. Also, the stack processing time varies from one message to another. To compensate for this delay and its jitter, the actual transmission time can be captured in a lower layer of the communication stack, such as noting the *transmit complete* feedback from the communication chip. This update time capture is then distributed in a follow-up message. The average transmission delay also is determined so that the time offset between the master and the slave clock can be compensated.

This protocol has been fully defined for Ethernet UDP/IP systems, and the protocol details for further industrial communication systems will follow. The clock synchronization accuracy that can be achieved with this system depends largely on the precision time capture of the master clock broadcast message. Hardware-assisted time capture systems can reach a synchronization accuracy of 250 ns or less. Some Ethernet chip manufacturers offer integrated IEEE 1588 hardware support.

### 9.5.1.3 Additional Object

CIP Sync requires the addition of a time synchronization object.

#### 9.5.1.3.1 Time Sync Object (Class ID: 0x43)

The Time Sync Object manages the real-time clock inside a CIP Sync device and provides access to the IEEE 1588 timing information.

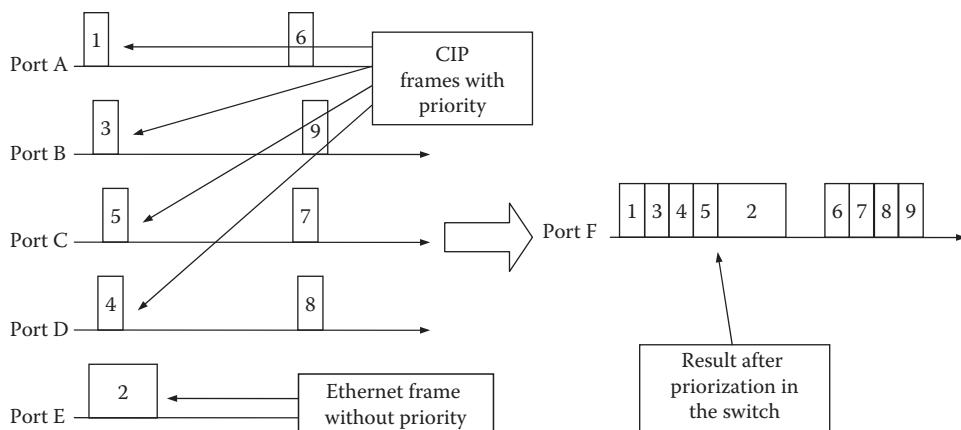

### 9.5.1.4 Fundamentals of CIP Sync Communication

Real-time clocks coordinated through the IEEE 1588 protocol do not, of their own accord, constitute a real-time system yet. Additional details showing how time stamping is used for input sampling and for the coordination of output actions need to be added. Some device profiles need to be extended as well to incorporate time information in their I/O Assemblies.

### 9.5.1.5 Message Prioritization

Combining these three elements (Sections 9.5.1.2 through 9.5.1.4) in conjunction with a collision-free infrastructure (see Section 9.3.3.21) is sufficient to build a real-time system. However, it is necessary to consider all traffic within the system and to arrange all application messages containing time-critical data in such a way that they are guaranteed to arrive at all consumers in time. When other Ethernet protocols—such as HTTP or FTP, which may have very long frames—need to coexist in the same system, careful configuration may be required. Ethernet frames with up to 1500 bytes of payload (approximately 122 µs long in a 100 Mbps system) can easily congest the system and delay important messages by an undetermined amount of time, possibly too long for the system to function correctly.

This is where message prioritization, known as QoS in the Ethernet world, becomes an important element. EtherNet/IP defines common usage for two standard QoS mechanisms: Differentiated

**FIGURE 9.52** Ethernet Frame Prioritization.

Services (Diffserv) and IEEE 802.1Q tagged frames. These schemes are supported by many switches available today. QoS allows preferential treatment of Ethernet frames in such a way that those frames with the highest priority will jump the message queues in a switch and will be transmitted first. Messages with high priority will be transmitted while those with lower priority typically have to wait. Suitable priority assignments for all time-critical messages then guarantee their preferential treatment. Standard EtherNet/IP and other Ethernet messages will receive low or no priority and thus have to wait until all higher-priority messages have passed. Once this prioritization scheme is implemented, one full-length frame can be accommodated within each communication cycle consisting of a set of prioritized input (port A through port E) and output (port F) messages. Figure 9.52 illustrates this process.

The overall approach to QoS for EtherNet/IP calls for devices to mark their packets with a priority value, using Diffserv Code Points and/or 802.1D priority values. By explicitly marking packets with a priority value, switches and routers are able to differentiate EtherNet/IP traffic from noncritical traffic as well as differentiate specific EtherNet/IP traffic streams (e.g., IEEE 1588 vs. I/O vs. Explicit Messaging).

The following list summarizes the QoS behavior for EtherNet/IP:

- For CIP transport class 0 and 1 connections (i.e., UDP-based), there is a defined mapping of CIP priorities to 802.1D priorities and DiffServ Code Points.
- For UCMM and CIP transport class 3 connections (i.e., TCP-based), there is a single defined DiffServ Code Point and 802.1D priority value.
- For PTP (IEEE 1588) messages, there are DiffServ Code Points and 802.1D priority values corresponding to the two different types of PTP messages.
- When QoS is implemented, the default behavior is to mark packets with DSCP values. Devices may optionally support sending and receiving 802.1Q frames with the corresponding priority values. If supported, sending tagged frames is disabled by default in order to prevent device interoperability problems. The end user is responsible for enabling the tagged frame behavior and ensuring interoperability between devices.
- The QoS Object provides a means to configure DSCP values and a means to enable/disable sending of 802.1Q tagged frames.
- There are no requirements for devices to mark traffic other than CIP or IEEE 1588, but devices are free to do so.

### 9.5.1.6 Applications of CIP Sync

Typical applications for CIP Sync are time-stamping sensor inputs, distributed time-triggered outputs, and distributed motion, such as electronic gearing or camming applications. For example, in motion applications, sensors sample their actual positions at a predetermined time, that is, in a highly synchronized way, and transmit them to the application master that coordinates the motion. The application master then calculates the new reference values and sends them to the motion drives. Using CIP Sync, the communication system is not required to have extremely low jitter; it is sufficient to transmit all time-critical messages, and their exact arrival time becomes irrelevant. The assignment of suitable priorities to CIP Sync communication guarantees that all time-critical messages always have the bandwidth they need, and all other traffic automatically is limited to the remaining bandwidth.

As a result of these measures, CIP Sync devices can coexist side by side with other EtherNet/IP devices without any need for network segmentation or special hardware. Even non-EtherNet/IP devices—provided they do not override any of the CIP Sync prioritizations—can be connected without any loss of performance in the CIP Sync application.

### 9.5.1.7 Expected Performance of CIP Sync Systems

As mentioned, CIP Sync systems can be built to maintain a synchronization accuracy of better than 250 ns, in many cases without the use of Boundary Clocks. The communication cycle and thus the reaction delay to unexpected events are largely governed by the number of CIP Sync devices in a system. Allowing some bandwidth (approximately 40%) for non-CIP Sync messages as described in Section 9.5.1.5, the theoretical limit (close to 100% wire load) for the communication cycle of a CIP Sync system based on a 100-Mbps Ethernet network is around 500 µs for 30 coordinated motion axes, with 32 bytes of data each.

### 9.5.1.8 CIP Sync Summary

CIP Sync is a natural extension of the EtherNet/IP system into the real-time domain. Unlike many other proposed or existing real-time extensions to other protocols, CIP Sync does not require any strict network segmentation between high-performance, real-time sections and other parts of the communication system. CIP Sync provides the ability to mix parallel TCP/IP-based protocols with industrial communication architectures of any size without compromising performance.

CIP Sync currently has been applied to EtherNet/IP, and an extension to other CIP implementations will follow.

### 9.5.1.9 CIP Sync and CIP Motion

CIP Motion utilizes CIP Sync to manage real-time motion control. As discussed previously, CIP Sync utilizes the IEEE-1588 “Standard for a Precision Clock Synchronization Protocol for Networked Measurement and Control Systems” [48] to synchronize devices to a very high degree of accuracy. CIP Sync encapsulates the IEEE-1588 services that measure network transmission latencies and correct for infrastructure delays. The result is the ability to synchronize distributed clocks to within hundreds of nanoseconds of accuracy, or less.

Once all the devices in a control system share a synchronized, common understanding of system time, real-time control can be accomplished by including time as a part of the motion information. Unlike the traditional approaches to motion control, the CIP Motion solution doesn’t schedule the network to create determinism. Instead, CIP Motion delivers the data and the time stamp for execution as a part of the packet on the network. This allows motion devices to plan and follow positioning path information according to a predetermined execution plan. Since the motion controller and the drives share a common understanding of time, the motion controller can tell the drive where to go—and what time to be there. This direct use of time in the data packet frees the network from the constraint of a rigid data delivery schedule. If data delivery fluctuates slightly on the network, the motion execution is unaffected.

There are many benefits to this approach. Since the network is not *scheduled*, there is flexibility in the amount of data that can be sent back from each device. During runtime, a drive can be reconfigured to send more or less data depending on the needs of the application. In addition, devices can be added or removed from the system because specific time slots are not allocated from the network bandwidth. The motion data packets that move between drives and controllers contain all the relevant information required for real-time motion execution; as long as basic clock synchronization is maintained, time is used as the event for execution—not the data delivery itself.

### 9.5.1.10 CIP Motion

CIP Motion was added to the CIP Networks Library in 2006, with the addition of the CIP Motion Axis Object and the CIP Motion Device Profile.

#### 9.5.1.10.1 CIP Motion Profile

The CIP application profile used on EtherNet/IP provides a comprehensive set of services and device profiles that provide a wide range of functionality and device support. CIP Motion extends the CIP capability by defining extensions focused on drive control as listed in the following text:

- Torque, velocity, or position control of servo drives and VFDs (Variable Frequency Drives)
- Servo drive and VFD configuration, status, and diagnostic parameters
- Support for feedback-only axes that can provide reference information for camming and line-shafting applications
- Unicast control-to-drive communications
- Multicast peer-to-peer communications (future)

The CIP Motion profile is designed to minimize the differences between servo drive and VFD handling. This facilitates features like common configuration services, common status and diagnostic services, and common application instruction support for servo drives and VFDs making them interchangeable at the application level.

The CIP Motion profile takes advantage of the latest advances in motion control technology to provide a comprehensive, state-of-the-art profile. Extensive use of floating point data eliminates the complexity typically associated with integer math and scaling. The profile focuses on a simplified slave interface, making it easier for drive vendors to develop products that connect to the EtherNet/IP network and utilize the CIP Motion extensions.

### 9.5.2 CIP Safety

Like other safety protocols based on industry standard networks, CIP Safety adds additional services to transport data with high integrity. Unlike other networks, CIP Safety presents a scalable, network-independent approach to safety network design, one in which the safety services are described in a well-defined layer. Since safety functionality is incorporated into each device—rather than in the network infrastructure—CIP Safety allows both standard and safety devices to operate on the same open network. This capability gives users a choice of network architectures—with or without a safety PLC—for their functional safety networks. This approach also enables safety devices from multiple vendors to communicate seamlessly across standard CIP Networks to other safety devices without requiring difficult-to-manage gateways.

A complete definition of all details of CIP Safety can be found in Volume 5 [49].

#### 9.5.2.1 General Considerations

Hardwired safety systems employ safety relays that are interconnected to provide a safety function. Hardwired systems are difficult to develop and maintain for all but the most basic applications. Furthermore, these systems place significant restrictions on the distance between devices.

Because of these issues, as well as distance and cost considerations, implementing safety services on standard communication networks is highly preferable. The key to developing safety networks is not to create a network that cannot fail, but to create a system where failures in the network cause safety devices to go to a known state. If the user knows which state the system will go to in the event of a failure, they can make their application safe. But this means that significantly more checking and redundant coding information is required.

So, to determine the additional safety requirements, the German Safety Bus committee [50] implemented and later extended an existing railway standard [51]. This committee provided design guidelines to safety network developers to allow their networks and safety devices to be certified according to IEC 61508 [52]. The latest version of this document has been published as GS-ET-26 [53].

Based on these standards, CIP was extended for high-integrity safety services. The result is a scalable, routable, network-independent safety layer that alleviates the need for dedicated safety gateways. Since all safety devices execute the same protocol, independent of the media on which they reside, the user approach is consistent and independent of media or network used.

CIP Safety is an extension to standard CIP that has been approved by TÜV Rheinland for use in IEC 61508 SIL 3 and EN 954-1 Category 4 applications, now ISO 13849-1, performance level e [54]. It extends the model by adding CIP Safety application layer functionality, as shown in Figure 9.53. The additions include several safety-related objects and Safety Device Profiles with specific implementation details of CIP Safety as implemented on DeviceNet, EtherNet/IP, and Sercos.

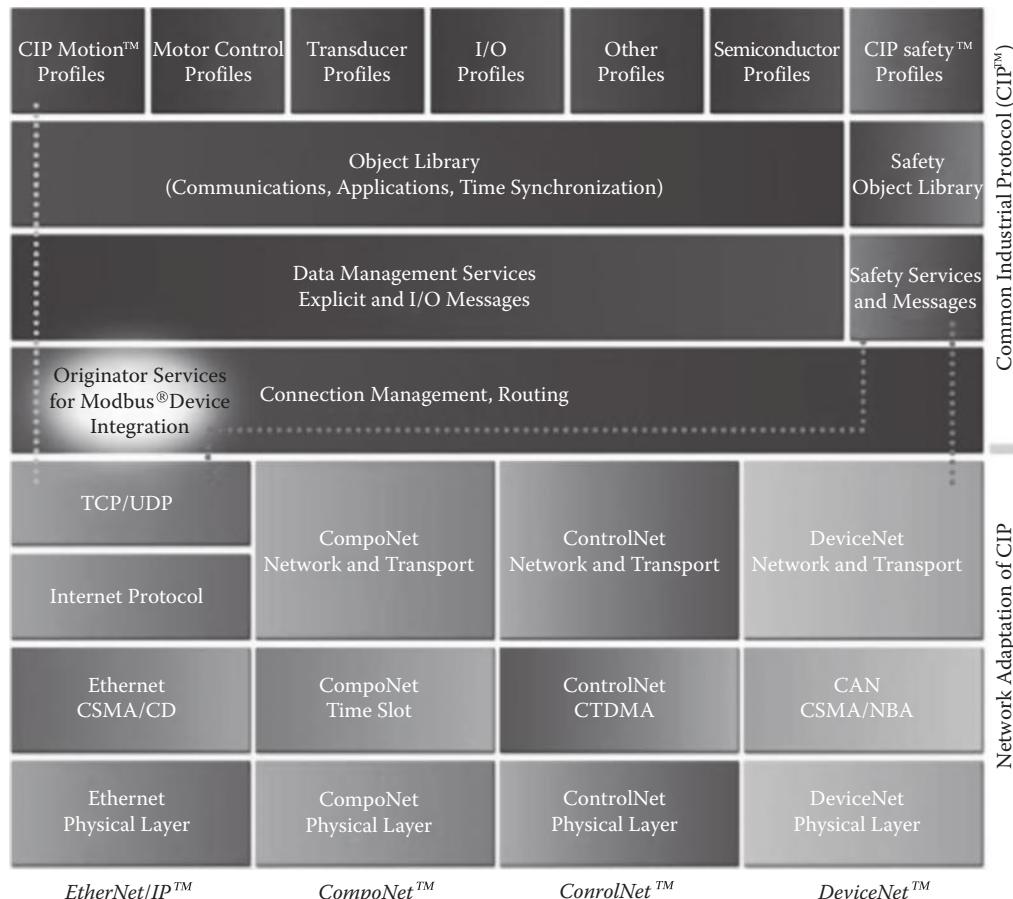

FIGURE 9.53 CIP communication layers, including safety.

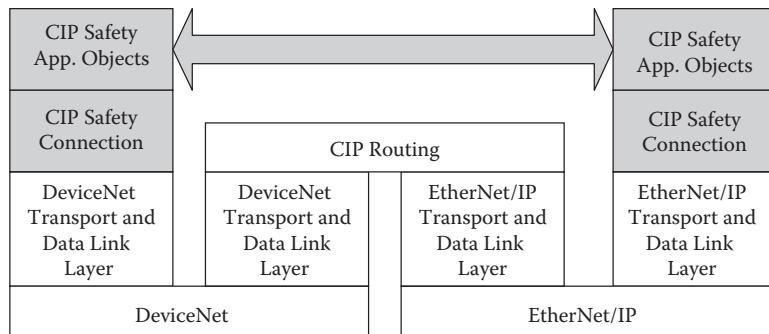

FIGURE 9.54 Routing of safety data.

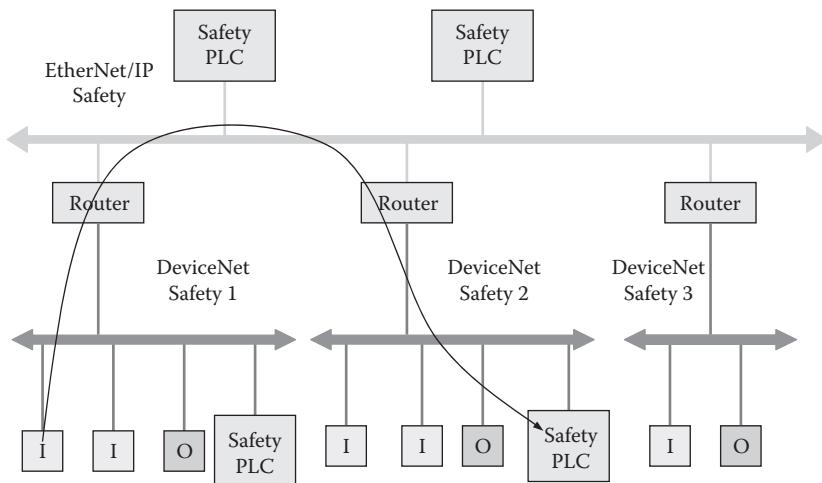

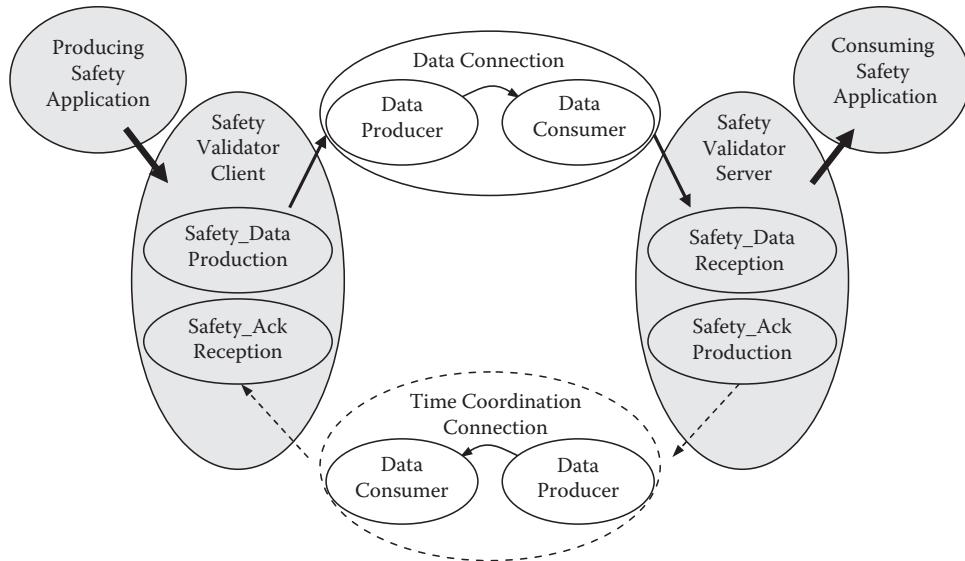

FIGURE 9.55 Network routing.

Because the safety application layer extensions do not rely on the integrity (see Section 9.5.2.3) of the underlying standard CIP as described in Section 9.2 and data link layers as described in Sections 9.3.1 through 9.3.3, single-channel (nonredundant) hardware can be used for the data link communication interface. This same partitioning of functionality allows the use of standard routers for safety data, as shown in Figure 9.54. Routing safety messages is possible because the end device is responsible for ensuring the integrity of the data. If an error occurs during data transmission or in the intermediate router, the end device will detect the failure and take appropriate action.

This routing capability allows the creation of safety cells on one network, for example, DeviceNet, with quick reaction times to be interconnected with other cells via a backbone network such as EtherNet/IP for interlocking, as shown in Figure 9.55. Only the safety data that is needed is routed to the required cell, which reduces individual bandwidth requirements. The combination of rapidly responding local safety cells and the intercell routing of safety data allows users to create large safety applications with fast response times. Another benefit of this configuration is the ability to multicast safety messages across multiple networks.

### 9.5.2.2 Implementation of Safety

As indicated in Figure 9.54, all CIP Safety devices also have underlying standard CIP functionality. The extension to the CIP Safety application layer is specified using a Safety Validator Object. This object is responsible for managing the CIP Safety Connections (standard CIP Connections are managed through

**FIGURE 9.56** Relationship of Safety Validators, Unicast Connection.

communication objects) and serves as the interface between the safety application objects and the link layer connections, as shown in Figure 9.56. The Safety Validator ensures the integrity of the safety data transfers by applying the measures described in Section 9.5.2.3.

Functions performed by the Safety Validator Object as follows:

- The producing safety application uses an instance of a Client Validator to produce safety data and ensure time coordination.
- The client uses a link data producer to transmit the data and a link consumer to receive time coordination messages.
- The consuming safety application uses a Server Validator to receive and check data.
- The server uses a link consumer to receive data and a link producer to transmit time coordination messages.

The link producers and consumers have no knowledge of the safety packet and fulfill no safety function. The responsibility for high-integrity transfer and checking of safety data lies within the Safety Validators.

### 9.5.2.3 Ensuring Integrity

CIP Safety does not prevent communication errors from occurring; rather, it ensures transmission integrity by detecting errors and allowing devices to take appropriate actions. The Safety Validator is responsible for detecting these communication errors. The nine communication errors that must be detected are shown in Figure 9.57, along with the five measures CIP Safety uses to detect these errors [51].

#### 9.5.2.3.1 Time Expectation via Time Stamp

All CIP Safety data are produced with a time stamp that allows Safety Consumers to determine the age of the produced data. This detection measure is superior to the more conventional reception timers. Reception timers can tell how much time has elapsed since a message was last received, but they do not convey any information about the actual age of the data. A time stamp allows transmission, media access/arbitration, queuing, retry, and routing delays to be detected.

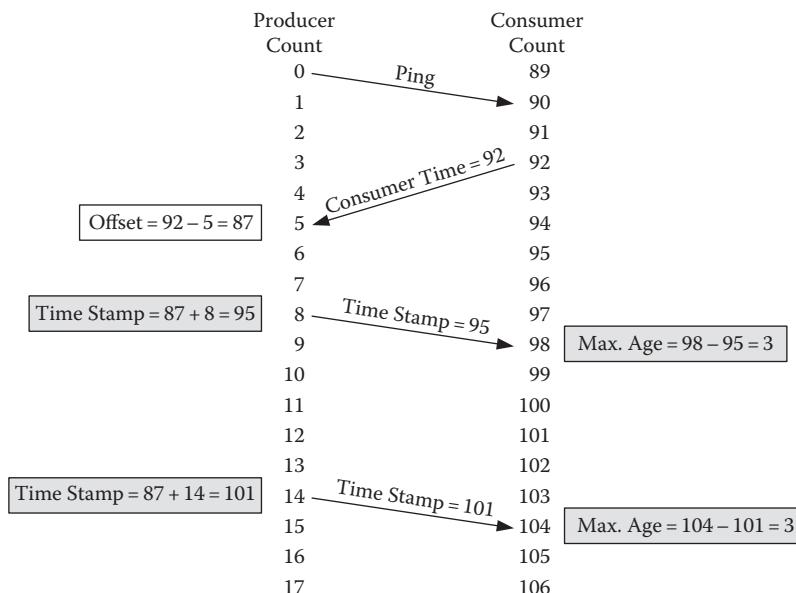

Communication Errors	Measures to Detect Communication Errors				
	Time Expectation via Time Stamp	ID for Send and Receive	Safety CRC	Redundancy with Cross-Checking	Diverse Measure
Message Repetition	X		X <sup>a</sup>		
Message Loss	X		X <sup>a</sup>		
Message Insertion	X	X	X <sup>a</sup>		
Incorrect Sequence	X		X <sup>a</sup>		
Message Corruption			X	X	
Message Delay	X				
Coupling of safety and safety data			X		
Coupling of safety and standard data	X	X	X	X	X
Increased age of data in bridge	X				

<sup>a</sup> The Safety CRC provides additional protection for communication errors in fragmented messages.

**FIGURE 9.57** Error Detection Measures.

Time is coordinated between producers and consumers using ping requests and ping responses, as shown in Figure 9.58. After a connection is established, the producer generates a ping request, which causes the consumer to respond with its consumer time. The producer will note the time difference between the ping production and the ping response and store this as an offset value. The producer will add this offset value to its producer time for all subsequent data transmissions. This value is transmitted as the time stamp. When the consumer receives a data message, it subtracts its internal clock from the time stamp to determine the data age. If the data age is less than the maximum age allowed, the data are applied; otherwise, the connection goes to the safety state. The device application is notified so that the connection safety state can be reflected accordingly.

The ping request-and-response sequence is repeated periodically to correct for any producer or consumer time base drift.

**FIGURE 9.58** Time stamp.

#### 9.5.2.3.2 Production Identifier

A Production Identifier (PID) is encoded in all data produced by a Safety Connection to ensure that each received message arrives at the correct consumer. The PID is derived from an electronic key, the device Serial Number, and the CIP Connection Serial Number. Any safety device inadvertently receiving a message with the incorrect PID will go to a safety state. Any safety device that does not receive a message within the expected time interval with the correct PID will also go to a safety state. This measure ensures that messages are routed correctly in multinet applications.

#### 9.5.2.3.3 Safety Cyclic Redundancy Code

All safety transfers on CIP Safety use Safety CRCs to ensure the integrity of the transfer of information. The Safety CRCs serve as the primary means of detecting possible corruption of transmitted data. They provide detection up to a Hamming distance of four for each data transfer section, though the overall Hamming distance coverage is greater for the complete transfer due to the protocol's redundancy. The Safety CRCs are generated in the Safety Producers and checked in the Safety Consumers. Intermediate routing devices do not examine the Safety CRCs. Thus, by employing end-to-end Safety CRCs, the individual data link CRCs are not part of the safety function. This eliminates certification requirements for intermediate devices and helps to ensure that the safety protocol is independent of the network technology. The Safety CRC also provides a strong protection mechanism that allows the detection of underlying data link errors, such as bit stuffing or fragmentation.

While the individual link CRCs are not relied on for safety, they are still enabled. This provides an additional level of protection and noise immunity by allowing data retransmission for transient errors at the local link.

#### 9.5.2.3.4 Redundancy and Cross-Check

Data and CRC redundancy with cross-checking provides an additional measure of protection by detecting possible corruption of transmitted data. By effectively increasing the Hamming distance of the protocol, these measures allow long safety data packets—up to 250 bytes—to be transmitted with high integrity. For short packets of 2 bytes or less, data redundancy is not required; however, redundant CRCs are cross-checked to ensure integrity.

#### 9.5.2.3.5 Diverse Measures for Safety and Standard

The CIP Safety protocol is present only in safety devices, which prevents standard devices from masquerading as safety devices.

### 9.5.2.4 Safety Connections

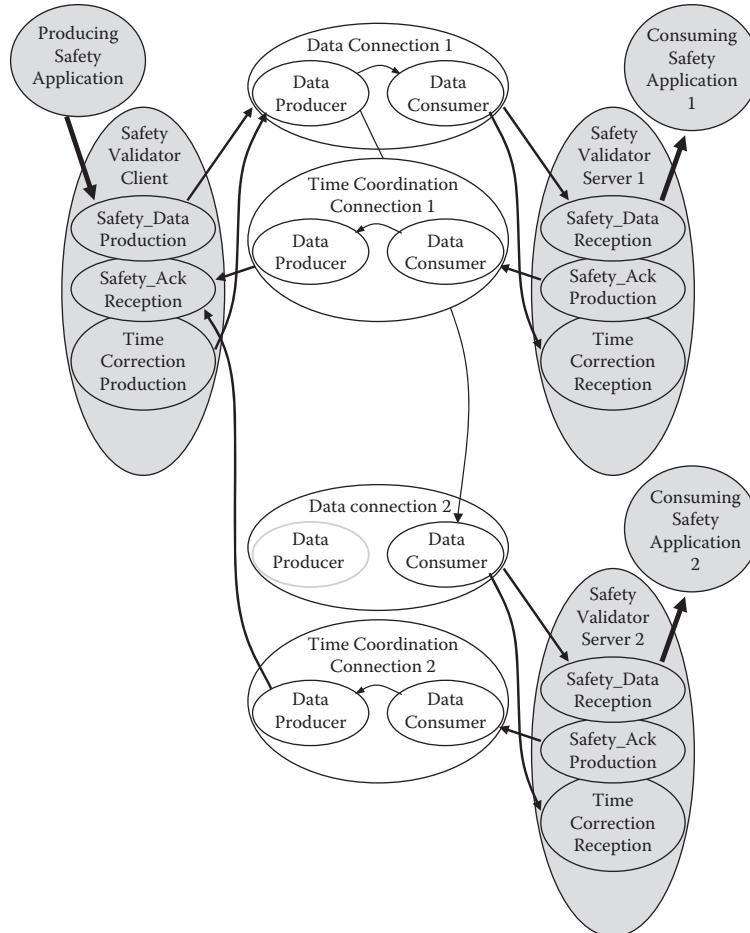

CIP Safety provides two types of Safety Connections:

1. Unicast Connections
2. Multicast Connections

A Unicast Connection, as shown in Figure 9.56, allows a Safety Validator Client to be connected to a Safety Validator Server using two link-layer connections.

A Multicast Connection, as shown in Figure 9.59, allows up to 15 Safety Validator Servers to consume safety data from a Safety Validator Client. When the first Safety Validator Server establishes a connection with a Safety Validator Client, a pair of link layer connections are established, one for data-and-time correction and the other for time coordination. Each new Safety Validator Server uses the existing data-and-time correction connection and establishes a new time coordination connection with the Safety Validator Client.

To optimize throughput on DeviceNet, each Multicast Connection uses three data link connections, as shown in Figure 9.60. CIP Safety implementations on other networks do not require

**FIGURE 9.59** Multicast Connection.

this split. The data-and-time correction messages are sent on separate connections. This allows short messages to be transmitted on DeviceNet within a single CAN frame and reduces the overall bandwidth, since the time correction and time coordination messages are sent at much slower periodic intervals.

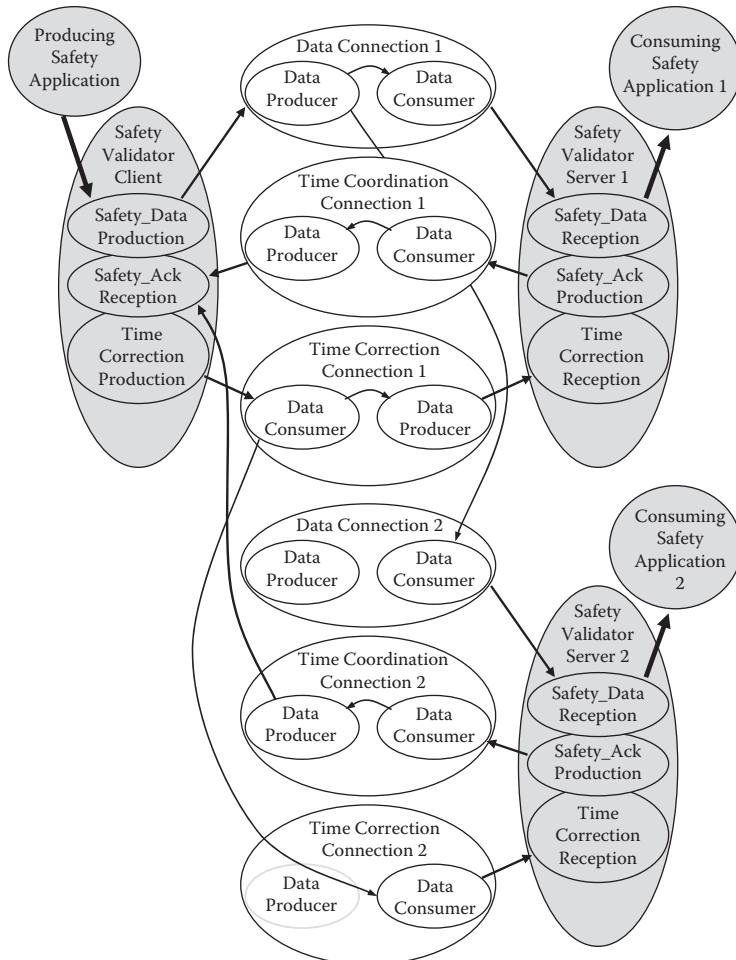

When multicast messages are routed off-link, the router combines the data-and-time correction messages from DeviceNet and separates them when messages reach DeviceNet. Since the safety message contents are unchanged, the router provides no safety function.

### 9.5.2.5 Message Packet Sections

CIP Safety has four message sections:

1. Data
2. Time stamp
3. Time correction
4. Time coordination

The description of these formats goes beyond the scope of this book. For available materials on this topic that go into more detail see [49,55].

**FIGURE 9.60** Multicast Connection on DeviceNet.

### 9.5.2.6 Configuration

Before safety devices can be used in a safety system, they first must be configured and connections must be established. The process of configuration requires placement of configuration data from a configuration tool in a safety device. There are two possible sequences for configuration:

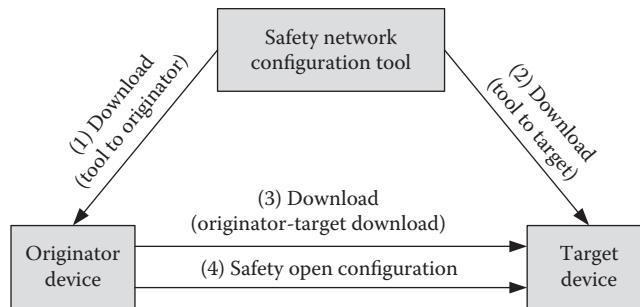

1. Configuration tool directly to device
2. Via an intermediate device

In the configuration tool-to-device case, as shown in Figure 9.61, the configuration tool writes directly to the device to be configured (1) and (2).

In the case of intermediate device configuration, the tool first writes to an originator (1) and the originator writes to the target using an Originator-to-Target Download (3) or a SafetyOpen service (4). The SafetyOpen service (4) is unique in that it allows a safety connection to be established at the same time that a device is configured.

### 9.5.2.7 Connection Establishment

CIP provides a connection establishment mechanism using a Forward\_Open service that allows producer-to-consumer connections to be established locally or across multiple networks via intermediate

**FIGURE 9.61** Configuration transfers.

routers. An extension of the Forward\_Open, called the SafetyOpen service, has been created to allow the same multinet connections for safety.

There are two types of SafetyOpen requests:

- Type 1: with configuration
- Type 2: without configuration

With the Type 1 SafetyOpen request, configuration and connections are established at the same time, allowing rapid configuration of devices with simple and relatively small configuration data.

With the Type 2 SafetyOpen request, the safety device first must be configured, and the SafetyOpen request then establishes a Safety Connection. This separation of configuration and connection establishment allows the configuration of devices with large and complex configuration data.

In both cases, the SafetyOpen request establishes all underlying link layer connections—across the local network as well as any intermediate networks and routers.

### 9.5.2.8 Configuration Implementation

CIP Safety provides the following protection measures to ensure configuration integrity:

- Safety Network Number
- Password Protection
- Configuration Ownership
- Configuration Locking

#### 9.5.2.8.1 Safety Network Number

The Safety Network Number provides a unique network identifier for each network in the safety system. The Safety Network Number, combined with the local device address, allows any device in the safety system to be uniquely addressed.

#### 9.5.2.8.2 Password Protection

All safety devices support the use of an optional password. The password mechanism provides an additional protection measure, prohibiting the reconfiguration of a device without the correct password.

#### 9.5.2.8.3 Configuration Ownership

The owner of a CIP Safety device can be specified and enforced. Each safety device can specify that it be configured only by a selected originator or that the configuration is accomplished by a configuration tool.

#### 9.5.2.8.4 Configuration Locking

Configuration Locking provides the user with a mechanism to ensure that all devices have been verified and tested prior to being used in a safety application.

### 9.5.2.9 Safety Devices

The relationship of the objects within a safety device is shown in Figure 9.62. Note that CIP Safety extends the CIP object model, with the addition of Safety I/O Assemblies, Safety Validator, and Safety Supervisor Objects.

### 9.5.2.10 Additional Objects

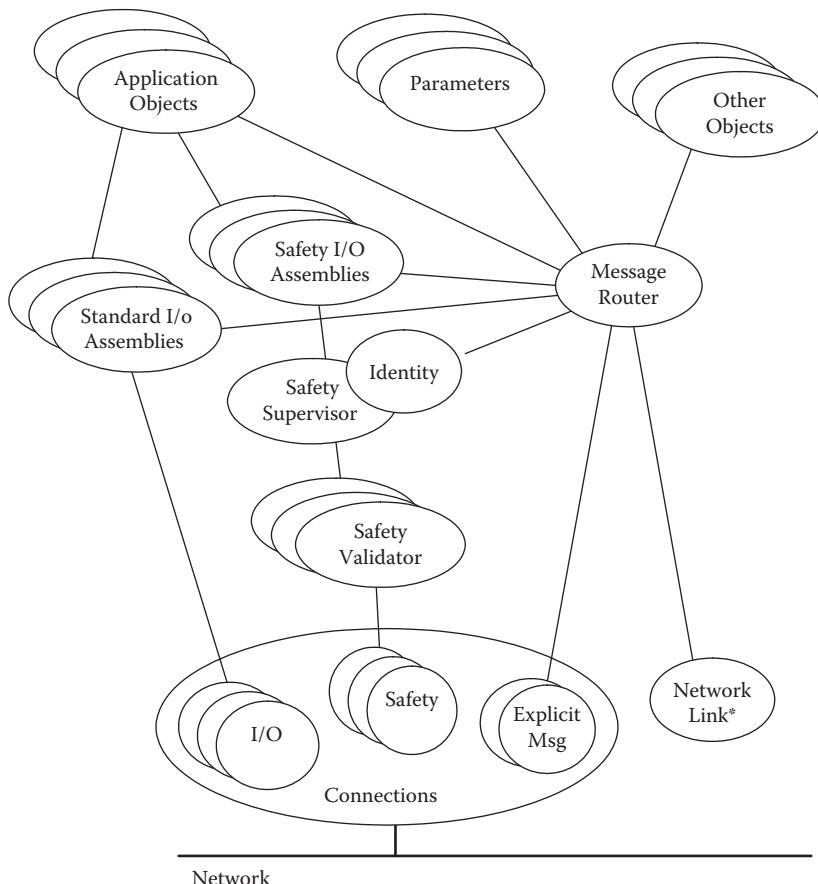

CIP Safety requires two additional objects, the Safety Supervisor Object and the Safety Validator Object.

#### 9.5.2.10.1 Safety Supervisor Object (Class ID: 0x39)

The Safety Supervisor Object provides a common configuration interface for safety devices. The Safety Supervisor Object centralizes and coordinates application object state behavior and related status information, exception status indications (alarms and warnings) and defines a behavior model which is assumed by objects belonging to safety devices.

#### 9.5.2.10.2 Safety Validator Object (Class ID: 0x3A)

The Safety Validator Object contains the information necessary to coordinate and maintain reliable safety connections between client and server safety applications. The primary role of the Safety Validator Object is to act as a safety transport manager of multiple low-level CIP connections that together form a complete safety connection.

**FIGURE 9.62** Safety device objects. Note: \* DeviceNet, ControlNet, Ethernet, and SERCOS.

### 9.5.2.11 CIP Safety on Sercos

#### 9.5.2.11.1 What Is Sercos?

Sercos (Serial Real-time COmmunication System), the digital drive interface approved as international standard IEC 61491 [56] in 1995, is optimized for high-speed deterministic motion control, where the exact synchronization of multiple drives is required. Sercos has become a globally accepted real-time networking standard for demanding motion control applications over the last decade. Sercos has outstanding technical features like real-time capabilities, high performance, noise immunity, and a very large variety of products and suppliers. Sercos not only defines the protocol structure but also includes an ample variety of profile definitions (parameters and functionalities), which are already successfully used in a large number of applications. Sercos is supported and maintained by Sercos International [57].

The third-generation Sercos (Sercos III) combines the proven mechanisms of Sercos interface with Ethernet's physics and protocol. Typical Sercos III networks use a double-ring structure that provides media redundancy with fast switch-over. In addition to the ring structure, a linear structure is also possible (see Figure 9.63). A Sercos ring or line structure consists of one master and multiple slaves—drives, I/O, and sensors. Multiple rings can be used in a network to realize distributed and hierarchical network structures.

The communication is based on a time-slot protocol using fixed and distinct communication cycles. A communication cycle is divided into two channels with a timing control.

In the real-time channel, collective Sercos III telegrams are transferred as broadcast data. This increases the bandwidth and improves the protocol efficiency. The addressing of the Sercos III devices is achieved by predefined addresses or by addresses assigned by the master (remote addressing). Sercos III telegrams are processed on the fly to reduce delay times in a network.

In the non-real-time channel, any non-real-time Ethernet frames can be sent as individual telegrams to any device in the network. The addressing for this is carried out directly via the MAC addresses allocated to the master and slave devices.

#### 9.5.2.11.2 CIP Safety on Sercos

CIP Safety on Sercos extends the functionality of the Sercos III real-time communication system to support both safety-relevant and non-safety relevant data transmission over one single network.

The CIP Safety Stack (CSS) is implemented corresponding to the CIP Safety specification without modifications. Thus, CIP Safety on Sercos uses the safe message format and the CIP Safety objects and services of the CIP Safety specification, as well as the same CRC polynomials and algorithms. For this reason, it is possible for the CIP Safety Adaptation Layer (CSAL) as well as the Sercos III subordinate communication system, including the Sercos Messaging Protocol (SMP), to be viewed as part of the non-safety-relevant transfer (see Figure 9.64).

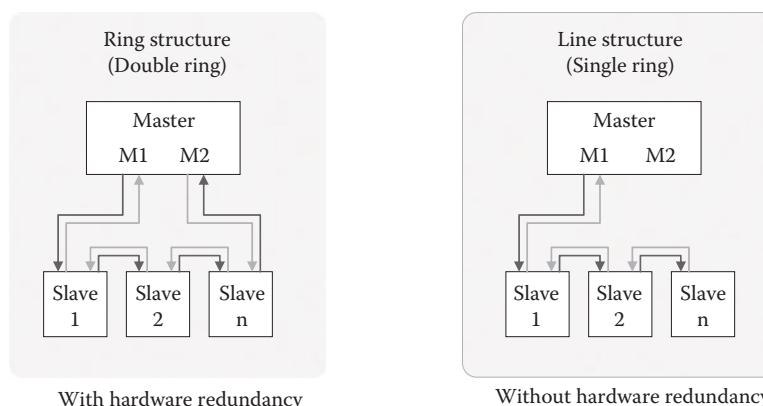

FIGURE 9.63 Sercos III ring and line topology.

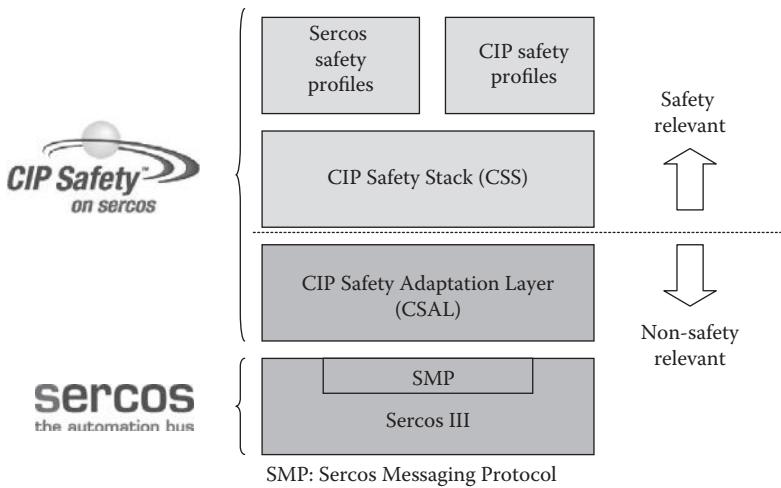

FIGURE 9.64 CIP Safety on Sercos—Structure.

The main task of the CSS in a CIP Safety Device is to create and process CIP Safety messages using cyclic process data and to correspondingly specify communication errors with the help of different error recognition measures. A CIP Safety Device can be a tool, an originator, or a target. In addition to the process data, the CSS must also process configuration data.

Because Sercos III does not provide any transport connections, an adaptation layer is required in order to fill the gaps between CIP Safety and Sercos III. An important task is assigned to the SMP, which is located above the cyclic Sercos III connections. It offers the CSAL services in order to send messages, which can be of any length, from a producer to the consumers. In order to transport these data, the SMP uses data containers with a fixed length in a cyclic connection. Messages that are larger than one data container are split up into several fragments and transferred subsequently. Messages with a higher priority can interrupt the transfer of long fragmented messages with lower priority. This means that an effective multiplexing of several logical communication channels in a single transport container is possible. The SMP is part of the non-safety-relevant transfer. Mechanisms and measures for the data integrity of CIP Safety are not influenced.

With Sercos III and CIP Safety, the implementation of a wide range of topologies is possible. The range stretches from structures with a central safety control to completely decentralized solutions without any safety control. With Sercos III and CIP Safety, it is also possible to route safe data beyond the limits of a Sercos network and also beyond non-safety-relevant participants.

CIP Safety on Sercos has been integrated into the CIP Specification by extending Volume 5 (CIP Safety) and through some minor adjustments to Volume 1 (CIP Common). Since the safety protocol was not changed at all, the main parts of Volume 5 were changed only in those areas where modified wording was needed to accommodate the additional network. However, there is a new appendix in Volume 5 (Appendix G) that describes how CIP Safety is being transported on the Sercos transport layer. Since the CIP Safety protocol as such remained unchanged, most of the adaptation work was done on the Sercos side, which is reflected in the CIP Safety on Sercos specification available from Sercos International [57].

### 9.5.2.12 CIP Safety Summary

CIP Safety is a scalable, routable, network-independent safety protocol based on extensions to the CIP architecture. This concept can be used in solutions ranging from device-level networks such as DeviceNet to higher-level networks such as EtherNet/IP. Designing network independence into CIP Safety allows multinetworke routing of Safety Connections. Functions such as multinetworke routing and

multicast messaging provide a strong foundation that enables users to create the rapidly responding local cells and interconnect remote cells that are required for today's safety applications. CIP Safety's design also enables expansion to future network technologies as they become available.

### 9.5.3 Integration of Non-CIP Networks

#### 9.5.3.1 Integration of Modbus into CIP

##### 9.5.3.1.1 Overview

With the advent of the Modbus translator, customers can take advantage of EtherNet/IP and Modbus capabilities in the same network. The simplicity of the Modbus protocol is combined with the unique values of EtherNet/IP. The relationship is further strengthened because the Modbus/TCP protocol and EtherNet/IP are both based on standard Ethernet technology. Both protocols can coexist in the same network because they both operate over standard Ethernet. Migration of existing products is enabled with no custom hardware required.

By establishing the Modbus Integration SIG within the ODVA, the seamless connection between the Modbus protocol and EtherNet/IP was enabled. Volume 7 [61], Integration of Modbus Devices into CIP, was developed within the SIG and later approved by the ODVA. Edition 1.0 of Volume 7 supports translation between EtherNet/IP and Modbus/TCP. The Modbus Serial protocol support was added to Volume 7 in Edition 1.1 and approved by the ODVA at the beginning of 2008. Clarifications and updates to Volume 7 are being considered to continually improve the volume.

The Modbus protocol and the EtherNet/IP protocol make up the majority of the installed Ethernet-based device level products to date. Both are widely accepted standards with strong international organizations behind them and solid membership and participation from those organizations. Volume 7 links the two protocols together.

The Modbus Integration SIG was formed in May 2007 with the purpose of creating the Modbus translator. More than 20 different companies belong to the Modbus Integration SIG. The diverse membership of the SIG insured an unbiased specification was developed. The diversity of the SIG membership brought all perspectives into the development of the specification from the Modbus target device developer to the PLC manufacturer to the EtherNet/IP target vendor to the CIP Originator designer. All aspects of the CIP and Modbus networks were and are represented.

The development of Volume 7 came with the requirement that the use of the Modbus translator would not force changes to existing Modbus target devices or the EtherNet/IP target devices. Also a requirement for the development was to minimize the impact to CIP Originators. These requirements were met. The impact to the CIP Originator was focused on the need to support both the Modbus/TCP and Ethernet/IP protocol on the same physical Ethernet port should a customer desire to do so.

The Modbus translator can be implemented in the CIP Originator or as a CIP router; that is, the translator can be in a PLC or as a stand-alone device. The Modbus translator effort and consequently Volume 7 of the CIP suite of protocols were targeted at CIP Originator developers, CIP router developers, and Modbus vendors. The first two audiences are obvious. The Modbus device vendor is targeted so that this vendor can better understand how their device can be more easily integrated into the CIP to Modbus solution.

As the name states, the Modbus translator translates CIP objects and services into Modbus messages and function codes. A CIP Originator communicates with and controls Modbus target devices through the Modbus translator. To the CIP Originator, the Modbus target devices appear as CIP target devices. The Modbus target devices believe that they are being controlled by a Modbus client. The translation is transparent.

The user would place a stand-alone Modbus translator in the user's CIP-based network and then connect Modbus target devices to the Modbus side of the translator. The other side of the translator would be connected to the CIP Originator.

The user also has the option to use a Modbus translator as a module inside the CIP Originator. In this case, the user would talk EtherNet/IP across the backplane to the translator. The Modbus target devices connect externally to the PLC-based translator.

A third approach places the Modbus translator and the Modbus/TCP target devices on the same network as the EtherNet/IP target devices using the shared cabling. The EtherNet/IP traffic destined for the Modbus target devices would be sent to the Modbus translator, and the Modbus translator would send the Modbus/TCP traffic over the same network to the Modbus/TCP target devices. The Modbus/TCP target devices would reply to the Modbus translator and then the translator will translate the Modbus traffic into EtherNet/IP traffic sent to the CIP Originator.

In all three cases, the CIP-to-Modbus translation allows communication using I/O Connections as well as Explicit Messaging. When Explicit Messaging is used, the translator may offer two types of access to the data in the Modbus device, through publicly defined instances for Modbus data in the Assembly Object using Common Services or through the Modbus Object using object-specific services.

Logically, in the OSI model of the TCP/IP stack, the Modbus translation on Ethernet sits above Modbus/TCP application in the application layer (Layer 7) and below the CIP application layers. The Modbus translator on Ethernet is on the same level as the EtherNet/IP encapsulation. The lower layers of the stack are the standard TCP/IP stack layering.

Changes to the CIP Originator were limited. Port types were added for Modbus/TCP and Modbus Serial devices with associated port names and numbering. The Identity Object was extended to include Modbus-specific information, and a Modbus Object was developed and included in the CIP Object Library. Status codes were added to identify errors and status items that are specific to Modbus. Other status codes were modified to better support Modbus and EtherNet/IP together.

All the capabilities of Modbus translator are detailed in Volume 7, *Integration of Modbus Devices into CIP*, within the CIP suite of protocols. The updated Volume 1, Common Industrial Protocol (CIP) Specification, includes support for the Modbus translation as does the updated Volume 2, EtherNet/IP Adaptation of CIP.

Customers now have greater opportunity to improve their automation networks by being able to incorporate Modbus devices into their existing CIP Networks seamlessly, especially in the case of EtherNet/IP and Modbus TCP devices on the same physical network. Customers have a broader range of products available to them and can mix and match features they need from a device without being restricted to a single protocol. Risk to the buyer is reduced by the availability of greater choices to use devices based on EtherNet/IP and Modbus/TCP.

### 9.5.3.1.2 Object Extensions

The definition of the Modbus translation has resulted in extensions of existing objects as well as the creation of new objects.

**9.5.3.1.2.1 Extension of Existing Objects** The main extension for the Modbus integration is within the Identity Object, which has been enhanced with an attribute containing Modbus-specific identity information plus a translation definition for standard CIP ID information.

A set of Assembly Object and Parameter Object Instances have been defined that mirror Modbus-specific data tables (Holding Registers, Input Registers, Coils, and Discrete Inputs). These instance numbers are now represented by 32-bit numbers (UDINT) to accommodate the four data set ranges represented by 16-bit numbers each.

### 9.5.3.1.3 Additional Objects

Volume 7 defines two additional objects that are found only on Modbus devices, the Modbus Object, and the Modbus Serial Link Object.

**9.5.3.1.3.1 Modbus Object (Class ID: 0x44)** The Modbus Object provides an interface to Modbus data existing in a CIP device. Within a CIP to Modbus translator, the Modbus object provides an interface to the data and functions within a target Modbus device.

No Instance Attributes are defined for this object; instead, the Modbus Object defines services that mirror Modbus Function Codes along with their associated address data.

**9.5.3.1.3.2 Modbus Serial Link Object (Class ID: 0x46)** The Modbus Serial Link Object is used for configuration of a Modbus serial data communication channel and includes link-specific counters and status information for the port. Each instance of this object represents the client portion of a Modbus serial channel, which allows the Modbus translator to read/write data with external Modbus serial servers.

### 9.5.3.2 Integration of IO-Link into CIP

IO-Link, standardized as IEC 61131-9, is a communication standard that extends the 24 VDC I/O interface of IEC 61131-2 [3] to allow serial communication between I/O devices (IO-Link Masters) and sensors and actuators (IO-Link Devices).

An ODVA SIG, established in fall 2012, is currently working on the definition of the integration of IO-Link Masters and Devices into CIP. The completion of this work is expected for late 2014/early 2015.

## 9.5.4 CIP Energy

The optimization of energy usage is a natural expansion of ODVA's application coverage for industrial automation. The objects that support this functionality were added to Volume 1 of the CIP Networks Library in Edition 3.12. The management of energy usage methodology described in the specification defines a set of standard attributes, services, and behaviors that will facilitate the reporting of industrial devices' use of operational energy and the control of industrial devices into and out of nonoperational energy conserving states.

Four objects have been defined as of the publication of this text. A *Base Energy Application Object* standardizes access to the most basic data and services common to the various energy resources used in industry. The Base Energy Object also provides the means to aggregate energy information at various levels of the enterprise and present these data consistently at all levels: from the asset level at the bottom of the energy usage tree, up through the machine and process level to the system level, and ultimately to the production and enterprise domains. Two resource type application objects are defined. An *Electrical Energy Object* provides electrical energy data reporting capabilities and diagnostics for the electrical energy consumers and producers found within the various levels of an industrial facility. A *Nonelectrical Energy Object* provides unified reporting of energy consumption and production of nonelectrical energy data such as gas and steam. A *Power Management Object* provides standardized attributes and services to support the control of devices into and out of paused or sleep states. An overview of these objects in the overall construct of CIP is shown in Figure 9.65.

What follows is a brief introduction to the objects involved in CIP Energy. More information can be found in Refs. [58,59].

### 9.5.4.1 Additional Objects

Four additional objects have been defined for energy management so far, the Base Energy Object, the Electrical Energy Object, the Nonelectrical Energy Object, and the Power Management Object.

#### 9.5.4.1.1 Base Energy Object (Class ID: 0x4E)

The Base Energy Object acts as an *Energy Supervisor* for energy implementations in CIP. It provides energy mode services and can provide aggregation services for aggregating energy values up through the

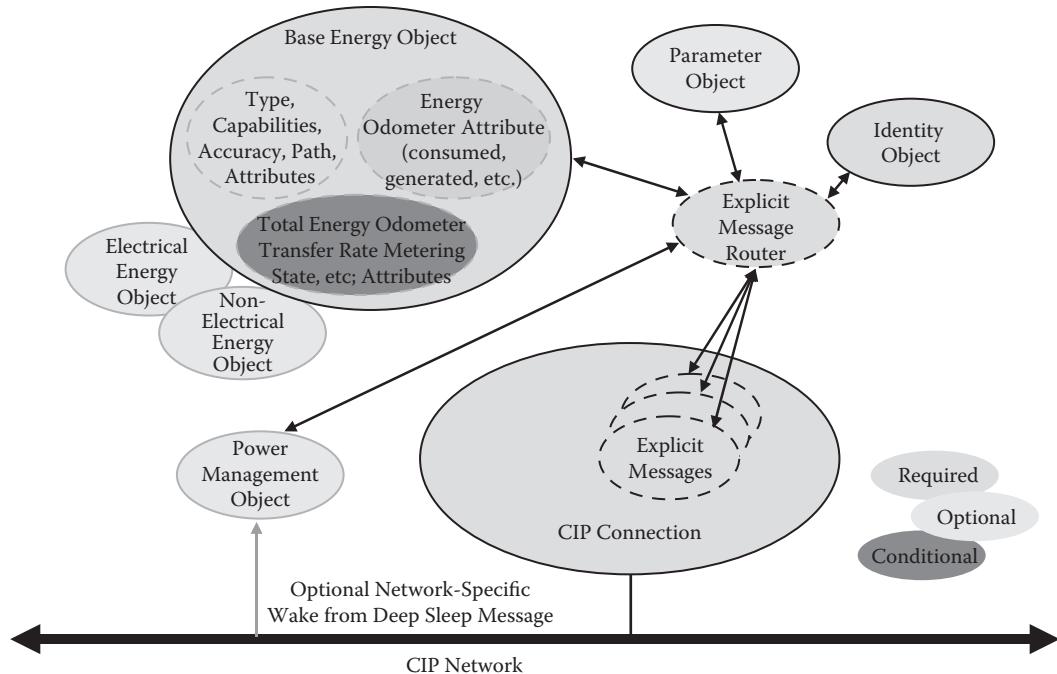

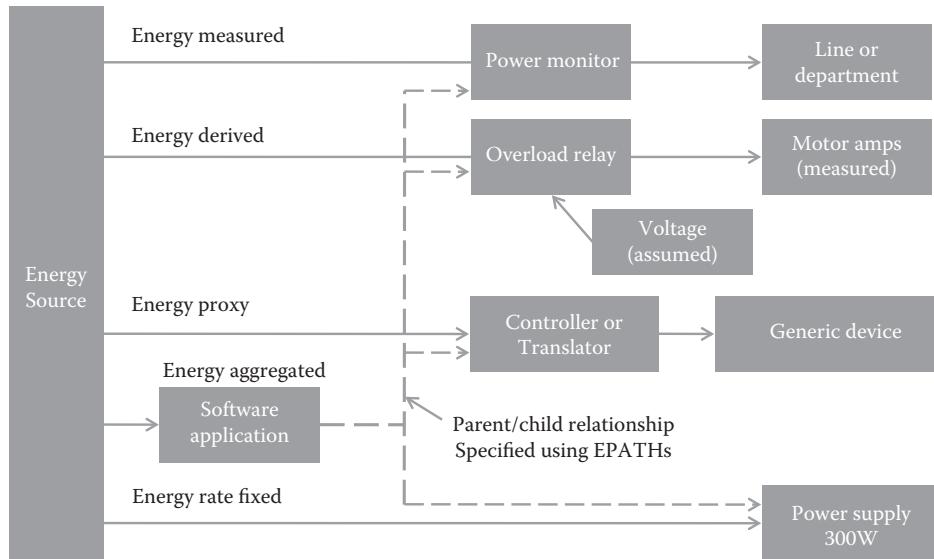

FIGURE 9.65 CIP Energy Objects.

various levels of an industrial facility. It also provides a standard format for reporting energy metering results. The object is independent of the energy type and allows data and functionality specific to the energy type to be integrated into an energy system in a standard way.

Multiple instances of the Base Energy Object may exist in a device. For instance, an electric power monitor may count metering pulse output transitions of a separate metering device. The count of such transitions, represented by a Base Energy Object instance, would reflect the energy consumption measured by the separate device. As another example, a device may act as a proxy for the energy consumed by a number of simple devices, where each device is associated with a separate instance of the Base Energy Object. An instance of the Base Energy Object may exist as a stand-alone instance, or it may exist in conjunction with an instance of either the Electrical Energy Object or the Nonelectrical Energy Object. If an instance of either the Electrical or Nonelectrical Energy Object is implemented in a device, it must be associated with a Base Energy Object instance in the device (i.e., it is a child of the Base Energy Object instance).

The object definition allows for creating five types of devices: Energy Measured, Energy Derived, Energy Proxy, Energy Rate Fixed, and Energy Aggregated devices.

- Energy Measured devices are devices such as a power monitor that measures voltage, current, phase angle, etc., and calculates power and energy.
- Energy Derived devices are devices such as an overload relay that measures motor current, assumes a value of motor voltage, and then derives the value of power and energy.
- Energy Proxy devices are devices such as a controller with discrete outputs that control external devices, each of which has an associated user-provided energy transfer rate that the controller uses to calculate the energy used based on the state of the output.
- Energy Rate Fixed devices are simple devices that report a nominal or user-defined energy value when operating and zero when in a nonoperating state.
- Energy Aggregated devices are devices that can collect energy usage of *child* devices and report them together as an aggregate value.

**FIGURE 9.66** Types of energy-related devices.

Array [4]	Array [3]	Array [2]	Array [1]	Array [0]
Terawatt-hours (kW h × 10 <sup>9</sup> )	Gigawatt-hours (kW h × 10 <sup>6</sup> )	Megawatt-hours (kW h × 10 <sup>3</sup> )	Kilowatt-hours (kW h)	Watt-hours (kW h × 10 <sup>-3</sup> )

**FIGURE 9.67** Energy Odometer

Figure 9.66 illustrates these devices.

Energy Odometers are defined to report large amounts of energy usage in a manner similar to a car odometer or a typical power meter on a residential home. The values are in multiples of kilowatt-hours as shown in Figure 9.67:

The Base Energy object may contain information about Electrical and Nonelectrical Energy object instances that it refers to, or it may be a stand-alone instance with no children.

#### 9.5.4.1.2 Electrical Energy Object (Class ID: 0x4F)

The Electrical Energy Object provides unified electrical energy-specific data reporting and diagnostics for the CIP-enabled devices and processes found within the various levels of an industrial facility. Energy management is typically related to the measurement and reporting of a variety of metering results. This object provides for the consistent reporting of electrical energy data. Electrical energy is organized in a separate object to accommodate its alternating and poly-phase characteristics, which result in a collection of attributes that are unique among energy sources.

Using the Electrical Energy Object in association with an instance of the Base Energy Object (via the Associated Base Energy Object Path, Attribute 41) provides a comprehensive approach to reporting usage of electrical energy in a consistent and open fashion.

#### 9.5.4.2 Nonelectrical Energy Object (Class ID: 0x50)

The Nonelectrical Energy Object provides unified nonelectrical energy-specific data reporting and diagnostics for the CIP-enabled devices and processes found within the various levels of an industrial facility. Energy management is typically related to the measurement and reporting of a variety of metering results. This object provides for the consistent reporting of nonelectrical energy data, including, without limitation, natural gas, fuel oil, steam, compressed air, hot water, and chilled water.

Using the Nonelectrical Energy Object in association with an instance of the Base Energy Object (via the Associated Base Energy Object Path, Attribute 41) provides a comprehensive approach to reporting usage of nonelectrical energy in a consistent and open fashion.

#### 9.5.4.3 Power Management Object (Class ID: 0x53)

The Power Management Object provides standardized attributes and services to support the control of devices into and out of paused or sleeping states. A device supporting the Power Management Object can transition between various energy-related states. A Power Management service and optional adaptation-specific sleep mechanisms are used to control entry into and exit from energy-saving states. Within the paused states, a device may have multiple internal energy-saving modes, each with a different power consumption level.

There are six basic energy-related states for CIP Power Management-capable devices:

1. Power Off.
2. Not Owned—Device is operational, but no client *owns* the Power\_Management service of the device.
3. Owned—The device is operational, and a client *owns* the Power\_Management service of the device.
4. Paused—Energy-saving state; CIP communication continues.
5. Sleeping—Energy-saving state; CIP communication is suspended.
6. Resuming—Device is transitioning from Paused to Owned.

Within a particular power management state, a device's operational capabilities and power levels may remain in transition for a time until the agreed power usage level is attained.

## 9.6 Conformance Testing

---

Open specifications, such as those managed by ODVA, both provide vendors with the ability to build products that will interoperate with products from other vendors and allow users to choose products that will interoperate in multivendor systems by ensuring a common network interface for given device types. In order to achieve interoperability of devices from multiple vendors, product compliance with these open specifications is essential.

ODVA drives product compliance with the CIP Network Specifications primarily in two ways. First, each vendor is required to sign a Terms of Usage Agreement for the ODVA technology or technologies, for which they intend to make, have made, sell, or have sold products. In signing this agreement, the vendor agrees to comply with the network technology specification and meet a set of user responsibilities, including the conformance testing of developed and/or sold products. A list of authorized vendors can be found on the ODVA website.

Second, ODVA administers a vendor-independent conformance testing process. The goal of the ODVA conformance testing process is to help to ensure, to the greatest extent practicable, that products implementing ODVA technologies and standards comply with the ODVA specifications and interoperate in multivendor systems.

A cornerstone of this process is the successful completion of the ODVA conformance test at an ODVA-authorized test service provider (TSP). A full list of ODVA-authorized TSPs can be found on the ODVA website. TSPs perform conformance tests that are designed, developed, and managed by ODVA and conduct the tests in accordance with ODVA test requirements and procedures. ODVA TSPs must meet certain standards, including vendor independence, neutrality, and technical competency in networks and testing practices. The ODVA conformance test is typically a composite test comprised of three parts:

1. An automated software test that verifies the function of the network protocol. Depending on the complexity of the device, several thousand messages are transmitted to the device under test (DUT). To ensure a test that is closely adapted to the characteristics of the DUT, the manufacturer must provide a formal description of all relevant CIP features of the DUT.

2. A hardware test that examines the characteristics of the physical layer for conformance. Physical layer tests vary by network and may include product labeling, indicator operation, isolation, connectors, mis-wiring, voltage ranges, timing, etc.
3. An interoperability test that exercises the product using prescribed test scenarios designed to demonstrate the successful interoperability of the product in multivendor systems.

The automated conformance test software is a Windows®-based tool that uses a network interface card in the PC to access the DUT. It is recommended that device developers run this test in their own lab before taking devices to a TSP. The hardware test (where appropriate) and the system interoperability test involve more complex test setups that typically are not available to device developers but are documented in the test plans or other ODVA publications. The vendor of the product may, at its option, observe the test at the TSP.

As of 2013, the range of composite conformance tests available from ODVA included those for DeviceNet, ControlNet, EtherNet/IP, and CompoNet devices or family of devices as listed in the following text:

#### CIP Safety Nodes

- CIP Safety on DeviceNet
- CIP Safety on EtherNet/IP

#### CIP Nodes

- CompoNet Master
- CompoNet Slave
- ControlNet I/O Scanner
- ControlNet I/O Adapter
- DeviceNet Node
- DeviceNet Embedded Technologies
- EtherNet/IP Node
- EtherNet/IP Embedded Technologies

#### Infrastructure Devices

- CompoNet Repeater
- DeviceNet Power Supply

Upon the product's successful completion of the test, the TSP submits the test results to ODVA for review and final approval. Contingent on passing results from the conformance tests and other requirements of ODVA, ODVA issues a Declaration of Conformity for the product. Declarations of Conformity are posted on ODVA's website at [www.odva.org](http://www.odva.org).

Adjunct tests are also available from the ODVA headquarters' TSP. These adjunct tests require that the device submitted for additional testing passes the appropriate conformance test first. Adjunct tests include

- DeviceNet Semiconductor Industry (test is in addition to DeviceNet Node test)
- EtherNet/IP performance test

Passing adjunct test results are listed on the Declaration of Conformity for the device or device family.

Products that have received an official Declaration of Conformity from ODVA earn the right to use ODVA's CONFORMANCE TESTED certification marks as appropriate for the network connectivity of the product. (Refer to the ODVA Identity Guidelines on the ODVA website for more information on logo usage.) End users should check the ODVA website under *Product Compliance* for the list of ODVA-issued Declarations of Conformity or look for one of the following marks on a product (Figure 9.68).

	DeviceNet CONFORMANCE TESTED®
	EtherNet/IP CONFORMANCE TESTED™
	CompoNet CONFORMANCE TESTED™
	ControlNet CONFORMANCE TESTED™
	CIP Safety on DeviceNet CONFORMANCE TESTED™
	CIP Safety on EtherNet/IP CONFORMANCE TESTED™

FIGURE 9.68 Conformance test marks.

## Abbreviations

For the purposes of this chapter, the following abbreviations apply:

Abbreviation	Meaning
ASCII	American Standard Code for Information Interchange
CIP	The Common Industrial Protocol defined by Volume 1 of the CIP Networks Library
CID	Connection Identifier
EPR	Expected Packet Rate
ISO	International Standards Organization
MAC ID	Media Access Control Identifier (another name for Network Address)
OSI	Open Systems Interconnection (see ISO 7498)
UCMM	Unconnected Message Manager
CRC	Cyclic Redundancy Check
LED	Light Emitting Diode
MAC	Media Access Control sublayer
NAP	Network Access Port
NUT	Network Update Time
RG-6	Standard for coaxial cable
SMAX	MAC ID of the maximum scheduled node
UMAX	MAC ID of the maximum unscheduled node
FTP	File Transfer Protocol. An Internet application that uses TCP reliable packet transfer to move files between different nodes
RFC	Request For Comments (RFCs)—This document series, which was launched in 1969, describes the Internet suite of protocols and related experiments. Not all (in fact, very few) RFCs describe the Internet Standards, but all Internet Standards are written up as RFCs. The RFC series is unusual in that the proposed protocols are forwarded by the Internet research and development community, acting on their own behalf, as opposed to the formally reviewed and standardized protocols that are promoted by organizations such as CCITT and ANSI [60].
TCP	Transmission Control Protocol (TCP)—An Internet Standard transport layer protocol defined in STD 7, RFC 793. It is connection oriented and stream oriented, as opposed to UDP. See also: connection-oriented, stream-oriented, User Datagram Protocol [60].
UDP	User Datagram Protocol (UDP)—An Internet Standard transport layer protocol defined in STD 6, RFC 768. It is a connectionless protocol that adds a level of reliability and multiplexing to IP. See also: connectionless, Transmission Control Protocol [60].

## Terminology

For the purposes of this document, the following definitions apply:

Term	Definition
Allocate	In the DeviceNet context, this is the process of reserving resources of the Predefined Master Slave Connection Set in a DeviceNet node. It is associated with services of a similar name, of the DeviceNet Object Class (Class ID 0x03).
Application	Typically refers to the application layer of the ISO-OSI model. The application layer is the part of the product that performs application-specific functions. Typically, application objects that provide the desired behavior are associated with the application.
Attribute	A description of an externally visible characteristic or feature of an object. The attributes of an object contain information about variable portions of an object. Typically, they provide status information or govern the operation of an object. Attributes also may affect the behavior of an object. Attributes are divided into Class Attributes and Instance Attributes.
Behavior	Indication of how the object responds to particular events. Its description includes the relationship between attribute values and services.
Bit	A unit of information consisting of a 1 or a 0. This is the smallest data unit that can be transmitted.
Broadcast	A message that is sent to all nodes on a network. It also refers to the property of a network where all nodes listen to all messages transmitted for purposes of determining bus access/priority.
Byte	A sequence of 8 bits that is treated as a single unit.
Class	A set of objects, all of which represent a similar system component. A class is a generalization of the object, a template for defining variables and methods. All objects in a class are identical in form and behavior, but they may contain different attribute values.
Object-specific service	A service defined by a particular object class to perform a required function that is not performed by any common services. A class-specific service is unique to the object class that defines it.
Client	1. An object that uses the services of another (server) object to perform a task. 2. An initiator of a message to which a server reacts.
Connection	A logical binding between two application objects. These application objects may be the same or different devices.
Connection Identifier	Identifier assigned to a transmission that is associated with a particular connection between producers and consumers that identifies a specific piece of application information.
Connection path	Is made up of a byte stream that defines the application object to which a connection instance applies.
Consumer	A node that is receiving (i.e., consumes) data from a producer.
Consuming application	The application that consumes data.
CRC error	Error that occurs when the cyclic redundancy check (CRC) value does not match the value generated by the transmitter.
Cyclic	Term used to describe events that repeat in a regular and repetitive manner.
Datagram	A transmitted message.
Device	A physical hardware connection to the link. A device may contain more than one node.

Device Profile	A collection of device-dependent information and functionality providing consistency between similar devices of the same device type.
Drop or drop line	The cable that connects one or more nodes to a trunk cable, usually accomplished using a tap.
Encapsulation	The technique used by layered protocols in which a layer adds header information to the protocol data unit (PDU) from the layer above for purposes of carrying one protocol within another.
Ethernet	A standard for LANs, initially developed by Xerox, and later refined by Digital, Intel, and Xerox (DIX). In its original form, all hosts are connected to a coaxial cable, where they contend for network access using a Carrier Sense Multiple Access with Collision Detection (CSMA/CD) paradigm. See also IEEE 802.3, Local Area Network [60].
Expected Packet Rate	A misnomer, the Expected Packet Rate (EPR) is basic interval at which a connection transmits its data.
Fixed tag	A two-byte field in a ControlNet Lpacket that identifies unconnected or station management services the node is expected to perform. The first byte is the specific service code, and the second byte contains the MAC ID of the destination node.
Frame	See MAC Frame.
Generic tag	A three-byte field in a ControlNet Lpacket that serves as the Connection Identifier (CID). It is associated with a specific piece of application information.
Guardband	It is the portion of ControlNet bandwidth that is allocated for the transmission of the moderator frame.
Instance	The actual physical presentation of an object within a class. Identifies one of potentially many objects within the same object class.
Keeper	Object responsible for holding and distributing the Connection Originator schedule data for all Connection Originator devices on a ControlNet Network.
Link or Data Link	Refers to the Data Link layer of the ISO/OSI model.
Lpacket	On ControlNet, the Lpacket (or link packet) is a portion of the MAC Frame where application information that contains a size, control byte, tag, and link data is transmitted. There may be one or more Lpackets in a single MAC Frame.
MAC frame	A collection of MAC symbols transmitted on the network medium that contains the required message formatting/framing necessary to pass a message to another node. For example, a ControlNet MAC Frame consists of a preamble, start delimiter, source MAC ID, Lpackets, CRC, and end delimiter.
Message Router	The object within a node that distributes Explicit Message requests to the appropriate application objects.
Multicast	A packet that is sent to multiple nodes on the network.
Network	A series of nodes connected by some type of communication medium. The connection paths between any pair of nodes can include repeaters and bridges.
Network Access Port	On ControlNet, this is an alternate physical layer connection point on a permanent node that allows a temporary node to be connected to the link. The temporary node has its own network address, but simply shares the permanent node's physical layer connection to the network.
Network address	An integer identification value assigned to each node on a CIP Network.

Network status indicators	Indicators (i.e., LEDs) on a node indicating the status of the Physical and Data Link Layers.
Network Update Time	Repetitive time interval on a ControlNet Network that is used to subdivide the network bandwidth. It determines the fastest rate that real-time data can be transferred on the network.
Node Object	<p>A connection to a link that requires a single MAC ID.</p> <p>1. An abstract representation of a particular component within a product. Objects can be composed of any or all of the following components:</p> <ul style="list-style-type: none"> <li>(a) Data (information which changes with time)</li> <li>(b) Configuration (parameters for behavior)</li> <li>(c) Methods (things that can be done using data and configuration)</li> </ul> <p>2. A collection of related data (in the form of variables) and methods (procedures) for operating on that data that have clearly defined interface and behavior</p>
Object-specific service	A service defined by a particular object class to perform a required function that is not performed by one of the common services. An object-specific service is unique to the object class that defines it.
Originator	The client responsible for establishing a connection path to the target.
Point-to-point Port	A one-to-one data exchange relationship between two, and only two nodes.
Producer	A CIP port is the abstraction for a physical network connection to a CIP device. A CIP device has one port for each network connection. Within the EtherNet/IP specific context, a TCP or UDP port is a transport layer demultiplexing value. Each application has a unique port number associated with it [60].
Redundant media	A node that is responsible for transmitting data.
Repeater	A system using more than one medium to help prevent communication failures.
Scheduled	Two-port active Physical Layer device that reconstructs and retransmits all traffic on one segment to another segment.
Segment	On ControlNet, these are data transfers that occur in a deterministic and repeatable manner, on preconfigured NUT-based intervals.
Serial Number	This term has two uses within CIP. With respect to cable topology, a segment is a length of cable connected via taps with terminators at each end; a segment has no active components and does not include repeaters. With respect to explicit messaging, segments (Logical Segments, Port Segments, etc.) are used in Explicit Messages to describe various addressing elements of devices such as Class IDs, Attribute IDs, ports, Connection Points, etc.
Server	A unique 32-bit integer assigned by each manufacturer to every device. The number needs to be unique only with respect to the manufacturer.
Service	A device or object that provides services to another device (the client).
Tap	Operation or function that an object performs upon request from another object.
Target	Point of attachment on the trunk where one or more drop lines are attached.
Terminator	The end node to which a connection is established.
Transceiver	A resistor placed at the physical extreme ends of trunk segments to prevent transmission reflections from occurring.
Trunk or trunkline	The physical component within a node that provides transmission and reception of signals onto and off of the medium.

Unconnected Message Manager	The function within a node that transmits and receives Unconnected Explicit Messages.
Unscheduled	On ControlNet, this refers to data transfers that use the unscheduled portion of the NUT.

### 10.1 Overview

---

#### 10.1.1 History

The Modbus™ protocol was created in 1978 by Modicon Inc. as a simple way for communicating control data between controllers and sensors using an RS232 port.

The protocol became widely adopted, quickly reaching the status of de facto standard in the industrial automation field. Today, the Modbus protocol is the single, most supported protocol among automation devices.

Schneider Electric transferred the specifications for Modbus and Modbus/TCP (Modbus over TCP/IP) to Modbus.org. See the web-based community [www.Modbus.org](http://www.Modbus.org).

### 10.1.2 Premise

The material presented in this chapter does not contain all the details of the Modbus protocol. The authoritative specifications are publicly available and can be found at the web-based community [www.Modbus.org](http://www.Modbus.org).

### 10.1.3 General

Modbus is an application layer messaging, protocol placed at OSI layer 7, for client/server communication between devices connected on different types of buses or networks. Figure 10.1 shows the messaging between one client and one server and the conventional names given to the messages at the source and the destination.

Modbus is currently transported using any of the following underlying layers:

- RS232, RS422, RS485
- TCP/IP
- Modbus Plus, a token-passing network
- Many other stacks over a variety of media (e.g., fiber, radio, cellular)

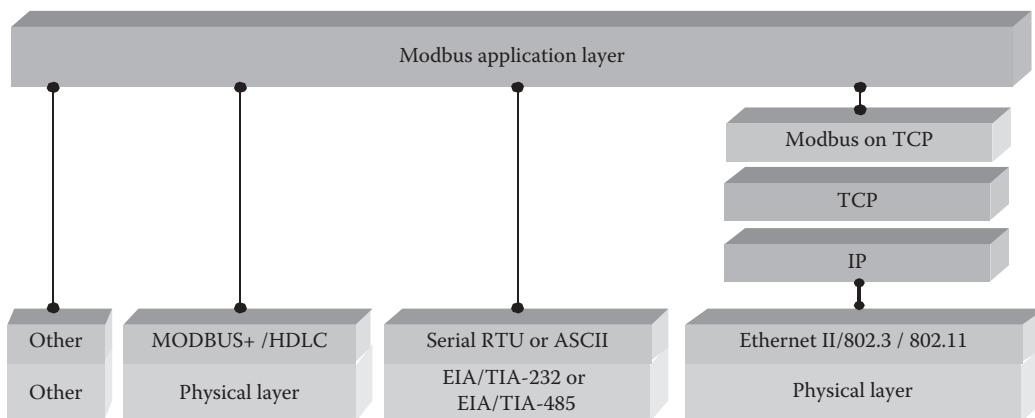

This is shown in Figure 10.2.

A network example is illustrated in Figure 10.3; gateways are used to connect the underlying layers, HMIs are human-machine interface stations, and PLCs are programmable logic controllers.

The Modbus messaging/transaction takes place exchanging application protocol data units ([APDUs] described later). While the APDU is the same for all underlying layers, the client/server mechanism employed by Modbus takes full advantage of the different possibilities offered by the currently used underlying layer (one to one, one to many, error checking, pipelining, etc.).

**FIGURE 10.1** Client–server messaging.

**FIGURE 10.2** Modbus communication stacks.

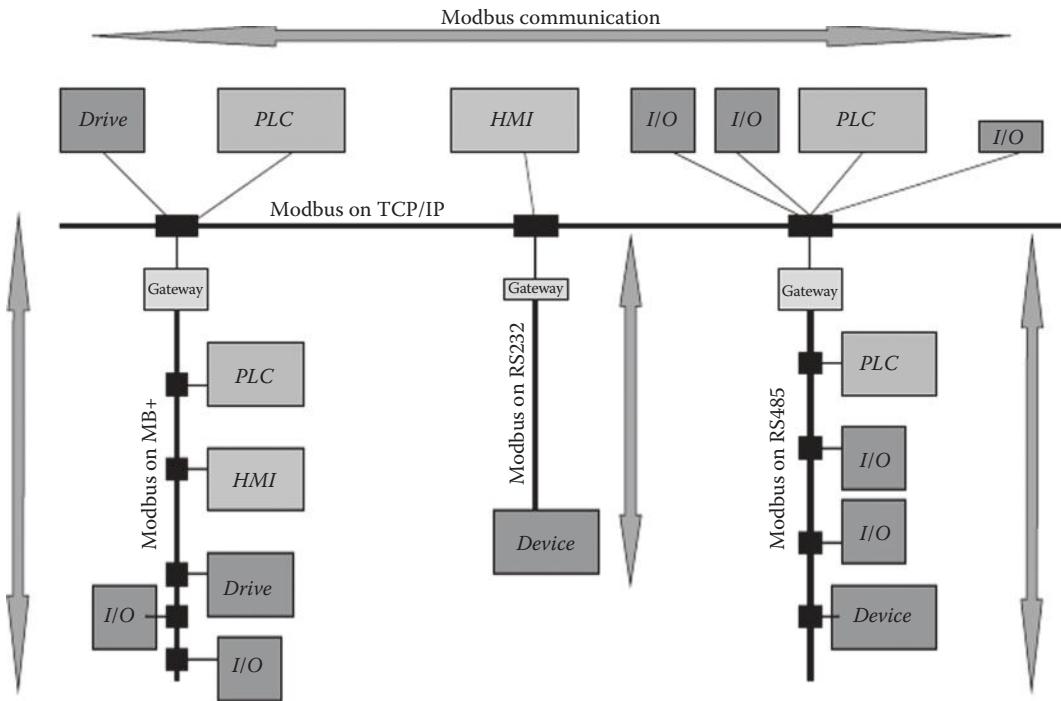

FIGURE 10.3 Example of Modbus network.

#### 10.1.4 Features

The popularity of Modbus stems from a commitment to simplicity, recognizing that industrial automation applications are the most diverse and that there are advantages in delegating the handling of diversity to the applications.

Some features are as follows:

- Simple to implement
  - Can be implemented in days
- Small footprint
  - Can run on any computer system, CPU, or microcontroller, allowing the networking of simple devices
- Scalable in complexity, scope, and range
  - Complexity: A device that has only a simple purpose needs only to implement the needed message types.
  - Scope: From real-time sensing to production data.
  - Range: A collection of devices using Modbus/TCP to communicate can range up to 10,000 or more on a single switched Ethernet network.
- It is simple to administer and enhance
  - There is no need to use complex configuration tools when adding a new node to a network.
- Open and low cost
  - The specifications are freely downloadable from the [www.Modbus.org](http://www.Modbus.org) website.
  - In addition to being a de facto standard, it has been standardized by the International Electrotechnical Commission (IEC), the Standardization Administration of China (SAC), and relevant parts by the Semiconductor Equipment and Materials International (SEMI) association.

- For most Modbus underlying layers, these layers—hardware and software—are commercially available (RS232, RS422, RS485, TCP/IP) with economy of scale, and they are already present at no extra cost to device vendors as part of the standard compendium of the devices.
- There is no vendor-proprietary equipment or software needed, and since there is no need to modify the underlying commercial standard layers, the protocol can readily take advantage of any improvements in those layers.
- Connectivity
  - It is very easy to build Modbus networks made of different underlying layers, via widely available flexible gateways.
- Installed base, experience, and tools
  - The installed base of Modbus devices is substantial, so is the experience in their deployment and the availability of monitoring/debugging tools.

## 10.2 Modbus Protocol

---

### 10.2.1 Protocol in the Abstract

This section will describe the full protocol and its client/server behavior in the abstract, with no particular instantiation of the layers. The most widely used instantiations, Modbus over serial line and Modbus/TCP, will be described in subsequent sections.

The material presented in this section does not contain all the details of the Modbus protocol. The authoritative specifications are publicly available and can be found at the web-based community [www.Modbus.org](http://www.Modbus.org).

### 10.2.2 Client/Server in General

The transfer of information between a Modbus client and a Modbus server is initiated when the client sends a request to the server to transfer information, to execute a command, or to perform one of many other possible functions.

After the server receives the request, it executes the command and/or prepares the required data. The server then responds to the client by acknowledging that the command is complete and/or providing the requested data.

The system response time is limited by two main factors: the time required for the client to send the request/receive the response and the ability of the server to answer within a specific amount of time.

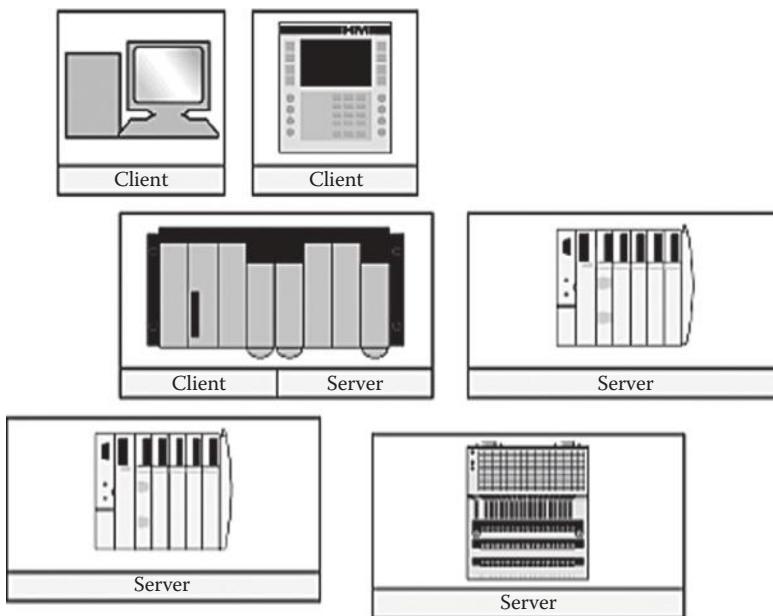

A device may implement a Modbus client service, a Modbus server service, or both, depending on the requirements of the device and in some cases on the particular Modbus underlying layer (e.g., in Modbus Plus, both services are always present at the same Modbus address/node, and the client or server role is directed by a token-passing mechanism).

Depending on the underlying layer, a client may be able to initiate Modbus messaging requests to one or more servers, and a server may be able to respond to requests received from one or more clients. These possibilities will be detailed later when the different transport mechanism/underlying layers will be discussed; the distinction between the various cases is not relevant at this time, since the Modbus application protocol is the same in all cases.

A typical HMI or SCADA application implements a client service to initiate communications with PLCs and other devices for information gathering. An I/O device implements a server service so that other devices can read and write its I/O values. Because this I/O device does not need to initiate communications, it does not implement a client service.

A PLC typically implements both client and server services so that it can initiate communications to other PLCs and I/O devices and can respond to requests from other PLCs, SCADA, HMIs, and other devices.

Figure 10.4 illustrates the preceding discussion.

**FIGURE 10.4** Clients, servers, and their possible colocation.

#### 10.2.2.1 Modbus Client Service

A device that implements the Modbus client service can initiate Modbus messaging requests to another device that implements a Modbus server. These requests allow the client to transact data with and/or send commands to the remote device.

#### 10.2.2.2 Modbus Server Service

A device that implements the Modbus server service can respond to requests from any Modbus client. The Modbus server service allows a device to make all its internal and I/O data available to remote devices for both reading and writing and allows for the execution of other commands.

#### 10.2.2.3 Specialized Client and Server Services

There are many devices on the market that package together useful Modbus functionality and make it available via easy configuration. One of them is a sophisticated client known as *scanner*; it allows to configure and execute repetitively read/writes of Modbus networked field devices, with handling of retries, all in an optimized fashion. These devices are applications of the protocol and provide higher-level services.

#### 10.2.2.4 Client and Server Messages

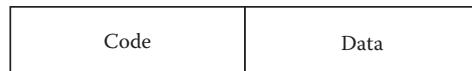

The messages exchanged by Modbus client and server services are defined by a structure called APDU, described in the next clause.

### 10.2.3 Application Protocol Data Unit

#### 10.2.3.1 Structure

While the Modbus application protocol payload, also known as Modbus protocol data unit (PDU), is made of two fields, the code and the data fields, as shown in Figure 10.5, it is convenient to describe the protocol considering at the same time also the unit identifier (ID) field. The aggregate structure is called Modbus APDU, and it is shown in Figure 10.6.

The reason for considering the APDU is that it is common across the various Modbus transports.

**FIGURE 10.5** Modbus PDU format.

**FIGURE 10.6** Modbus APDU format.

### 10.2.3.2 Unit ID Field

Server devices are addressed using a unit ID. This ID is assigned to servers, not to clients.

Depending on the underlying transport, the unit ID may represent the full address or just a part of a segmented address leading to a server. In the latter case, the other parts are represented in the transport mechanism. The address needs to be unique across all the servers addressable by a client. In case the unit ID is just a part of a segmented address, then the unit ID assigned to a server has to be unique within that segment.

The unit ID field size is 1 octet.

Not all unit ID values represent addresses; some values of the unit ID have a special meaning, as described in Table 10.1.

A request with a unit ID field set to broadcast is sent to all the servers in the address space of that unit ID. A broadcast request does not have a response. The broadcast mode of communication will be detailed later.

In all allowed cases but the broadcast—which does not have a response—the unit ID field value in the response is the unit ID value of the addressed server (i.e., the unit ID is echoed back).

A unit ID value of 255 is a flag indicating that the server address is being fully specified by the transport. This flag is used in two situations:

1. When the server is already fully identified via the addressing in the transport layer and there is no interest in assigning to it a dedicated unit ID
2. When the server, already fully identified via the addressing in the transport layer, is actually a gateway and the service is being requested locally to the gateway itself

Both situations will be clearer when discussing transport layers and gateways.

### 10.2.3.3 Code Field

The code field accommodates the encoding of the service asked to the server when in a request and signals the success or failure of the requested service in a response (excluding the broadcast case that does not have a response).

Function codes are the encodings used to indicate the requested services; they have selected values in the 0x01–0x7F range; 0x00 is invalid and 0x80–0xFF are reserved for the exception mechanism, as described in the following. The function code encodings will be discussed later.

The success of a function code processing is signaled by echoing the function code value of the request in the same code field in the response.

**TABLE 10.1** Unit ID Field

Broadcast	Server Addressing	Reserved	Address Fully Determined by Next Layer
0	From 1 to 247	From 248 to 254	255

**TABLE 10.2** Code Field

Request	Normal Response (Response to Successful Processing)	Exception Response (Response to Unsuccessful Processing)
Function code	Echo function code in request	Exception = OR-ing of 0x80 with function code in request

The failure of a function code processing is signaled by returning the OR-ing of 0x80 with the function code value of the request in the same code field in the response. In this case, the returned value is called an exception.

The code field size is 1 octet. Exceptions are easy to detect as the code field value will have its high bit turned on.

Table 10.2 summarizes the usage of the code field.

#### 10.2.3.4 Data Field

This field contains additional function information when in a request and the results of the function processing when in a response. For successful processing, the contents will be whatever has been requested by the function. For unsuccessful processing, the content will be an exception code.

The data field size is from 0 to 252 octets, depending on the value of the code field.

The maximum size of the data field is dictated by the size inherited from the first Modbus implementation on a serial line network, with an RS485 frame of 256 octets made of unit ID field (1 octet) + code field (1 octet) + data field + cyclical redundancy check (CRC) (2 octets).

#### 10.2.4 Client/Server Interactions

##### 10.2.4.1 General

From a network point of view, the interactions can be of two types:

1. Broadcast (unconfirmed)
2. Unicast (confirmed)

Interactions can succeed or fail due to many reasons. There is a distinction between failures due to communication and failures due to processing; in addition, the failures due to processing return exceptions.

The client issues a request and starts an application-specified time-out.

If the interaction is a broadcast, then the time-out is the so-called turnaround delay and the following will happen:

- No response is expected; the client simply waits for the specified time-out before issuing any other request.

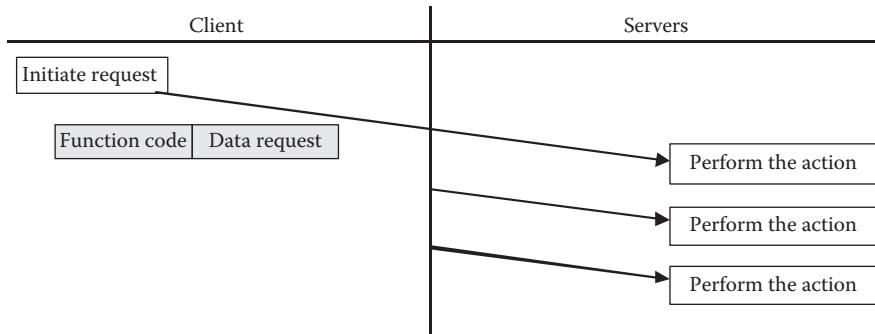

If the interaction is a unicast, then the time-out is the so-called response time-out and one of the following will happen:

- There can be a communication failure, the server never receives the request, and the client eventually times out while waiting for the response.
- The server receives the request, processes it (successfully or not), and issues the response, but then there is a communication failure and the client eventually times out while waiting for the response.
- The server receives the request, processes it successfully, and issues the response, and the response is received within the time-out.
- The server receives the request, processes it unsuccessfully, and issues the response, and the response is received within the time-out.

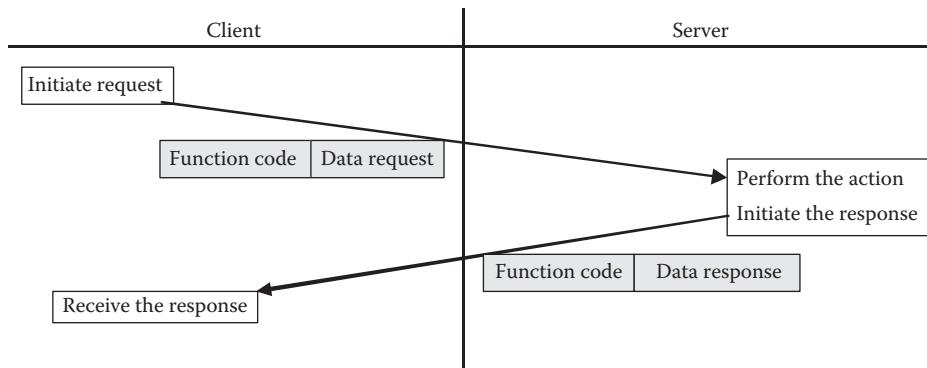

Figure 10.7 shows a broadcast on a network having three servers. Only a subset of the possible actions can be performed via a broadcast, as detailed later, since there is no response.

Figure 10.8 shows a unicast with successful processing, returning a normal response.

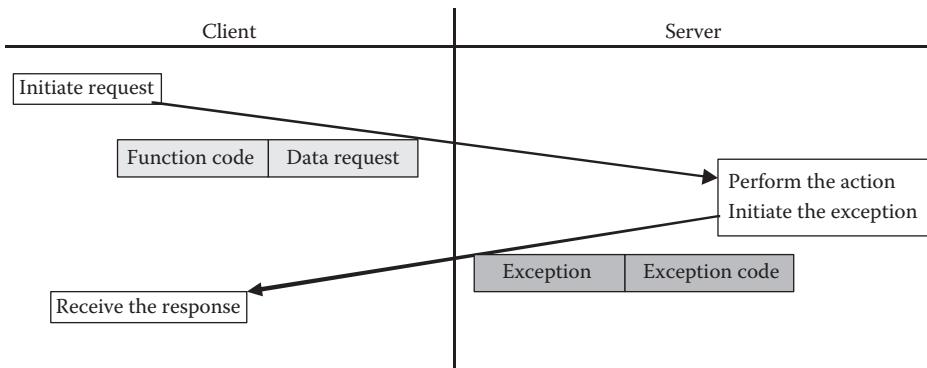

Figure 10.9 shows a unicast with unsuccessful processing, returning an exception response.

**FIGURE 10.7** Broadcast.

**FIGURE 10.8** Unicast with normal response.

**FIGURE 10.9** Unicast with exception response.

### 10.2.4.2 State Machines

From a client and server individual point of view, the aforementioned is illustrated using state machine diagrams, drawn following the UML standard notation as shown in Figure 10.10, with the following semantics: When a *trigger event* occurs in a system being in *State\_A*, that system will transit into *State\_B* only if the *guard condition* is true; upon transiting, the specified action is performed.

The client state diagram is shown in Figure 10.11 and the server state diagram is shown in Figure 10.12. With some underlying layers, the state diagrams get a little more complicated, as there are more possibilities (transaction processing in Modbus/TCP), but the protocol essentials are the same as represented here.

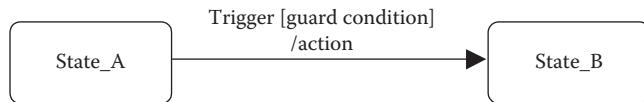

FIGURE 10.10 Syntax of state diagram representation.

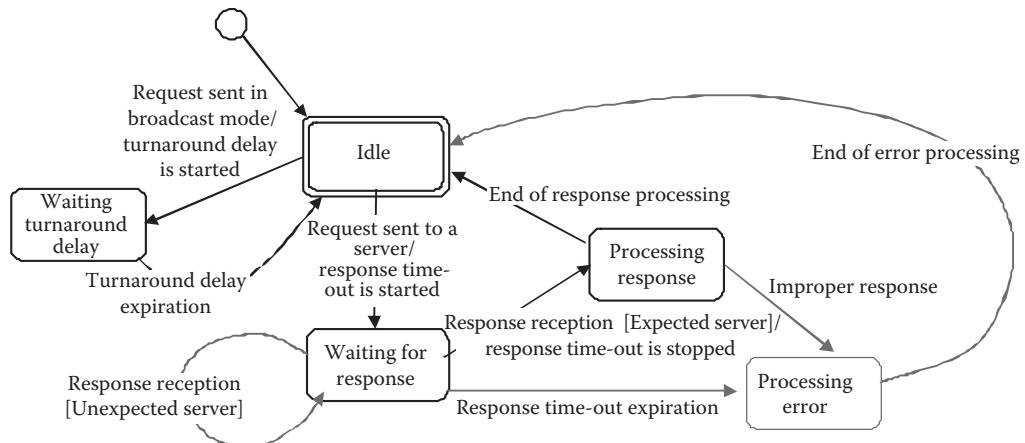

FIGURE 10.11 Client state diagram.

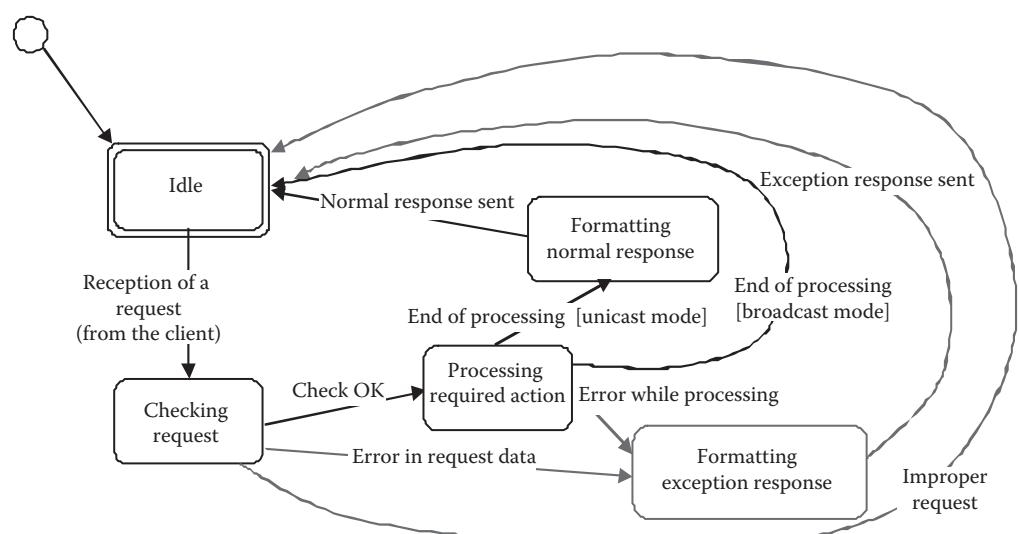

FIGURE 10.12 Server state diagram.

## 10.2.5 Data Types

### 10.2.5.1 Discrete, Coil, Input Register, and Holding Register

The most used Modbus data types are the discrete, coil, input register, and holding register, described in Table 10.3.

### 10.2.5.2 Record and File

The Modbus record and file data types are less known and used only with few function codes.

The Modbus record data type, from an application user (client user) point of view, is a set of contiguous registers of a specified type, characterized by the address of the first register and by the quantity of registers; in the context of this definition, the registers involved have also been called references.

The Modbus file data type is an organization of records, characterized by an unsigned number.

## 10.2.6 Data Models

The distinctions between inputs and outputs, and between bit-addressable and word-addressable data items, do not imply any application behavior. It is perfectly acceptable, and customary, to regard all four tables as overlaying one another, if this is the most natural interpretation on the target machine in question.

Strictly speaking, the data types refer to what is exchanged *on the wire*, and the actual physical or logical model on the device is up to the application, even if often they may map to real tables.

Figures 10.13 and 10.14 give some common but by no means exhaustive interpretations when using actual tables, respectively, as distinct memory tables and overlapping memory tables.

Discretes, coils, input registers, and holding registers are often collectively called data references or data items. For each of the aforementioned data item types, the protocol allows individual selection of 65,536 data items, and the operations of read or write of those items are in quantities dependent on the service function code.

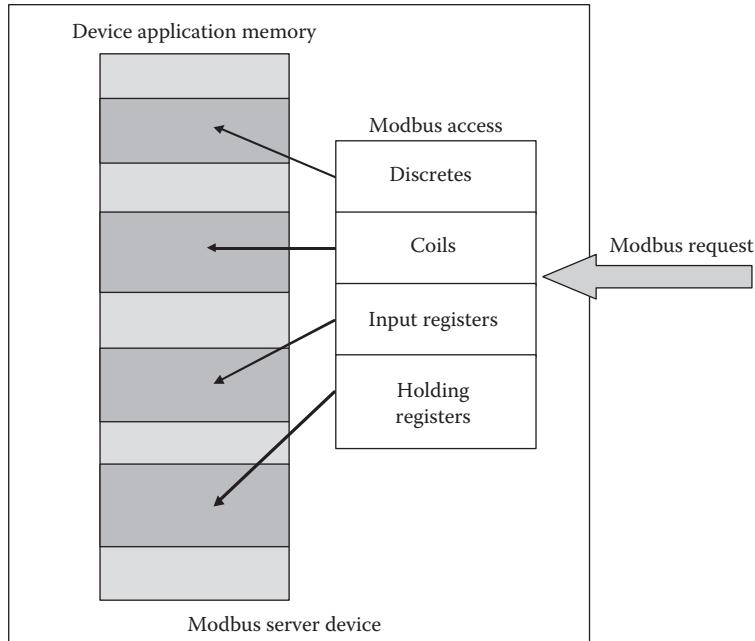

The possible association of client/server data references (bits, registers) and actual physical storage or logical meaning within devices is a local matter.

The meaning of the content of any data reference is entirely up to the application.

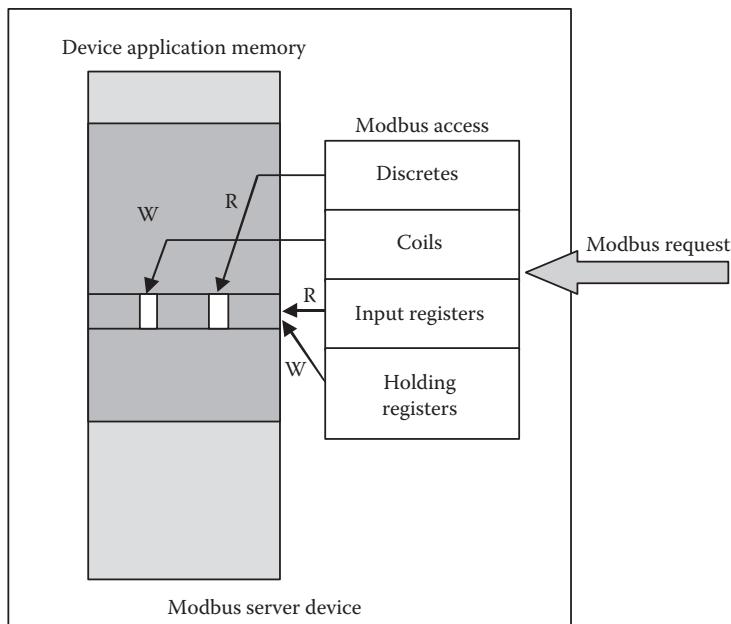

The client/server data reference addresses, used in client/server service function codes, are unsigned integers starting at 0.

**TABLE 10.3** Modbus Primitive Data Types

Modbus Data Type	Raw Data Type	Comment
Discrete	Single bit	Read-only, its value can be provided by an I/O system. This Modbus data type is useful in the modeling of binary-valued real objects that are manipulated by the server application and are supposed to be only observed by the client user. The integrity of the above contract is under control of the server, which can confine the exposure of the real objects to discretes.
Coil	Single bit	Read-write, its value can be altered by a client application program.
Input register	16-bit word	Read-only, its value can be provided by an I/O system. This Modbus data type is useful in the modeling of analog-valued real objects that are manipulated by the server application and are supposed to be only observed by the client user. The integrity of the above contract is under control of the server, which can confine the exposure of the real objects to input registers.
Holding register	16-bit word	Read-write, its value can be altered by a client application program.

**FIGURE 10.13** Interpretation as distinct tables.

**FIGURE 10.14** Interpretation as overlapping tables.

### 10.2.7 Function Code Categories

Client/server service identifiers are commonly called function codes (FCs).

Function codes are encodings of services requested to a server. Some function codes are further specialized by means of a subcode, specified as part of the data field. These encodings are partitioned in three categories, and since the subdivision may propagate to the subcodes, for the sake of completeness, despite being part of the data field, they will also be mentioned here:

*Publicly assigned function codes.* These function codes are either assigned to a standard service or reserved for future assignment. The function codes currently assigned to a standard service will be listed in an upcoming section.

*User-definable function codes.* These function codes can be used for experimentation in a controlled laboratory environment. *They must not be used in an open environment.* There are two ranges: FC 65 (0x41) to 72 (0x48) included and 100 (0x64) to 110 (0x6E) included.

*Reserved function codes.* These function codes are currently used by some companies for legacy products and are not available for public use.

### 10.2.8 Function Codes

The function codes publicly assigned to a standard service are the ones described in Table 10.4. Details can be found in the authoritative specifications publicly available at the web-based community [www.Modbus.org](http://www.Modbus.org).

The Modbus protocol does not mandate the presence of any particular subset of these function codes. A Modbus implementation can have any subset.

The function codes publicly assigned to a standard service are listed in Table 10.4.

### 10.2.9 Exception Codes

Exception codes provide the data field content of exception responses. See Table 10.5.

### 10.2.10 Transmission Order

Data representation *on the wire*: Modbus uses a *big-endian* convention for addresses and data items. This means that when a numerical quantity larger than a single octet is transmitted, the most significant octet is sent first. An example is given as follows:

*Register size, 16 bits; value, 0x1234; then the first octet sent is 0x12 and the second is 0x34.*

Note that the remote terminal unit's (RTU) CRC wants CRC low and CRC high (CRC high is the last octet of the RTU message frame) (see Figure 10.23).

## 10.3 Modbus over Serial Line

---

### 10.3.1 General

This section describes the Modbus protocol over serial line, that is, how the Modbus application protocol, at OSI layer 7, is realized over OSI layers 2 and 1, where layer 1 is a serial line, EIA/TIA-485 (RS485) or EIA/TIA-232 E (RS232).

The material presented in this section does not contain all the details of the Modbus protocol. The authoritative specifications are publicly available and can be found at the web-based community [www.Modbus.org](http://www.Modbus.org).

Most of the discussion of this section will be on layer 2 and its support for the client/server behavior described in the previous section. This stack is shown in Table 10.6.

**TABLE 10.4** Function Codes Publicly Assigned to a Standard Service

Function Code	Description
FC 2 (0x02)	Read discrete.
FC 1 (0x01)	Read coils.
FC 5 (0x05)	Write single coil.
FC 15 (0x0F)	Write multiple coils.
FC 5 (0x05) with unit ID = 0	Broadcast write single coil.
FC 15 (0x0F) with unit ID = 0	Broadcast write multiple coils.
FC 4 (0x04)	Read input registers.
FC 3 (0x03)	Read holding registers.
FC 6 (0x06)	Write single holding register.
FC 16 (0x10)	Write multiple holding registers.
FC 22 (0x16)	Mask write holding register.
FC 23 (0x17)	Read/write holding registers.
FC 24 (0x18)	Read FIFO.
FC 6 (0x06) with unit ID = 0	Broadcast write single holding register.
FC 16 (0x10) with unit ID = 0	Broadcast write multiple holding registers.
FC 20 (0x14)	Read file record.
FC 21 (0x15)	Write file record.
FC/subcode 43 (0x2B)/14 (0x0E)	Read device identification.
FC 7 (0x07)	Read exception status.
FC 8 (0x08)	Diagnostics.
FC 11 (0x0B)	Get com event counter.
FC 12 (0x0C)	Get com event log.
FC 17 (0x11)	Report server ID.
FC/subcode 43 (0x2B)/13 (0x0D)	CANopen general reference request and response PDU. Please see Note 4.

*Note 1:* Function code assignments are managed by the Modbus.org industrial consortium.

*Note 2:* The following function codes, while publicly assigned and described by the Modbus.org specifications, are not covered by the IEC Modbus standardization: FC 7 (0x07, read exception status), FC 8 (0x08, diagnostics), FC 11 (0x0B, get com event counter), FC 12 (0x0C, get com event log), and FC 17 (0x11, report server ID). The applicability of some of these function codes may depend on the underlying layer; please refer to the Modbus.org specifications.

*Note 3:* The following function codes and function code/subcodes are reserved: FC 8/19 (0x08/0x13), FC 8/21-255 (0x08/0x15-0xFFFF), FC 9 (0x09), FC 10 (0x0A), FC 13 (0x0D), FC 14 (0x0E), FC 41 (0x29), FC 42 (0x2A), FC 43/0-12 (0x2B/0x00-0x0C), FC 43/15-255 (0x2B/0xF-0xFF), FC 90 (0x5A), FC 91 (0x5B), FC 125 (0x7D), FC 126 (0x7E), and FC 127 (0x7F).

*Note 4:* The function code FC 43/13 (0x2B/0x0D) is CANopen general reference request and response PDU. Subcode 13 of FC 43 is a Modbus assigned number licensed to CAN in Automation (CiA) for the CANopen General Reference. Please refer to the Modbus.org website or the CiA website for a copy and terms of use that cover function code 43/13. It is not covered by the IEC Modbus standardization.

The network is a serial bus, with only one client at a time on it, by configuration.\* An RS485 network is shown in Figure 10.15 and an RS232 network is shown in Figure 10.16.

The addressing of a server by a client is fully accomplished using the unit ID previously described in Section 10.2.3.2. There can be up to 247 servers on the network; each must have a unique unit ID between 1 and 247. RS232 is a point-to-point network; the unit ID, even if not needed, is still required.

The messaging is performed exchanging APDUs (Figure 10.6, but augmented with error checking as will be shown shortly).

The state machines described in Section 10.2.4.2 are in effect, with a specialization of the *improper response* and *improper request*.

\* In the RS485 case, there could be more than one client on the bus, but something must ensure, at the application above the Modbus protocol, that only one is active at a time, across a complete client/server interaction, the synchronization between the clients may be complicated.

**TABLE 10.5** Exception Codes

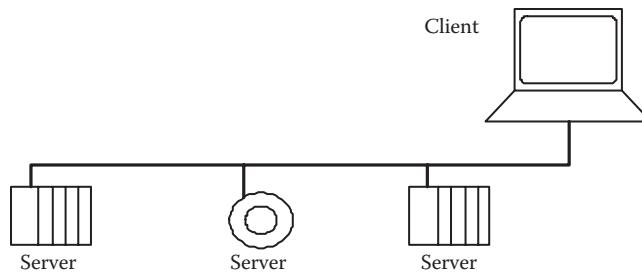

Encoding	Name	Description
0x01	Illegal function	The function code received in the request is not an allowable action for the server. This may be because the function code is only applicable to newer devices and was not implemented in the unit selected. It could also indicate that the server is in the wrong state to process a request of this type, for example, because it is not configured and it is being asked to return register values.
0x02	Illegal data address	The data address received in the request is not an allowable address for the server. More specifically, the combination of reference number and transfer length is invalid. For example, for a controller with 100 registers, a request with offset (data address) 96 and length 4 would succeed, and a request with offset 96 and length 5 would generate exception code 0x02.
0x03	Illegal data value	A value contained in the request data field is not an allowable value for server. This indicates a fault in the structure of the remainder of a complex request, such as that the implied length is incorrect. It specifically does <i>not</i> mean, for example, that a data item submitted for storage in a register has a value outside the expectation of the application program, since the client/server protocol is unaware of the significance of any particular value for any particular register.
0x04	Server device failure	An unrecoverable error occurred, while the server was attempting to perform the requested action.
0x05	Acknowledge	The server accepted the service invocation but the service requires a relatively long time to execute. The server therefore returns only an acknowledgment of the service invocation receipt. This response is returned to prevent a time-out error from occurring in the client.
0x06	Server busy	The server was unable to accept the request. The client application has the responsibility of deciding if and when to resend the request.
0x08	Memory parity error	For specialized use in conjunction with function codes 20 (0x14) and 21 (0x15), to indicate that the extended file area failed to pass a consistency check. For example, the server attempted to read record file but detected a memory parity error. The client can retry the request, but service may be required on the server device.
0x0A	Gateway path unavailable	For specialized use in conjunction with gateways, hubs, switches, and similar network devices, to indicate that the gateway was unable to allocate an internal communication path from the input port to the output port for processing the request. This usually means that the gateway is misconfigured or overloaded.
0x0B	Gateway target device failed to respond	For specialized use in conjunction with gateways, hubs, switches, and similar network devices, to indicate that no response was obtained from the target device. This usually means that the device is not present on the network.

*Note 1:* The following exception codes are reserved: 0x00, 0x07, 0x09, and 0x0C-0xFF.

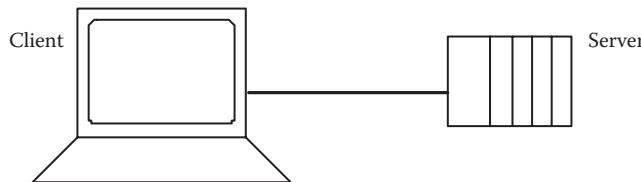

*Note 2:* The exception code table is as from the Modbus.org Modbus protocol specification. Some exception code descriptions date back to the origin of the protocol. The exception codes 0x02 and 0x03 have historically been interpreted in different ways, to the point that Modbus.org decided to accept them interchangeably when running the conformance test. Going forward, the advice is as follows: An exception response should use exception code 0x02 when the Modbus request was correct, data-wise, but not for this server configuration. An exception response should use exception code 0x03 when the Modbus request was wrong, data-wise, for any server (and indeed the problem could have been detected by the client, i.e., a smarter client would not have produced such a request, irrespective of the server configuration).

**TABLE 10.6** OSI Layers and Modbus over Serial Line

Layer	ISO/OSI Model	
7	Application	Modbus application protocol
6	Presentation	Empty
5	Session	Empty
4	Transport	Empty
3	Network	Empty
2	Data link	Modbus over serial line
1	Physical	EIA/TIA-485 or EIA/TIA-232

**FIGURE 10.15** A serial bus (RS485 shown).

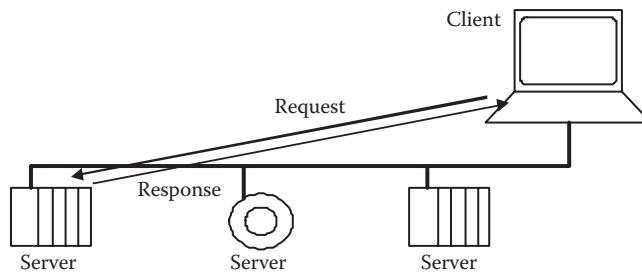

**FIGURE 10.16** A serial bus (RS232 shown).

For the client state machine, the *improper response* is a response with a frame error, and such a response is just dropped.

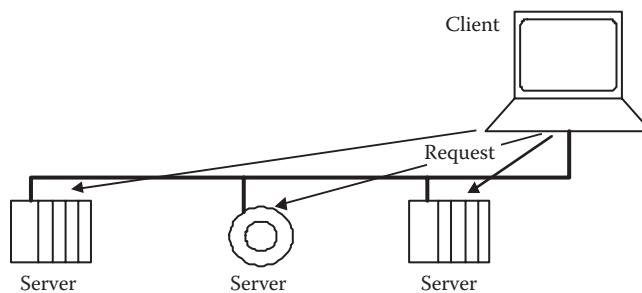

For the server state machine, the *improper request* is either a frame error or a request not addressed to the server, and in both cases, the request is dropped.

The unicast interaction is illustrated in Figure 10.17.

The broadcast interaction, obtained with unit ID = 0 for selected function codes as from Table 10.4, is illustrated in Figure 10.18.

**FIGURE 10.17** Unicast on serial bus (RS485 shown).

**FIGURE 10.18** Broadcast on serial bus (RS485 shown).

### 10.3.2 Modbus Serial Line PDU

The APDU for client/server as described previously is reported for convenience in Figure 10.19.

The Modbus serial line PDU is obtained by adding an error checking field to the APDU. The error checking is described in Table 10.7, and its kind is different depending on the transmission mode (described next).

The Modbus serial line PDU is described in Figure 10.20.

### 10.3.3 Modbus Transmission Modes

Modbus over serial line uses one of two distinct transmission modes: remote terminal unit (RTU) and American Standard Code for Information Interchange (ASCII). RTU is more efficient but slightly more complicated to implement; ASCII is very simple. They will be described in upcoming sections.

The transmission mode (and serial port parameters) must be the same for all devices on a Modbus serial line.

### 10.3.4 RTU Transmission Mode

#### 10.3.4.1 General

When devices communicate on a Modbus serial line using the RTU mode, each character on the wire contains an application message octet. The main advantage of this mode is that its greater density allows better data throughput than ASCII mode for the same baud rate. Each message *must* be transmitted as a continuous stream of characters.

This mode is more efficient than ASCII since each application message octet needs only one character on the wire.

The RTU transmission mode identifies the transmission element boundaries based on time.

Unit ID	Code	Data
---------	------	------

FIGURE 10.19 APDU format.

TABLE 10.7 Error Checking Field

Parameter	Length	Description
Redundancy checking	2 octets	CRC or LRC, depending on the transmission mode, RTU and ASCII, respectively

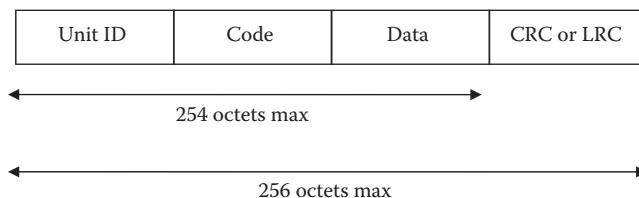

FIGURE 10.20 Modbus serial line PDU.

The format for each character on the wire (11 bits) in RTU mode is as follows:

#### Coding System

8-bit binary

Two hexadecimal characters (0–9, A–F) contained in the 8-bit field of the character on the wire.

#### Bits per Character on the Wire

1 start bit

8 data bits, least significant bit (LSB) sent first

1 bit for even/odd parity, no bit for no parity

1 stop bit if parity is used; 2 bits if no parity

*Even parity is required*, other modes (odd parity, no parity) may also be used. In order to ensure a maximum compatibility with other products, it is *recommended* to support also the no parity mode. The default parity mode *must* be even parity. The format with parity checking is shown in Figure 10.21.

#### Error Check Field

CRC

#### How Characters on the Wire Are Transmitted Serially

Each character on the wire is sent in this order (left to right): LSB to most significant bit (MSB)

Devices *may* accept by configuration both even or odd parity checking and no parity checking. If no parity is implemented, an additional stop bit is transmitted to fill out the character on-the-wire frame. The format without parity checking is shown in Figure 10.22.

Figure 10.23 shows the RTU message frame, complete of CRC (CRC low, CRC high).

The maximum size of the Modbus RTU frame is 256 octets.

#### 10.3.4.2 Modbus Message RTU Framing

A Modbus message is placed by the transmitting device into a frame that has a known beginning and ending point. This allows devices that receive a new frame to begin at the start of the message and to know when the message is completed. Partial messages *must* be detected and errors *must* be set as a result.

With parity checking

Start	1	2	3	4	5	6	7	8	Par	Stop
-------	---	---	---	---	---	---	---	---	-----	------

FIGURE 10.21 Bit sequence in RTU mode (with parity).

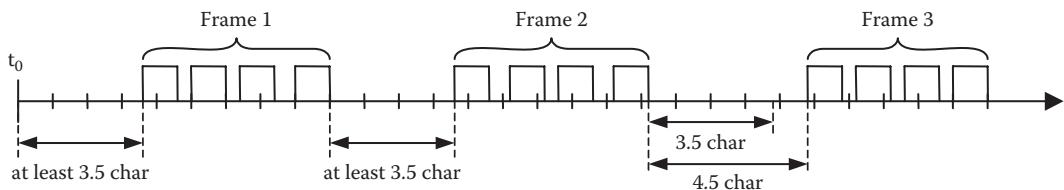

Without parity checking

Start	1	2	3	4	5	6	7	8	Stop	Stop
-------	---	---	---	---	---	---	---	---	------	------

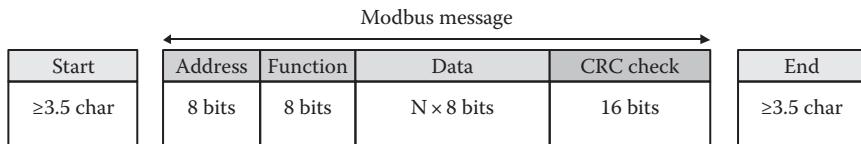

FIGURE 10.22 Bit sequence in RTU mode (no parity case).

Unit ID	Code	Data	CRC
1 octet	1 octet	0 up to 252 octets	2 octets CRC Low, CRC Hi

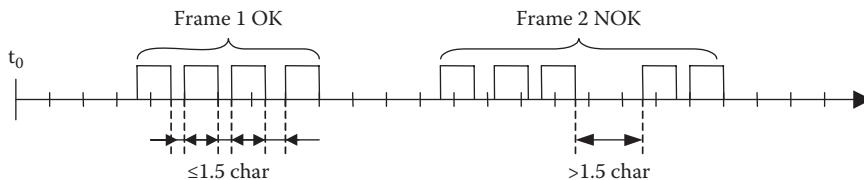

FIGURE 10.23 RTU Modbus message.

**FIGURE 10.24** RTU message frames and separation.

**FIGURE 10.25** RTU message frame.

**FIGURE 10.26** Good frame and bad frame.

In the RTU mode, message frames are separated by a silent interval of *at least* 3.5 character (on the wire) times. In the following sections, this time interval is called t3.5, and it is shown in Figures 10.24 and 10.25.

The entire message frame *must* be transmitted as a continuous stream of characters.

If a silent interval of more than 1.5 character (on the wire) times occurs between two characters on the wire, the message frame is declared incomplete and should be discarded by the receiver. See Figure 10.26.

Please consult the *Modbus over serial line* specification at [www.Modbus.org](http://www.Modbus.org) for more details on timing, on various checks, and on the CRC.

### 10.3.5 ASCII Transmission Mode

#### 10.3.5.1 General

When devices communicate on a Modbus serial line using the ASCII mode, each application message octet is sent as two ASCII characters on the wire, that is, it will require two characters on the wire. This mode is used when the capabilities of the device do not allow the conformance with RTU mode requirements regarding timers' management.

This mode is less efficient than RTU since each application message octet needs two characters on the wire.

Example: The application message octet 0x5B is encoded as two characters for the wire: 0x35 and 0x42 (0x35 = 5 and 0x42 = B in ASCII).

While there are time-outs involved, the ASCII transmission mode identifies the transmission element boundaries based on character values.

The format for each character on the wire (10 bits) in ASCII mode is as follows:

#### *Coding System*

Hexadecimal, ASCII characters 0–9, A–F

One hexadecimal character contained encoded 7-bit ASCII character in the 7-bit field of the character on the wire.

#### *Bits per Character on the Wire*

1 start bit

7 data bits, LSB sent first

1 bit for even/odd parity; no bit for no parity

1 stop bit if parity is used; 2 bits if no parity

*Even parity is required*; other modes (odd parity, no parity) may also be used. In order to ensure a maximum compatibility with other products, it is *recommended* to support also no parity mode. The default parity mode *must* be even parity. The format with parity checking is shown in Figure 10.27.

#### *Error Check Field*

Longitudinal redundancy check (LRC)

#### *How Characters on the Wire Are Transmitted Serially*

Each character on the wire is sent in this order (left to right): LSB to MSB

Devices *may* accept by configuration both even or odd parity checking and no parity checking. If no parity is implemented, an additional stop bit is transmitted to fill out the character on-the-wire frame. The format without parity checking is shown in Figure 10.28.

### 10.3.5.2 Modbus Message ASCII Framing

A Modbus message is placed by the transmitting device into a frame that has a known beginning and ending point. This allows devices that receive a new frame to begin at the start of the message and to know when the message is completed. Partial messages *must* be detected and errors *must* be set as a result.

In ASCII mode, a message is delimited by specific ASCII characters as start of frames and end of frames. A message *must* start with a *colon* (:) character (ASCII 3A hex) and end with a *carriage return-line feed* (CRLF) pair (ASCII 0D and 0A hex).

With parity checking									
Start	1	2	3	4	5	6	7	Par	Stop

FIGURE 10.27 Bit sequence in ASCII mode (with parity).

Without parity checking									
Start	1	2	3	4	5	6	7	Stop	Stop

FIGURE 10.28 Bit sequence in ASCII mode (no parity case).

Start	Unit ID	Code	Data	LRC	End
1 char :	2 chars	2 chars	0 up to $2 \times 252$ char(s)	2 chars	2 chars CR,LF

FIGURE 10.29 ASCII message frame.

The allowable characters transmitted for all other fields are hexadecimal 0–9, A–F (ASCII coded). The devices monitor the bus continuously for the *colon* character. When this character is received, each device decodes the next character until it detects the end of frame.

Intervals of up to one second may elapse between characters within the message. If a greater interval occurs, the receiving device assumes that an error has occurred.

A typical ASCII message frame is shown in Figure 10.29.

*Remark:* Each data octet needs two characters for encoding. Thus, to ensure compatibility at the Modbus application level between ASCII mode and RTU mode, the maximum data size for the ASCII data field ( $2 \times 252$ ) is twice the maximum data size for the RTU data field (252).

Consequently, the maximum size of a Modbus ASCII frame is 513 characters.

Please consult the *Modbus over serial line* specification at [www.Modbus.org](http://www.Modbus.org) for more details on various checks and on the LRC.

The official specification will also provide information about the physical layer.

## 10.4 Modbus/TCP

### 10.4.1 General

This section describes Modbus/TCP in general and the client/server encapsulation when the transport layer is TCP/IP. Figure 10.30 shows the Modbus/TCP stack and Table 10.8 shows the positioning with respect to the OSI layers.

The material presented in this section does not contain all the details of the Modbus protocol. The authoritative specifications are publicly available and can be found at the web-based community [www.Modbus.org](http://www.Modbus.org).

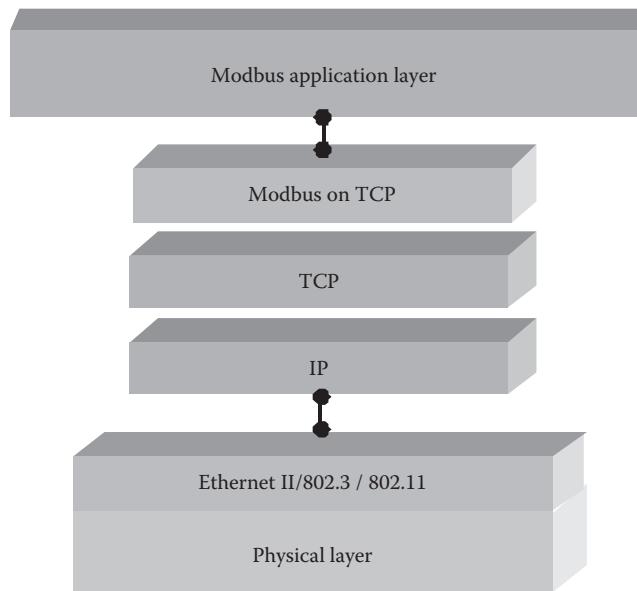

FIGURE 10.30 Modbus/TCP stack.

**TABLE 10.8** OSI Layers and Modbus/TCP

Layer	ISO/OSI Model	
7	Application	Modbus application protocol
6	Presentation	Empty
5	Session	Empty
4	Transport	TCP
3	Network	IP
2	Data link	Network access Ethernet II or 802.3 or 802.11
1	Physical	

### 10.4.2 TCP/IP Encapsulation

The APDU for client/server as described previously is reported for convenience in Figure 10.31.

TCP/IP encapsulation is obtained by adding a header to the APDU. The parameters of the header are described in Table 10.9.

The PDU carried as payload by TCP/IP becomes the one described in Figure 10.32.

### 10.4.3 Role of the Transaction ID

The set of the servers addressable by a client is determined by the underlying layer. In the case of Modbus/TCP, this set is very large since the address is the combination of the IP address and the unit ID.

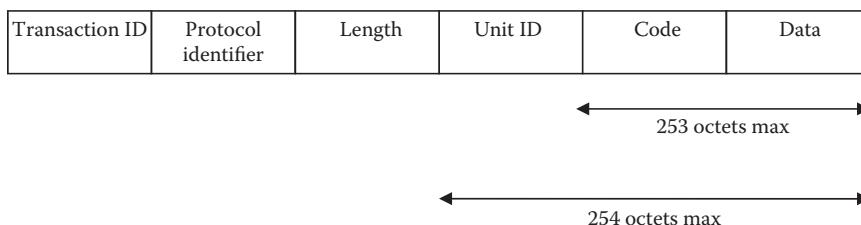

Given a client, the transaction ID generated by the client and placed in a request must be unique across all the transaction IDs still pending on the set of its addressable servers. The transaction ID allows the Modbus/TCP stack more flexibility than, for example, the Modbus serial stack.

**FIGURE 10.31** APDU format.

**TABLE 10.9** Encapsulation Parameters for Client/Server on TCP/IP

Parameters/Fields	Length	Description	Client	Server
Transaction ID	2 octets	Identification of a Modbus request/response transaction	Initialized by the client	Echoed by the server from the received request; returned in the response
Protocol ID	2 octets	0 = Modbus protocol	Initialized by the client	Echoed by the server from the received request; returned in the response
Length	2 octets	Number of following octets in APDU	Initialized by the client based on the request	Initialized by the server based on the response

**FIGURE 10.32** TCP/IP PDU format.

A client requests a service on the set of its addressable servers with the help of the transaction ID, managed (created and destroyed) by the client. The transaction mechanism is exposed at the application layer due to the client/server possibility of having more than one outstanding request at a time, with the consequent need to properly associate requests and confirmations. It also controls the maximum number of such requests, which could be 1. The capabilities of a client/server application layer client depend on lower layers and on the particular implementation; these factors are captured in the configuration of the transaction mechanism allowing programmatic adaptation.

#### 10.4.4 Assigned Port

Modbus/TCP communicates using port 502, assigned by IANA.

#### 10.4.5 Protocol ID

The protocol ID must be 0.

*Note 1:* All other protocol IDs are reserved.

#### 10.4.6 Unit ID and Gateways

On TCP/IP, when no gateways or IP colocated application entities are involved, the client and the server are the intended end points of the connection, and they are fully identified using the IP address. In this case, the unit ID may be ignored by the server, and the client should set it to the value of 255.

In case of gateways or IP colocated application entities, the unit ID is used to identify the server connected to the gateway or the server among the IP colocated application entities. In this case, the value of 255 is recommended for addressing the gateway itself or the IP device hosting the application entities.

#### 10.4.7 TCP as a Streaming Protocol

The length field in the TCP envelope is used to identify the transaction payload boundaries, since TCP is a streaming protocol.

The server must be able to handle situations with several outstanding indications in pipelined transaction on the same connection and others in different connections, up to an implementation-dependent number, usually dictated by resource constraints. If such a number is exceeded, the server must respond with exception code = 0x06: server busy.

The aforementioned limit may be per connection, or it may be a shared limit across all the connections on the same server.

The streaming nature of the TCP protocol allows for cases where the server received only a partial transaction, according to a valid length. The server must be able to buffer the partial transaction and wait for the remaining payload. The server may implement mechanisms, for example, via a timer, to reclaim resources if the wait exceeds a configured time.

#### 10.4.8 Connection Establishment and Management

The connection establishment possibilities, with creation of clients and servers limited only by software resources, require dedicated and novel processing. The *Modbus Messaging on TCP/IP Implementation Guide* available at [www.Modbus.org](http://www.Modbus.org) provides valuable information about TCP connection management.

#### 10.4.9 State Machines

The state machines described in Section 10.2.4.2 are still valid, but they need a good amount of extrapolation to accommodate the possibility of multiple clients and the added flexibility provided by the transaction ID. Moreover, they need extra mechanisms to handle the streaming protocol nature of TCP.

### 10.4.10 Modbus/TCP Flowcharts

To go beyond the trivial Modbus/TCP cases where there is only one client on the network and that client cannot have more than one outstanding transaction, it is helpful to explicitly describe flowcharts that cover the more realistic usage/deployment of Modbus/TCP. The flowcharts that follow will not deal with connection establishment and management, which will be considered already in place. The flowcharts describe the behavior considering the request, indication, response, and confirmation between Modbus/TCP clients and servers and between them and the application software above Modbus/TCP, at the user level.

The MBAP referred in the flowcharts is the header that includes transaction ID, protocol ID, and length and unit ID.

The Modbus/TCP client activity is illustrated in Figure 10.33.

The build Modbus request activity of Figure 10.33 is expanded in Figure 10.34.

The process Modbus confirmation activity of Figure 10.33 is expanded in Figure 10.35.

The server activity (indication processing) is illustrated in Figure 10.36.

The Modbus/TCP PDU checking activity of Figure 10.36 is expanded in Figure 10.37.

The Modbus/TCP service processing activity of Figure 10.36 is expanded in Figure 10.38.

### 10.4.11 [Informative] TCP Interfaces and Parameterization

The Berkeley Software Distribution (BSD) socket interface is often used to communicate using TCP (see, e.g., *TCP/IP Illustrated, Volume 2, Gary R. Wright and W. Richard Stevens*).

A socket is an end point of communication. After the establishment of the TCP connection, the data can be transferred. The `send()` and `recv()` functions are designed specifically to be used with sockets that are already connected.

The `setsockopt()` function allows a socket's creator to associate options with a socket. These options modify the behavior of the socket. The description of these options and recommended settings will follow.

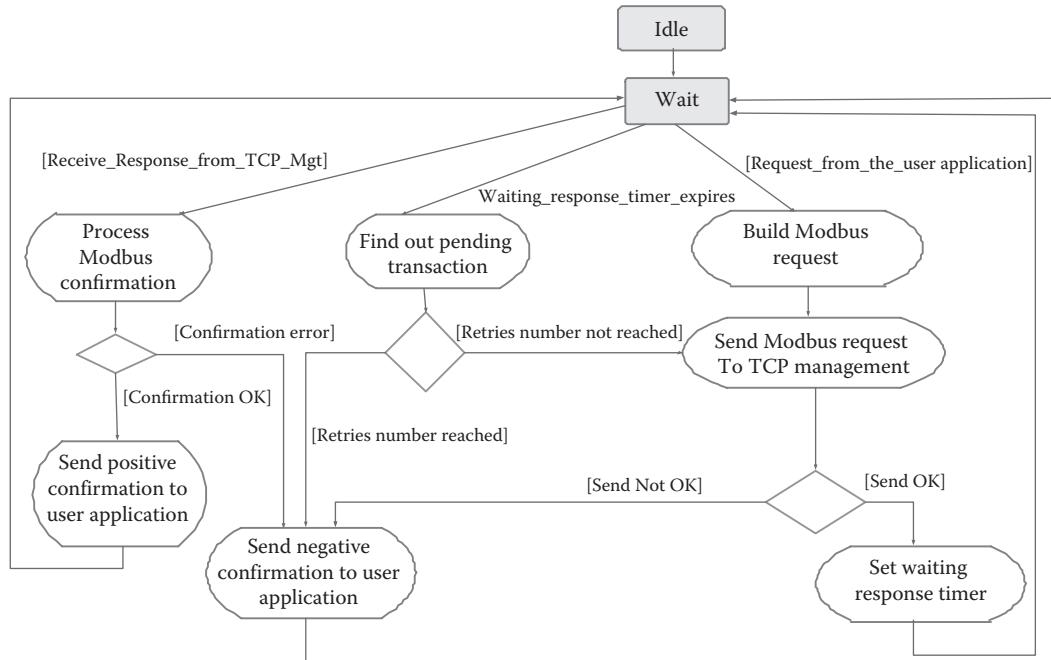

FIGURE 10.33 Modbus/TCP client activity flowchart.

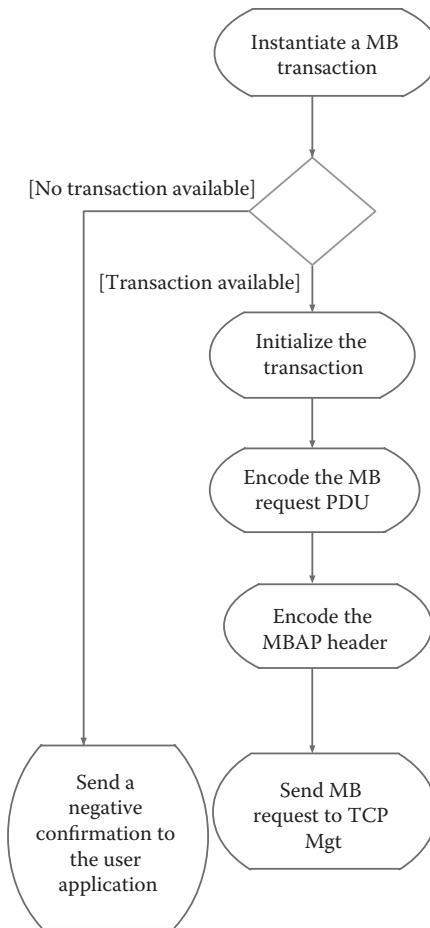

FIGURE 10.34 Modbus/TCP request building (in client) flowchart.

#### 10.4.11.1 Connection Parameters

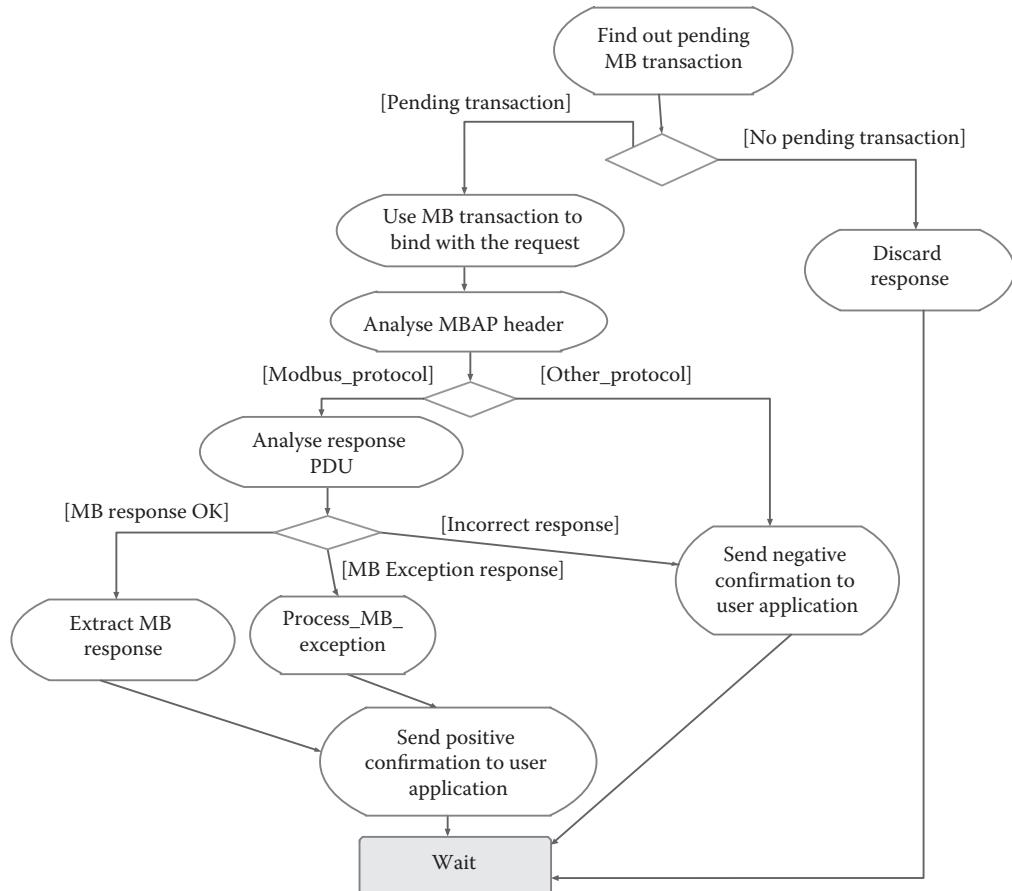

##### 10.4.11.1.1 SO-RCVBUF, SO-SNDBUF

These parameters allow setting the high watermark for the send and the receive sockets. They can be adjusted for flow control management. The size of the receive buffer is the maximum size advertised window for that connection. Socket buffer sizes must be increased in order to increase performances. Nevertheless, these values must be smaller than internal driver resources in order to close the TCP window before exhausting internal driver resources.

The receive buffer size depends on the TCP Windows size, the TCP maximum segment size, and the time needed to absorb the incoming frames. With a maximum segment size of 300 octets (easily accommodating a client/server request), to accommodate 3 frames, the socket buffer size value can be adjusted to 900 octets.

##### 10.4.11.1.2 TCP-NODELAY

Small packets (called tinygrams) are normally not a problem on Local Area Networks (LANs), since most LANs are not congested, but these tinygrams can lead to congestion on wide-area networks. A simple solution, called the *Nagle algorithm*, is to collect small amounts of data and send them in a single segment when the TCP acknowledgments of a previous packet arrive.

**FIGURE 10.35** Process Modbus confirmation (in client) flowchart.

In order to have better behavior, it is recommended to send small amounts of data directly without trying to gather them in a single segment. That is why it is recommended to force the TCP-NODELAY option that disables the *Nagle algorithm* on client and server connections.

#### 10.4.11.1.3 SO-REUSEADDR

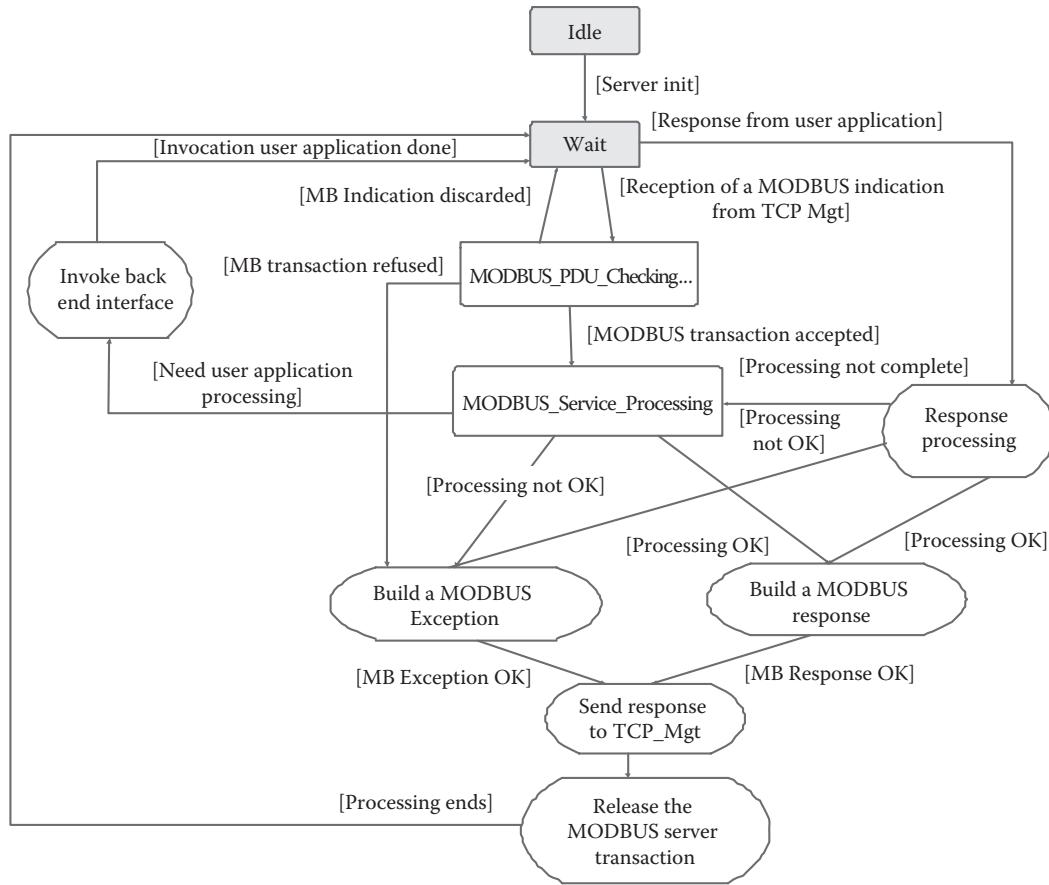

When a server closes a TCP connection initialized by a remote client, the local port number used for this connection cannot be reused for a new opening while that connection stays in the *time-wait* state (during two maximum segment lifetime [MSL]).

It is recommended to specify the SO-REUSEADDR option for each client and server connection to bypass this restriction. This option allows the process to assign itself a port number that is part of a connection that is in the two MSL wait for client and listening socket.

#### 10.4.11.1.4 SO-KEEPALIVE

By default on the TCP/IP protocol, there are no data sent across an idle TCP connection. Therefore, if no process at the ends of a TCP connection is sending data to the other, nothing is exchanged.

Under the assumption that either the client application or the server application uses timers to detect inactivity in order to close a connection, it is recommended to enable the KEEPALIVE option on both client and server connections in order to poll the other end to know its status.

**FIGURE 10.36** Modbus/TCP server activity (indication processing) flowchart.

Nevertheless, it must be considered that enabling KEEPALIVE can cause perfectly good connections to be dropped during transient failures and that it consumes unnecessary bandwidth if the keep-alive timer is too short.

#### 10.4.11.2 TCP Layer Parameters

##### 10.4.11.2.1 Time-Out on Establishing a TCP Connection

Most Berkeley-derived systems set a time limit of 75 s on the establishment of a new connection; this default value should be adapted to the constraint of the application.

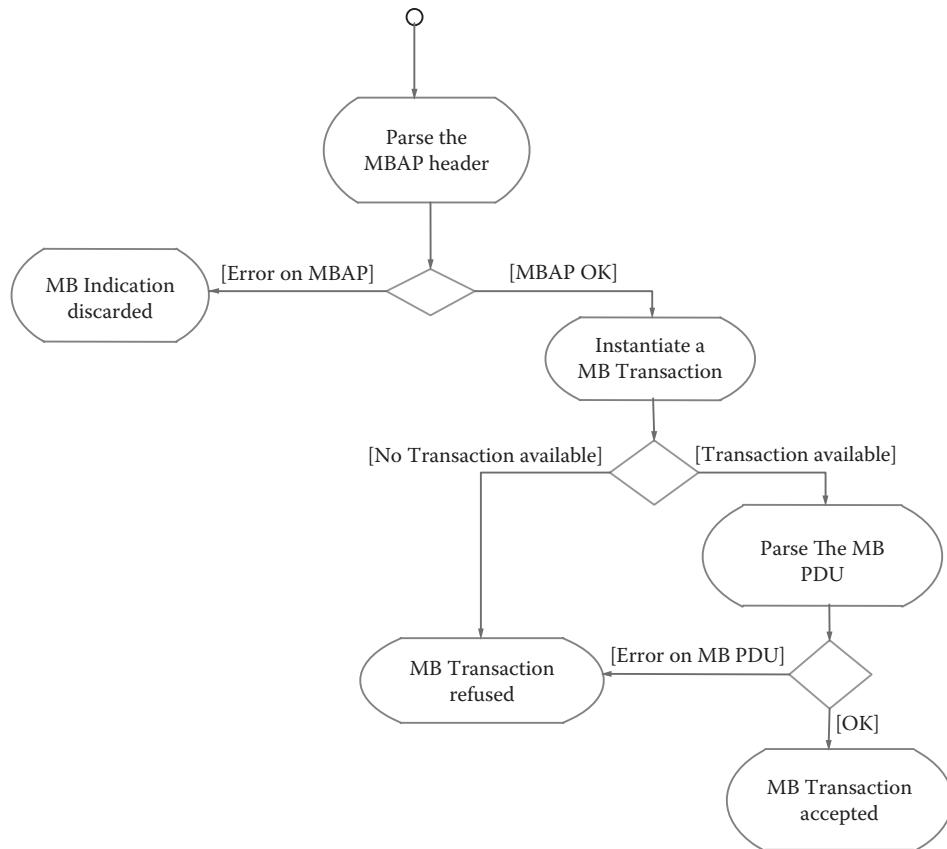

##### 10.4.11.2.2 Keep-Alive Parameters

The default idle time for a connection is 2 h. Idle times in excess of this value trigger a keep-alive probe. After the first keep-alive probe, a probe is sent every 75 s for a maximum number of times unless a probe response is received.

The maximum number of keep-alive probes sent out on an idle connection is 8. If no probe response is received after sending out the maximum number of keep-alive probes, TCP signals an error to the application that can decide to close the connection.

##### 10.4.11.2.3 Time-Out and Retransmission Parameters

A TCP packet is retransmitted if its loss has been detected. One way to detect the loss is to manage a retransmission time-out (RTO) that expires if no acknowledgment has been received from the remote side.

**FIGURE 10.37** Modbus/TCP PDU checking (in server) flowchart.

TCP manages a dynamic estimation of the RTO. For that purpose, a round-trip time (RTT) is measured after the sending of every packet that is not a retransmission. The RTT is the time taken for a packet to reach the remote device and to get back an acknowledgment to the sending device. The RTT of a connection is calculated dynamically; nevertheless, if TCP cannot get an estimate within 3 s, the default value of the RTT is set to 3 s.

If the RTO has been estimated, it applies to the sending of the next packet. If the acknowledgment of the next packet is not received before the estimated RTO expiration, the *exponential backoff* (detailed below) is activated. A maximum number of retransmissions of the same packet are allowed during a certain amount of time. After that if no acknowledgment has been received, the connection is aborted.

Some TCP/IP stacks allow the setup of the maximum number of retransmissions and the maximum amount of time before the abort of the connection.

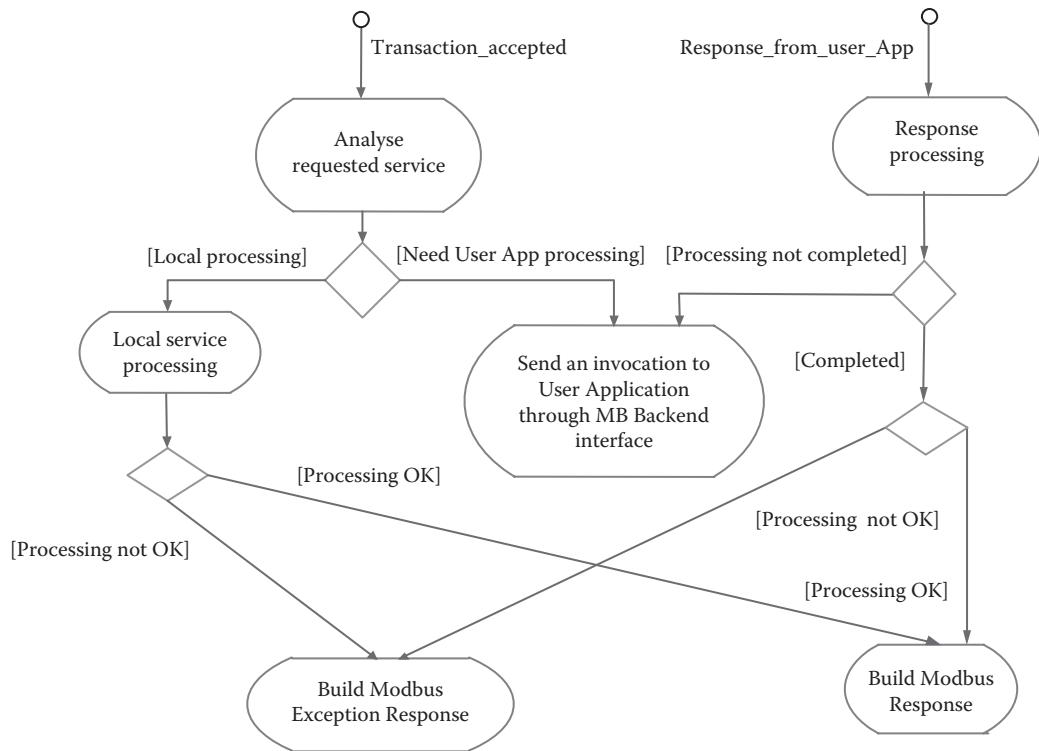

Some retransmission algorithms are defined in TCP IETF RFCs and other papers:

*Jacobson's RTO estimation algorithm* is used to estimate the RTO.

*Karn's algorithm* says that the RTO estimation should not be done on a retransmitted segment.

The *exponential backoff* defines that the RTO is doubled for each retransmission with an upper limit of 64 s.

The *fast retransmission algorithm* allows retransmitting after the reception of three duplicate acknowledgments. This algorithm is advised because on a LAN it may lead to a quicker detection of the loss of a packet than waiting for the RTO expiration.

**FIGURE 10.38** Modbus/TCP service processing (in server) flowchart.

The use of these algorithms is recommended; they are described in *TCP/IP Illustrated, Volume 2*, Gary R. Wright and W. Richard Stevens, which also points to the original sources.

## 10.5 Gateways and Similar Devices

### 10.5.1 General

Gateways involving Modbus have been around for a very long time, and new ones keep being developed, with Modbus being the common second protocol available side by side other protocols, or providing the gateways between different Modbus stacks.

The gateway between Modbus serial and Modbus/TCP, a very successful one, enabled many legacy products to ride the TCP/IP wave without having to be replaced or left behind.

Often gateways perform the duty of proxy clients, for instance, the aforementioned gateway between Modbus serial and Modbus/TCP allows multiple clients on the Modbus/TCP side to access quasi-concurrently servers on the Modbus serial side, by buffering and maintaining separate queues, with no need for user synchronization.

Modbus has been used to access other protocols in two major ways: by interpretation and by mapping. It has also been used with other protocols for tunneling and bridging.

The major reason Modbus is a big player in these protocol activities is that it makes no assumptions about the application semantics and it has an excellent performance/resource ratio on generic services instead.

### 10.5.2 Interpretation

When using this method, the gateway is knowledgeable about Modbus and the other protocol, or about Modbus on different stacks, and manages services and activities on both protocols, essentially by mapping activities. An example is the aforementioned Modbus/TCP to Modbus serial gateway or various BACnet to Modbus gateways.

### 10.5.3 Mappings

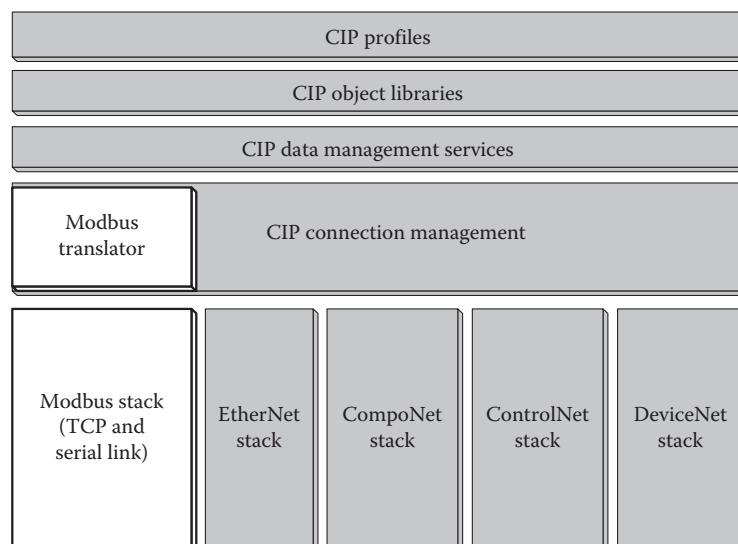

When using this method, two protocols share a memory mapping, where both can read and write or communicate activities/commands. Examples are the Sunspec Alliance to Modbus register mapping and the Wireless Cooperation Team (WCT) WirelessHART to Modbus register mapping. Once the mapping is agreed, it is very easy to write a Modbus client that can access the other protocol's information with no need to know anything about the other protocol.

### 10.5.4 Tunneling and Bridging

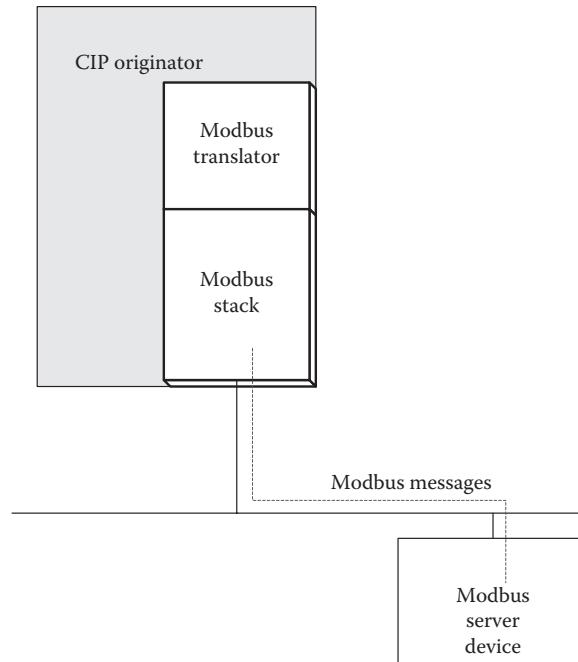

While the terminology is by no means agreed, in a Modbus tunnel, another protocol carries Modbus as a payload, while a Modbus bridge uses Modbus to carry another protocol in its payload. The market has examples with both.

## 10.6 Modbus as Part of the CIP Stack, in ODVA

Schneider Electric joined the ODVA organization (see [www.odva.org](http://www.odva.org)) as a principal member in 2007. The ODVA maintains a suite of industrial protocols called the Common Industrial Protocols (CIPs™). This suite consists of four protocols: DeviceNet™, EtherNet/IP™, ControlNet™, and CompoNet™. One of the goals of this membership was to integrate Modbus into the CIP in order to provide a bridge between CIP networks and Modbus networks. The Modbus translator provides this bridge. A layered architecture view of the CIP protocols and the placement of the Modbus translator is shown in Figure 10.39.

**FIGURE 10.39** Modbus integration into CIP through the Modbus translator.

**FIGURE 10.40** A Modbus translator located in a CIP originator.

The details of the Modbus translator are located in Volume 7 of the CIP Networks Library. Volume 7 is titled *Integration of Modbus Devices into the CIP Architecture* and is governed by the ODVA.

A Modbus translator houses the Modbus translation functionality used for the bridging. A Modbus translator can be located in a CIP originator (which is a client device as shown in Figure 10.40) or as a stand-alone device (sometimes referred to as a router as shown in Figure 10.41) or embedded in a device between the device's Modbus functionality and the CIP network (called a CIP device with native Modbus as shown in Figure 10.42).

The CIP originators receive the downstream Modbus data in the CIP format consistent with the CIP communication model. The CIP originator communicates with a CIP device, and the Modbus functionality is hidden from the CIP originator through the translation function. A Modbus translation function for Modbus/TCP in a dual IP stack is shown in Figure 10.43.

The Modbus translation function performs the *translation* between the CIP protocols and the Modbus protocols. An example of a CIP service request that is processed by the Modbus translator is shown in Figure 10.44.

The CIP network views the Modbus devices as CIP devices, while the Modbus devices view the communication as though it is from a Modbus device. The Modbus translation function housed in a Modbus translator that sits between the CIP network and the Modbus network allows this seamless communication. Any existing Modbus serial link server device or Modbus/TCP server device can communicate with a CIP network using the Modbus translator.

Throughout the integration of Modbus into the CIP environment, care was taken to ensure that the impact to the CIP originator devices was minimized. There was no impact to existing CIP target devices. Equally important, there was no impact to existing Modbus devices. Furthermore, existing vendor-specific CIP to Modbus gateway products can continue to work without any changes to these devices.

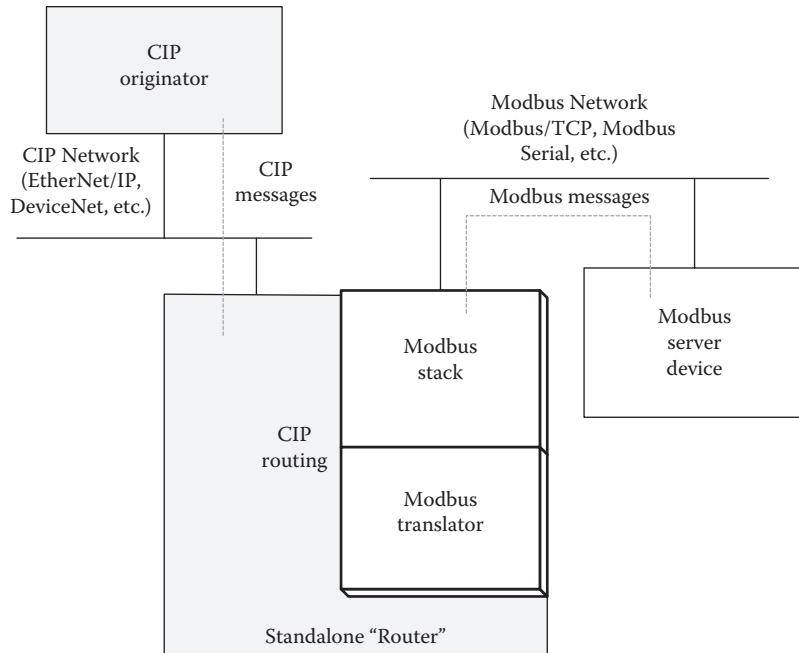

FIGURE 10.41 A Modbus translator as a stand-alone *router* device in a CIP network.

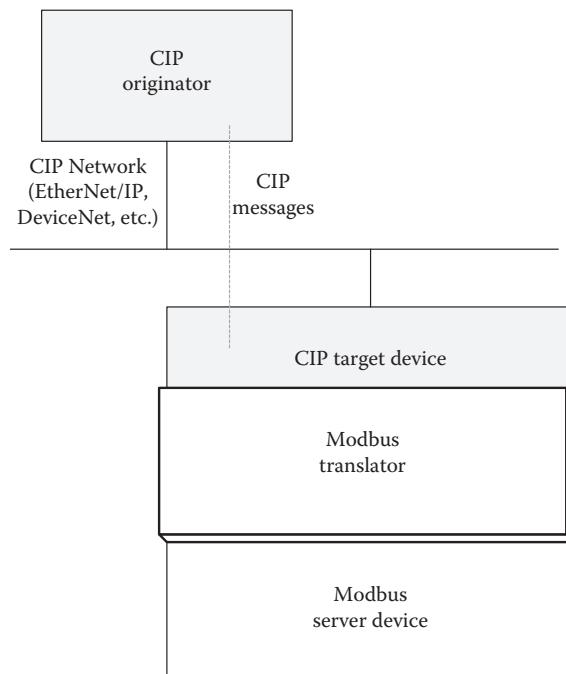

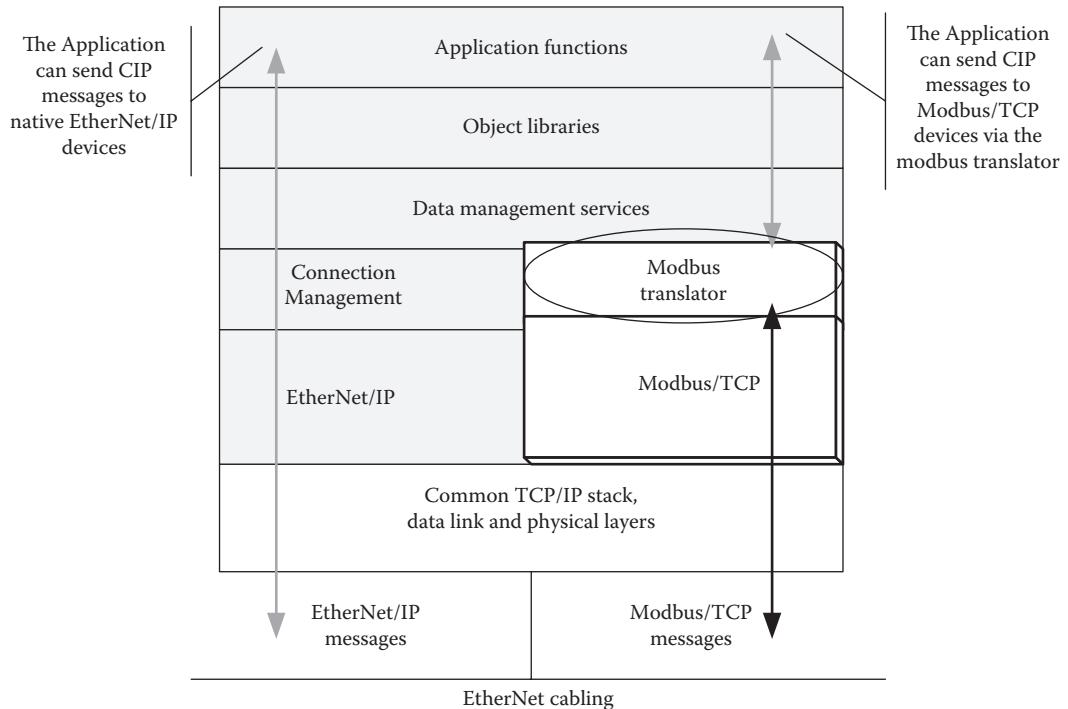

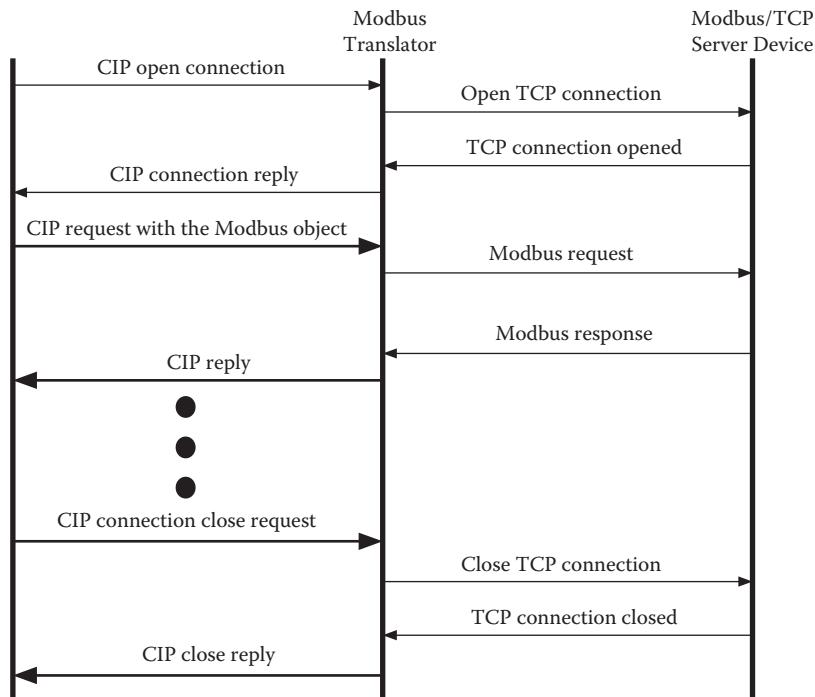

FIGURE 10.42 A Modbus translator embedded in CIP device where the CIP device has native Modbus functionality.

**FIGURE 10.43** Diagram of the Modbus translation function in a dual EtherNet/IP and Modbus/TCP stack implementation.

**FIGURE 10.44** Sequence diagram of typical communication between a CIP originator and Modbus server (target) device through a Modbus translator.

Simply explained, the Modbus translator translates CIP object service requests into Modbus messages. The Modbus translator can be implemented inside a CIP originator or a CIP router or in a CIP device with native Modbus addressing if desired. This allows for efficient engineering design. CIP object service requests are delivered to the Modbus translator where the translator interprets these service requests, maps the service requests to Modbus function codes, and generates Modbus transactions. For efficient operation, the Modbus object was created inside the CIP library of objects. The Modbus object is structured to better expose CIP services to Modbus functionality and to allow Modbus responses to be easily placed into the CIP object format. For best operation, the CIP originator uses the Modbus object as the basis for communication to the Modbus translator. The translator sends the appropriate function code(s) (reads and writes) to the Modbus devices, which the translator is servicing. CIP communication uses two forms of messaging called explicit messaging and implicit messaging. The Modbus translator can handle both forms of CIP communication, each being turned into Modbus requests to the Modbus devices. The Modbus responses to the translator are formatted into the appropriate CIP object service replies and sent to the CIP originator.

To ease configuration, CIP uses electronic data sheet (EDS) files with CIP configuration tools. Modbus devices can help improve the access by the CIP network to the Modbus device by providing an EDS file for the Modbus device. In order to facilitate the use of EDS files with Modbus devices, a generic Modbus EDS file was created. The generic Modbus EDS file is formatted to walk the Modbus user that is not familiar with CIP through the process of creating a meaningful Modbus device EDS file containing the significant features of the Modbus device. The CIP network manager can use this Modbus EDS file to tailor the CIP objects and services including the Modbus object that provides an interface to the Modbus translator to provide the best and most efficient communication to and from that Modbus device.

Modbus integration into the CIP environment is targeted at developers of CIP originators and at developers of CIP router devices who wish to implement the Modbus translator directly into their CIP originators and routers. The integration is also targeted to Modbus device vendors who wish to understand how their device can be utilized by a Modbus translator. The Modbus vendor through the Modbus translator can access new markets where CIP protocols are the basis for network communication.

This integration does not require a Modbus device to support specific Modbus function codes since Modbus devices may not share a common set of function codes. There are recommended Modbus function codes that a Modbus device supports to allow for the best communication through a Modbus translator. The recommended Modbus function codes are read holding registers (FC 03), write multiple registers (FC 16), read/write multiple registers (FC 23), and read device identification (FC 43/14). Using these four function codes allows for the most efficient communication between CIP originator and a Modbus device. Vendors designing new Modbus products or updating existing Modbus products are encouraged to support the four recommended Modbus function codes for best integration with CIP.

In the Modbus device, it is recommended to minimize address fragmentation when possible. Minimization of address fragmentation in the Modbus device aids communication from CIP network. The work in the Modbus translator is reduced and fewer Modbus transactions are needed to accomplish particular data exchanges.

The CIP and Modbus protocol specifications differ in the architecture, features, and operations they define. For example, the CIP protocol defines time-outs, data refresh/consumption rates, and message sequence numbers, while the Modbus protocol does not. The Modbus translator does not manage these differences between the two protocols. Some of these protocol differences can be mitigated using configuration techniques to tailor the communication system to the application.

For example, the CIP protocol uses a refresh rate to allow for communication timing differences on a CIP network or to accommodate differences in target device performance. Modbus does not define a refresh rate. In order for the CIP device to work best with the Modbus target device,

it is important that the CIP refresh rate is not faster than the speed at which the Modbus target device can consume or process a corresponding write. Since the Modbus translator does not manage the refresh rate of CIP or the write processing time of the Modbus target device, it is possible to have multiple pending writes from the CIP network to the corresponding Modbus target device on the Modbus network.

To maintain proper ordering of CIP messages, CIP uses a sequence number on each message. Modbus/TCP uses a similar feature called the Modbus transaction ID. There is no correlation between the CIP sequence number and the Modbus/TCP transaction ID.

The CIP and Modbus protocols transmit multibyte data elements differently on the wire. The Modbus protocol uses *big-endian* encoding and the CIP protocol uses *little-endian* encoding. The Modbus translator will handle the byte swapping between the CIP originator and the Modbus devices.

Changes were made to the CIP protocol to accommodate the Modbus translation function of the Modbus translator. As stated earlier, these changes were kept to a minimum. The changes are as follows:

- Two new port types were added to the CIP port object. The first is the Modbus/TCP port and the second is the Modbus/SL port.
  - A Modbus/TCP port is indicated in the CIP port object as Modbus/TCP and the CIP semantic number in the object is 201.
  - A Modbus serial link port is indicated in the CIP port object as Modbus/SL and has a CIP semantic number of 202.
- The port name attribute of the CIP port object was updated to require that all CIP ports on the same physical network have the same port name.

The Modbus protocol is managed and administered by the Modbus organization. Even though Volume 7 of the CIP Networks Library is administered by the ODVA, the ODVA only governs the Modbus translator and the Modbus translation function. The Modbus protocol is independent of the ODVA, which remains solely the property of Modbus.

## 10.7 Modbus on Other Stacks

---

Modbus has been architected and deployed on several stacks, like power line carrier stacks, many 802.15.4 stacks, and cellular.

## 10.8 Conformance

---

Modbus.org provides conformance tests; see [www.Modbus.org](http://www.Modbus.org).

### 11.1 Basics

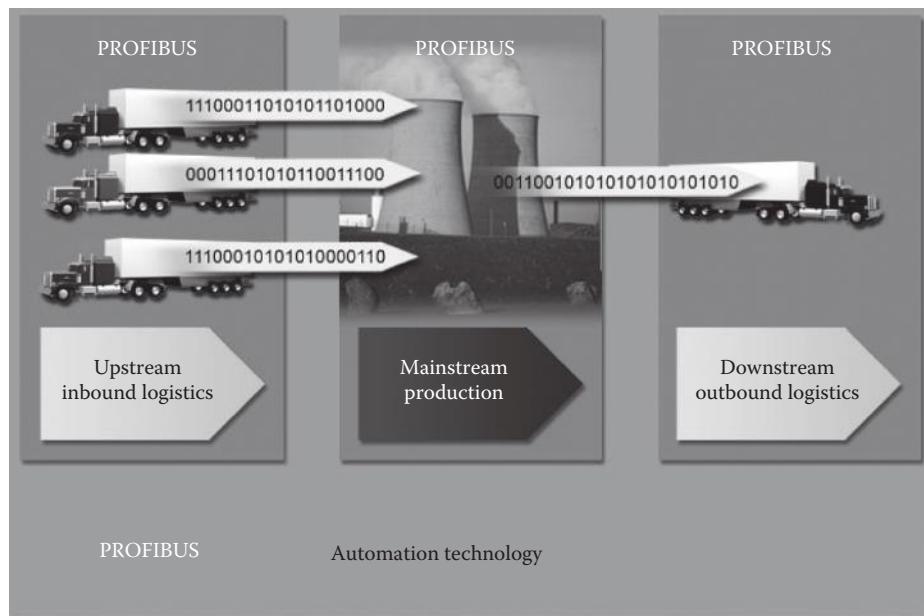

---

Fieldbuses are industrial communication systems with bit-serial transmission that use a range of media such as copper cable, fiber optics, or radio transmission to connect distributed field devices (sensors, actuators, drives, transducers, analyzers, etc.) to a central control or management system. Fieldbus technology was developed in the 1980s with the aim to save cabling costs by replacing the commonly used central parallel wiring and dominating analog signal transmission (4–20 mA or ±10 V interface) with digital technology. Due to different industry-specific demands, the result of sponsored research and development projects, or the preferred proprietary solutions of large system manufacturers, several bus systems with varying principles and properties were established in the market. The key technologies are now included in the adopted standards IEC 61158 and IEC 61784 [1]. PROFIBUS is an integral part of these standards.

Fieldbuses originally created the basic prerequisite for distributed automation systems in the manufacturing industry. Meanwhile, they evolved to a standard technology also in process automation where they significantly increased productivity and flexibility compared to conventional technology.

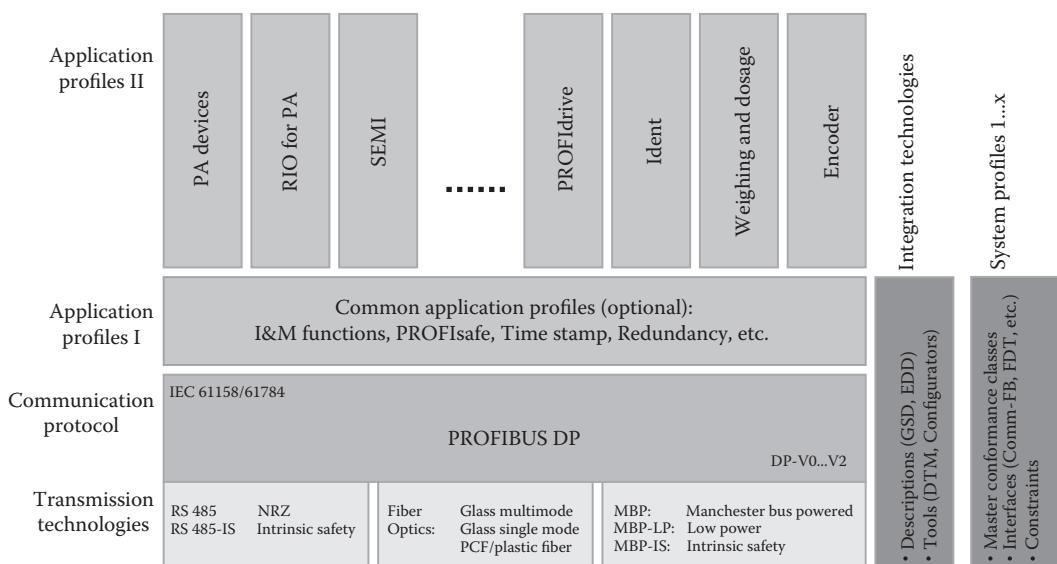

PROFIBUS is an open, digital communication system with a wide range of applications, particularly in the fields of factory and process automation, transportation, and power distribution. PROFIBUS is suitable for both fast, time-critical applications and complex communication tasks (Figure 11.1).

The application and engineering aspects are specified in the generally available guidelines of PROFIBUS & PROFINET International (PI) [2]. This fulfills user demand for standardization, manufacturer independence and openness, and ensures communication between the devices of various manufacturers.

**FIGURE 11.1** PROFIBUS suitable for all decentralized applications.

Based on a very efficient and extensible communications protocol combined with the development of numerous application profiles (communication models for device type families) and a fast-growing number of devices and systems, PROFIBUS began its market success initially in factory automation, and then in process automation, from 1995. Today, PROFIBUS is the world leader in the fieldbus market with more than 20% share of the market, over 1 million plants equipped with the PROFIBUS installations, and more than 50 million nodes. Today, there are more than 2500 PROFIBUS products available from a wide range of manufacturers.

**FIGURE 11.2** Structure of PROFIBUS system.

The success of PROFIBUS stems in equal measures from its progressive technology and the strength of its noncommercial PROFIBUS User Organization e.V. (PNO), the trade body of manufacturers and users founded in 1989. Together with other 27 regional associations in countries all around the world, and the international umbrella organization PI founded in 1995, this pan-national organization now totals more than 1400 members worldwide. The objectives are continuing development of the PROFIBUS technology and increase of its worldwide acceptance.

PROFIBUS has a modular structure (PROFIBUS Tool Box) and offers a range of transmission and communication technologies, numerous application and system profiles, as well as device management and integration tools [3]. PROFIBUS covers various and application-specific demands from the field of factory to process automation, from simple to complex applications, by selecting the adequate set of components out of the toolbox (Figure 11.2).

## 11.2 Transmission Technologies

---

The physical layer is the first layer of the Open System Interconnection (OSI) model. It deals with bit-level transmission between different devices and supports electrical or mechanical interfaces connecting to the physical medium for synchronized communication. The physical layer is usually a combination of software and hardware programming and may include electromechanical devices. It does not include the physical media as such. PROFIBUS features a number of different transmission technologies, all of which are based on international standards. They all are assigned to PROFIBUS in both IEC 61158 and IEC 61784: RS485/485-IS, MBP/MBP-IS (IS stands for intrinsic safety protection), and fiber optics.

### 11.2.1 EIA/TIA-485 (Former RS485)

EIA/TIA-485 transmission technology is simple and cost-effective and is primarily used for tasks that require high transmission rates. Shielded, twisted pair copper cable with one conductor pair is used. The bus structure allows the addition or removal of stations, or the step-by-step commissioning of the system without interfering with the operation of other stations. Subsequent expansions (within defined limits) have no effect on stations already in operation.

In 1983, the Electronics Industries Association (EIA) approved a new *balanced transmission standard* called, at that time, Recommended Standard (RS) 485 (RS485). It found widespread acceptance and usage in industrial, medical, and consumer applications. Subsequently, the Telecommunications Industry Association/Electronic Industries Association (TIA/EIA) officially replaced *RS* with *EIA/TIA* to help identify the origin of its standards (TIA/EIA).

EIA/TIA-485 is a standard defining the electrical characteristics of communication in balanced digital multipoint systems. Digital communications networks implementing the EIA/TIA-485 standard can be used effectively over long distances and in electrically noisy environments.

EIA/TIA is an electrical aspect-only standard. In contrast to complete interface standards, which define the functional, mechanical, and electrical specifications, it only defines the electrical characteristics of drivers and receivers that could be used to implement a balanced multipoint transmission line. This standard is intended to be referenced by higher level standards, specifying EIA/TIA-485 as the physical layer standard.

EIA/TIA-485 refers to a physical layer that uses a differential voltage to transmit the data. An electrical circuit in the receiving device measures the voltage between the two incoming lines (Figure 11.3) and looks at the difference between them to determine which stands for a 0 and which for a 1.

- If the difference ( $A - B$ ) is between  $-1.5$  and  $-6$  V, it is a *logical 1*.
- If the difference is between  $+1.5$  and  $+6$  V, it is a *logical 0*.

As balanced system, EIA/TIA-485 is inherently more immune to noise. If fed via a twisted pair, noise induced into the A line is the same as that induced into the B line. When the difference is calculated, the noise is eliminated and the system will still work.

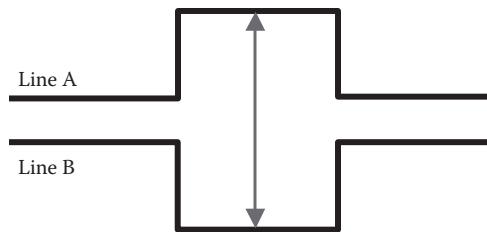

FIGURE 11.3 Logical 1 and 0 determination (EIA/TIA-485).

#### 11.2.1.1 Number of Devices and Type of Cables

EIA/TIA-485 can have as many as 32 devices (masters or slaves) on one segment. A segment is a section of the network, where the same electrical signal flows uninterrupted. The 32 device limit is set by the natural limitations of an electrical circuit. After the signal has been sensed by 31 receivers, the signal degrades to a point where it cannot be read correctly. The number of devices can be expanded by using repeaters.

Different cable types (designated A – D) for different applications are available for connecting devices either to each other or to network elements (segment couplers, links, and repeaters).

The PI recommends that when EIA/TIA-485 is used, cable type A be used.

#### 11.2.1.2 Network Speed and Distances

The PROFIBUS version of EIA/TIA-485 is a modification of the original standard, which could only transmit a maximum rate of 187.5 kbps. The network speed can be set to different transmission rates ranging from 9.6 to 12 Mbps with a typical transmission rate of 1.5 Mbps.

There is a proportional relationship between the transmission rate and the maximum distance of the segment (sum of all cable lengths, including spurs). As the distance increases, the maximum transmission rate decreases (Table 11.1).

#### 11.2.1.3 Intrinsically Safe Operation

EIA/TIA-485-IS, in its IS-variant, supports the use of fast transmission rates within intrinsically safe areas. A PROFIBUS guideline [4] is available for the configuration of intrinsically safe RS485 solutions

TABLE 11.1 Transmission Rates and Cable Lengths

Transmission Rate [Kbit/s]	Transmission Range per Segment [m]	Applies to
9,6 19,2 45,45 93,75	1200	RS485
187.5	1000	RS485
500	400	RS485
1500	200	RS485
3000 6000 12000	100	RS485
31.25	1900	MBP

The values above apply to cable type A with the following properties

Wave resistance	135 ... 165 $\Omega$
Capacitance per unit	$\leq 30 \text{ pF/m}$
Loop resistance	$\leq 110 \text{ } \Omega/\text{km}$
Core diameter	$> 0.64 \text{ mm}$
Core cross-section	$> 0.34 \text{ mm}^2$

with simple device interchangeability. The interface specification details the levels for current and voltage that must be adhered to by all stations in order to ensure safe operation during interconnection. An electric circuit limits currents at a specified voltage level. When active sources are connected, the sum of the currents of all stations must not exceed the maximum permissible current. In contrast to the field-bus intrinsically safe concept (FISCO) model, all stations represent active sources. Up to 32 stations may be connected to the intrinsically safe bus circuit.

#### 11.2.1.4 Conclusion

EIA/TIA-485 is the ideal physical layer for PROFIBUS DP (Decentralized Peripherals) communication:

- It has great noise immunity.
- It can go over long distances.
- It can include up to 32 devices on one segment.
- It can transmit data up to 12 Mbps.

#### 11.2.2 Manchester Encoded Bus Powered (MBP, IEC 61158-2)

*MBP* (Manchester encoded, *Bus Powered*) transmission technology is a new term that replaces the previously common terms for intrinsically safe transmission such as *physics in accordance with IEC 61158-2, 1158-2*, etc. The current version of the IEC 61158-2 (physical layer) describes several different transmission technologies, MBP technology being just one of them. Thus, differentiation in naming was necessary.

MBP is a synchronous, Manchester-coded transmission with a defined transmission rate of 31.25 kbps. In its version *MBP-IS*, MBP is frequently used in process automation as it satisfies the key demands of the chemical and petrochemical industries for IS and bus powering using two-wire technology (Figure 11.4).

##### 11.2.2.1 Power and Communication on the Same Cable

The IEC 61158-2 Standard defines the physical layer that uses a special method called MBP to deliver power (direct current) and digital signal communication (alternating current) on the same two-wire

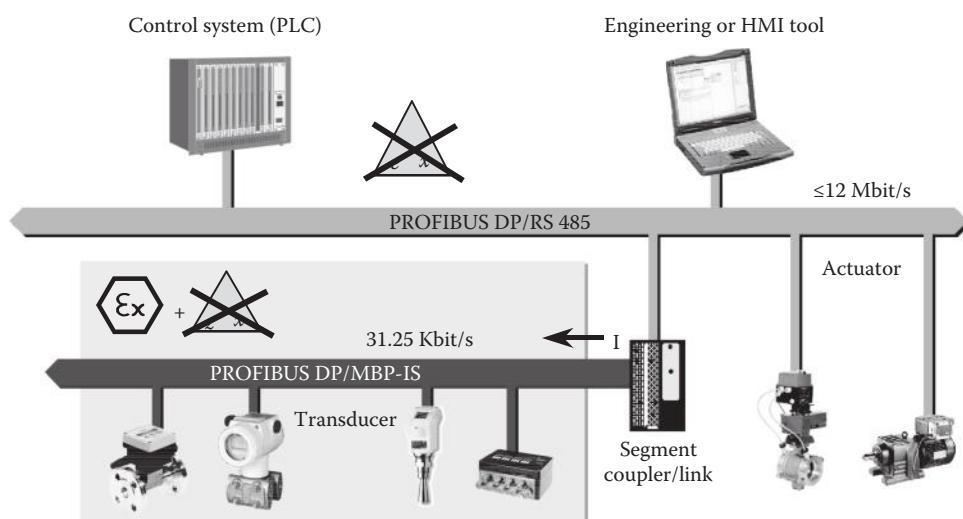

FIGURE 11.4 Intrinsic safety and powering of field devices using MBP-IS.

**TABLE 11.2** MBP Characteristics

Fieldbus Standard IEC 61158-2 for MBP Transmission Technology
Up to 32 nodes in one segment
Data transmission rate 31.25 Kbit/s
Per field device: Min. working voltage 9 V DC Min. current consumption 10 mA
Transmission of digital communication signal in zero-mean Manchester II coding (MBP) through $\pm 9$ mA amplitude
Signal transmission and remote power supply using twisted-pair cable
Fieldbus cable type A
Connection of field devices via stubs (spur) to a main cable (trunk) for trouble-free disconnection of devices without affecting other nodes
Max. total length of main cable, including all stubs, is 1900 m

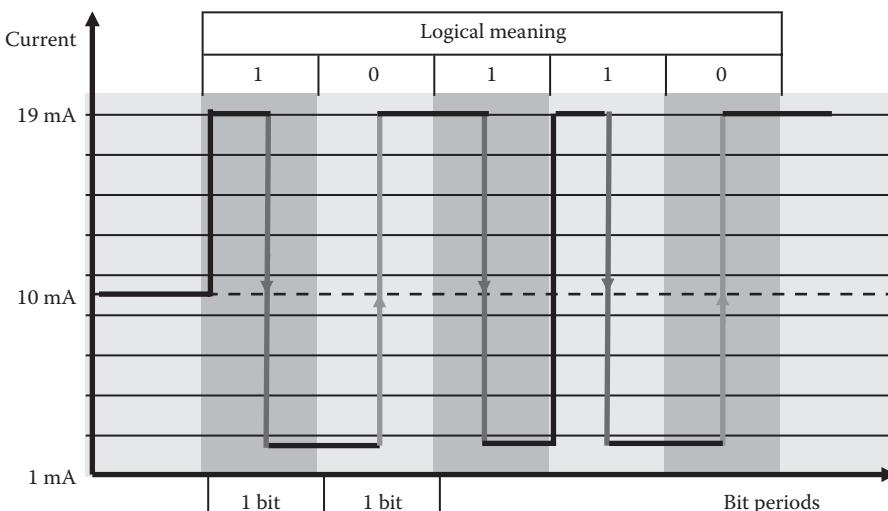

cable. Information is transmitted by varying the power draw on the power cable. This standard defines some general conditions for the structure of a fieldbus network. Table 11.2 summarizes the most decisive of these conditions.

### 11.2.2.2 Manchester Coding

In telecommunication, Manchester coding is a line code in which the encoding of each data bit has at least one transition and takes place in a fixed time period. Manchester code always has a transition in the middle of each bit period and may have, depending on the information to be transmitted, a transition at the start of the period as well. The direction of the mid-bit transition indicates the data, while transitions at the period boundaries do not carry information and are used to place the signal in the correct state to allow the mid-bit transition.

The minimum base current is 10 mA. The physical layer works by having the devices vary the power drawn over time. The transmission of a 1 or 0 depends on whether the power is increased or decreased (Figure 11.5)

- If the power draw at the mid-bit transition goes from high to low, then it is a logical 1.
- If the power goes from a low to a high, then it is a logical 0.

**FIGURE 11.5** Logical 1 and 0 determination (MBP).

### 11.2.2.3 Application and Topology

MBP transmission technology according to IEC 61158-2 type 1 is used with PROFIBUS PA. The same procedure is also used with other fieldbuses, such as the Foundation Fieldbus (FF).

In its version MBP-IS, MBP can be used in potentially explosive environments of the chemical and petrochemical industries for IS and bus powering using two-wire technology (EEx ia(ib) IIC).

MBP transmission technology is usually limited to a specific segment (field devices in hazardous areas) of a plant, which is then linked to an RS485 segment via a segment coupler or links (Figure 11.4).

PROFIBUS DP acts as backbone of PROFIBUS PA segments, which are attached through couplers, links, or gateways. Different equipment is available for that from various manufacturers. They provide different solutions, for example, regarding transmission rate on the PROFIBUS DP side (fixed or any transmission rate) or the use of address space (same or different) on PROFIBUS PA side as on PROFIBUS DP side. More information is available in [5]. Tree or line structures (and any combination of the two) are network topologies supported by PROFIBUS with MBP transmission with up to 32 stations per segment and a maximum of 126 per network.

### 11.2.2.4 FISCO

The internationally recognized FISCO model considerably simplifies the planning, installation, and expansion of PROFIBUS networks in potentially explosive areas. It has been developed by the German Physikalisch-Technische Bundesanstalt (PTB) [6]. The model is based on the specification that a network is intrinsically safe and requires no individual intrinsic safety calculations when the relevant four bus components (field devices, cables, segment couplers, and bus terminators) fall within predefined limits with regard to voltage, current, output, inductance, and capacity. The corresponding proof can be provided by certification of the components through authorized accreditation agencies, such as PTB (Germany) or Underwriters Laboratories Inc. (UL) and Factory Mutual Global (FM) (the United States) and others.

If FISCO-approved devices are used, not only is it possible to operate more devices on a single line, but the devices can also be replaced during runtime by the devices of other manufacturers, or the line can be expanded—all without the need for time-consuming calculations or system certification. That allows for *plug and play*, even in hazardous areas!

### 11.2.2.5 High-Power Trunk Concept

IS is the method of choice for instrument connections in hazardous areas, but it does not satisfy completely the needs regarding the cable length and a number of devices, compared with applications outside of hazardous areas.

A new approach to hazardous area applications is based on the *high-power trunk* concept (Figure 11.6), which may be applied to areas where no access is required for maintenance or device replacement during its operation. The high-power trunk concept utilizes a trunk, which is protected using increased safety ignition protection. The trunk is installed in Zone 1/Class I, Div. 1/2 and allows a supply current of up to 1000 mA. Field barriers (known also as field couplers) are connected to the trunk and provide galvanically isolated, intrinsically safe outputs for field device connection. Field devices may be located in Zone 1/Class I, Div. 1/2 or Zone 0/Class I, Div. 1. Up to 40 mA output current is made available for each device, which is sufficient even for high-performance field devices. This allows end users to get the maximum number of devices on a segment while also being able to achieve maximum cable lengths. Typical values for a high-power trunk solution are 30 V at 500 mA.

### 11.2.2.6 Conclusion

- MBP provides communication and power on the same two wires, saving considerable installation costs because power and communication do not require separate lines.
- MBP works with the current signal on the bus.

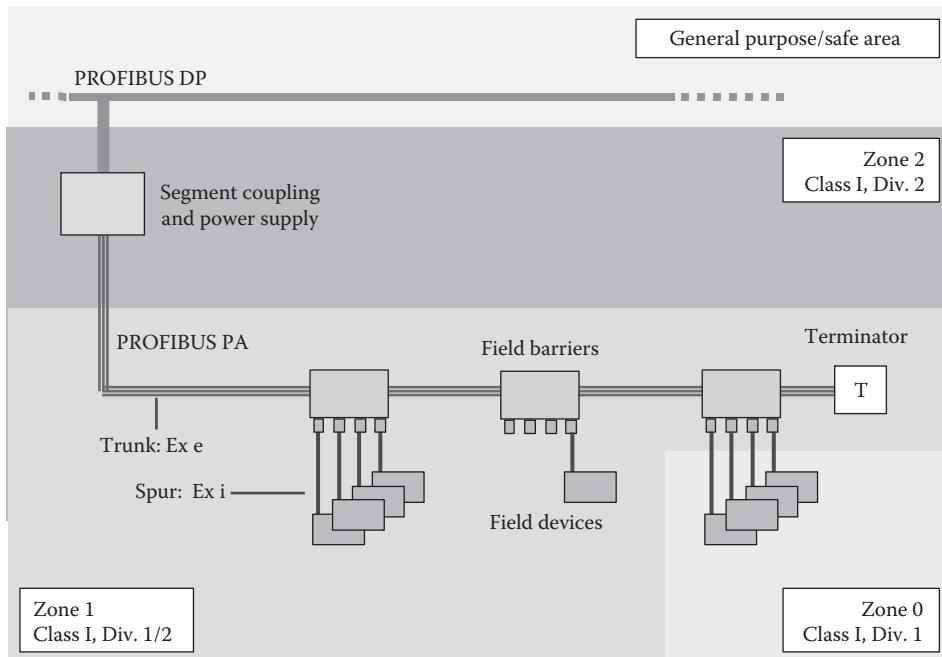

FIGURE 11.6 High-power trunk.

- MBP has considerable electrical noise immunity, so it can be used in industrial settings where electromagnetic noise typically exists.
- A logical “1” is defined as a midpoint transition from low to high, and a “0” is a midpoint transition from high to low.
- MBP segments are created with DP/PA couplers or link modules. Each MBP segment can connect up to 32 stations (including coupler or linking device) with a total distance of up to 1.9 km. With MBP-IS explosion-save installations, these values are reduced.

### 11.2.3 Fiber Optic

Under certain conditions, wired transmission technology reaches its limits, for example, in an environment with heavy interferences or when bridging long distances. In these cases, optical transmission via fiber optic cables is a good solution. The fiber optical physical layer uses light to transmit data.

Modern fiber optic communication systems generally include an optical transmitter to convert an electrical signal into an optical signal to send into the optical fiber, a cable containing bundles of multiple optical fibers, multiple kinds of amplifiers, and an optical receiver to recover the signal as an electrical signal.

PROFIBUS has a number of different fiber optic solutions specified depending on cost and distances (see Table 11.3). The available technologies for fiber optic transmission include multimode and single-mode glass fiber, plastic fiber, and HCS® fiber.

The implementation of a fiber optic cable network in the simplest case involves the use of electro-optical converters, which are connected to the field device with the RS485 interface and the fiber optic cable on the other side. This also makes it possible to switch between RS485 and fiber optic cable transmission within an automation system, depending on the prevalent conditions. Due to the transmission characteristics, typical topology structures are star and ring, but linear structures are also possible.

**TABLE 11.3** Supported Fiber Optic Cable Types

Fiber Type	Core Diameter [μm]	Transmission Range
Multimode glass fiber	62,5/125	2–3 km
Single-mode glass fiber	9/125	>15 km
Plastic fiber	980/1000	Up to 100 m
HCS® fiber	200/230	Approx. 500 m

## 11.3 Communication Protocol

At the protocol level, PROFIBUS with DP and its versions DP-V0 to DP-V2 offers a broad spectrum of optional services, which enable optimum communication between different applications [3,7].

DP has been designed for a fast data exchange at a field level. Data exchange with distributed devices is primarily cyclic. The communication functions required for this are specified through the DP basic functions (version DP-V0). Geared toward the special demands of the various areas of application, these basic DP functions have been expanded step-by-step with special functions so that DP is now available in three versions, DP-V0, DP-V1, and DP-V2, whereby each version has its own special key features. All versions of DP are specified in detail in the IEC 61158 and IEC 61784.

*Version DP-V0* provides the basic functionality of DP, including cyclic data exchange as well as station diagnosis, module diagnosis, and channel-specific diagnosis.

*Version DP-V1* contains enhancements geared toward process automation, in particular, acyclic data communication for parameter assignment, operation, visualization, and alarm handling of intelligent field devices, in coexistence to cyclic user data communication. This permits online access to stations using engineering tools. In addition, DP-V1 defines alarms. Examples of different types of alarms are status alarm, update alarm, and a manufacturer-specific alarm.

*Version DP-V2* contains further enhancements and is geared primarily toward the demands of the drive technology. Due to additional functionalities, such as isochronous slave mode and slave-to-slave(s) communication (data exchange broadcast [DXB]), etc., the DP-V2 can also be implemented as a drive bus for controlling fast movement sequences of drive axes.

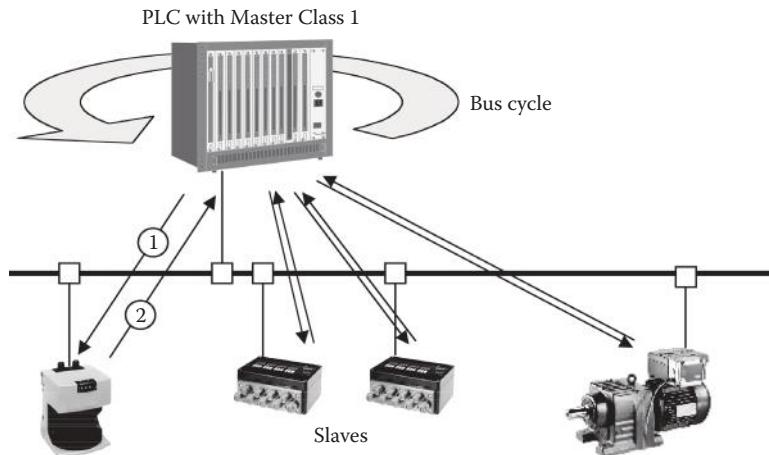

### 11.3.1 System Configuration and Device Types

DP supports the implementation of both monomaster and multimaster systems. This affords a high degree of flexibility during system configuration. A maximum of 126 devices (masters or slaves) can be connected to a bus segment. In monomaster systems, only *one* master is active on the bus during the operation of the bus system. Figure 11.7 shows the system configuration of a monomaster system. In this case, the master is hosted by a programmable logic controller (PLC).

The PLC is the central control component. The slaves are connected to the PLC via the transmission medium. This system configuration enables the shortest bus cycle times. In multimaster systems, several masters are sharing the same bus. They represent both independent subsystems, comprising masters and their assigned slaves, and additional configuration and diagnostic master devices. The masters coordinate themselves by passing a token from one to the next. Only the master that holds the token can communicate. PROFIBUS DP differentiates three groups of device types on the bus.

*DP master class 1* (DPM1) is a central controller that cyclically exchanges information with the distributed stations (slaves) at a specified message cycle. Typical DPM1 devices are PLCs or personal computers (PCs). A DPM1 has active bus access with which it can read measurement data (inputs) of the field devices and write the setpoint values (outputs) of the actuators at fixed times. This continuously repeating cycle is the basis of the automation function.

*DP masters class 2* (DPM2) are engineering, configuration, or operating devices. They are put in operation during commissioning and for maintenance and diagnostics in order to configure connected

**FIGURE 11.7** PROFIBUS DP monomaster system (DP-V0).

devices, evaluate measured values and parameters, and request the device status. A DPM2 does not have to be permanently connected to the bus system. It also has active bus access.

Slaves are peripherals (input/output [I/O] devices, drives, human machine interfaces [HMIs], valves, transducers, and analyzers), which read in process information and/or use output information to intervene in the process. There are also devices that solely provide input information or output information. As far as communication is concerned, slaves are passive devices, and they only respond to direct queries (see Figure 11.7, sequence ① and ②). This behavior is simple and cost-effective to implement. In the case of DP-V0, it is already completely included in the bus application-specific integrated circuit (ASIC).

### 11.3.2 Cyclic and Acyclic Data Communication Protocols

*Cyclic data communication* between the DPM1 and its assigned slaves is automatically handled by the DPM1 in a defined, recurring sequence (Figure 11.7). The appropriate services are called cyclic master slave communication services of PROFIBUS DP (MS0). The user defines the assignment of the slave(s) to the DPM1 when configuring the bus system. The user also defines which slaves are to be included/excluded in the cyclic user data communication. DPM1 and the slaves are passing three phases during start-up: parameterization, configuration, and cyclic data exchange (Figure 11.8).

Before entering the cyclic data exchange state, the master first sends information about the transmission rate, the data structures within a protocol data unit (PDU), and other slave-relevant parameters. In a second step, it checks whether the user-defined configuration matches the actual device configuration. Within any state, the master is enabled to request slave diagnosis in order to indicate faults to the user.

An example for the telegram structure for the transmission of information between master and slave is shown in Figure 11.9. The telegram starts with some synchronization bits, the type (SD) and length (LE) of the telegram, source and destination address, and a function code (FC). The FC indicates the type of message or content of the *load* (processing data unit) and serves as a guard to control the state machine of the master. The PDU, which may carry up to 244 bytes, is followed by a safeguard mechanism frame checking sequence (FCS) and a delimiter (see Figure 11.9 for abbreviations).

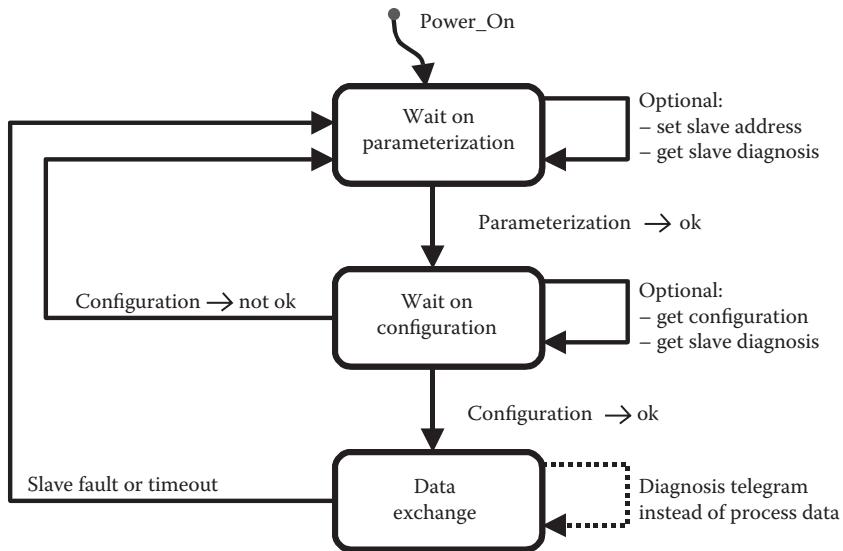

FIGURE 11.8 State machine for slaves.

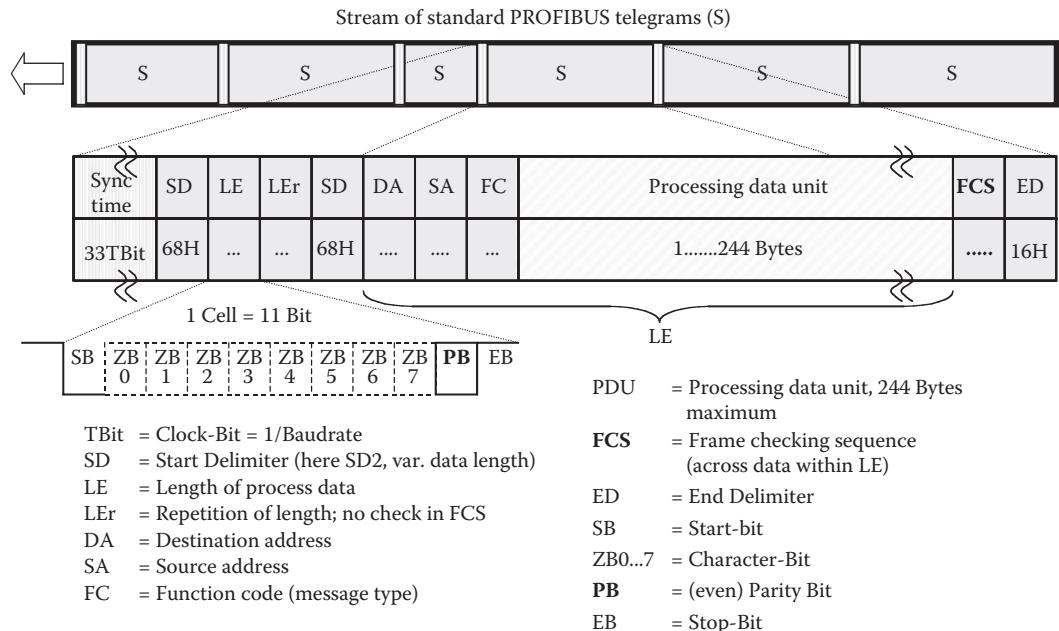

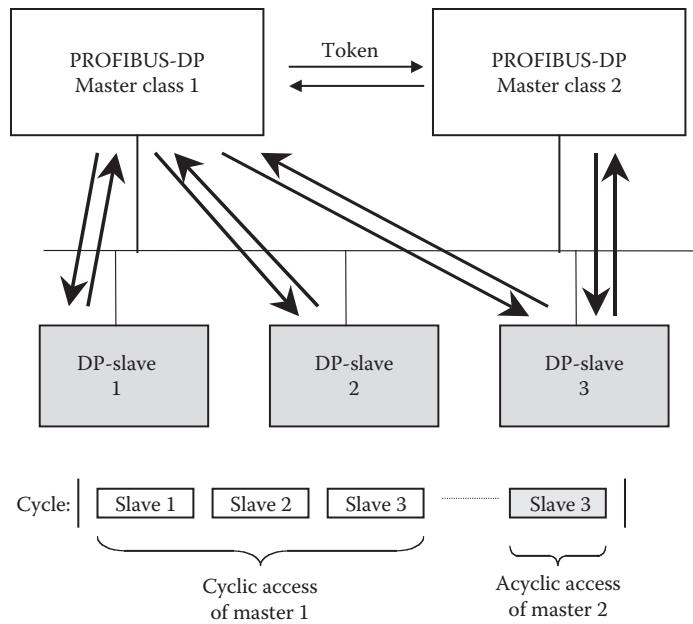

FIGURE 11.9 PROFIBUS DP telegram structure (example).

One example for the usage of the FC is the indication of a fault situation on the slave side. In this case, the master sends a special diagnosis request instead of the normal process data exchange that the slave replies with a diagnosis message. The message comprises six bytes of fixed information and user-definable device and module- or channel-related diagnosis information.

In addition to the single station-related user data communication, which is automatically handled by the DPM1, the master can also send control commands to all slaves or a group of slaves simultaneously.

**FIGURE 11.10** Cyclic and acyclic data communication with DP-V1.

These control commands are transmitted as multicast messages and enable sync and freeze modes for event-controlled synchronization of the slaves.

For safety reasons, it is necessary to ensure that DP has effective protective functions against incorrect parameterization or failure of transmission equipment. For this purpose, the DP master and the slaves are fitted with monitoring mechanisms in the form of time monitors. The monitoring interval is defined during configuration.

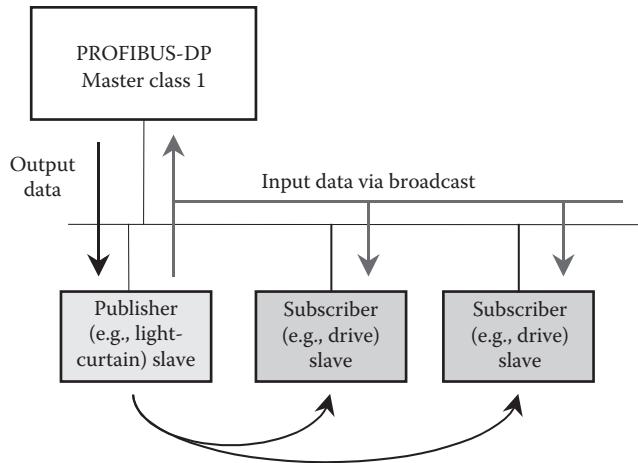

*Acyclic data communication* is the key feature of version DP-V1. This forms the requirement for parameterization and calibration of the field devices over the bus during runtime and for the introduction of confirmed alarm messages. Transmission of acyclic data is executed parallel to cyclic data communication, but with lower priority. Figure 11.10 shows some sample communication sequences for a master class 2, which is using MS2 services. In using MS1 services, a master class 1 is able to execute acyclic communications also.

*Slave-to-slave communications* (DP-V2) enable direct and time-saving communication between slaves using broadcast communication without the detour over a master. In this case, the slaves act as *publisher*; that is, the slave response does not go through the coordinating master but directly to other slaves embedded in the sequence, the so-called *subscribers* (Figure 11.11). This enables slaves to directly read data from other slaves and use them as their own input. This opens up the possibility of completely new applications; it also reduces response times on the bus by up to 90%.

*Isochronous mode* (DP-V2) enables clock synchronous control in masters and slaves, irrespective of the busload.

The function enables highly precise positioning processes with clock deviations of less than one microsecond (<1 µs). All participating device cycles are synchronized to the bus master cycle through a *global control* broadcast message. A special sign of life (consecutive number) allows monitoring of the synchronization.

*Clock control* (DP-V2) via a new synchronizing mechanism between masters and slaves synchronizes all stations to a system time with a deviation of less than one millisecond (<1 ms). This allows the precise tracking of events. This is particularly useful for the acquisition of timing functions in networks.

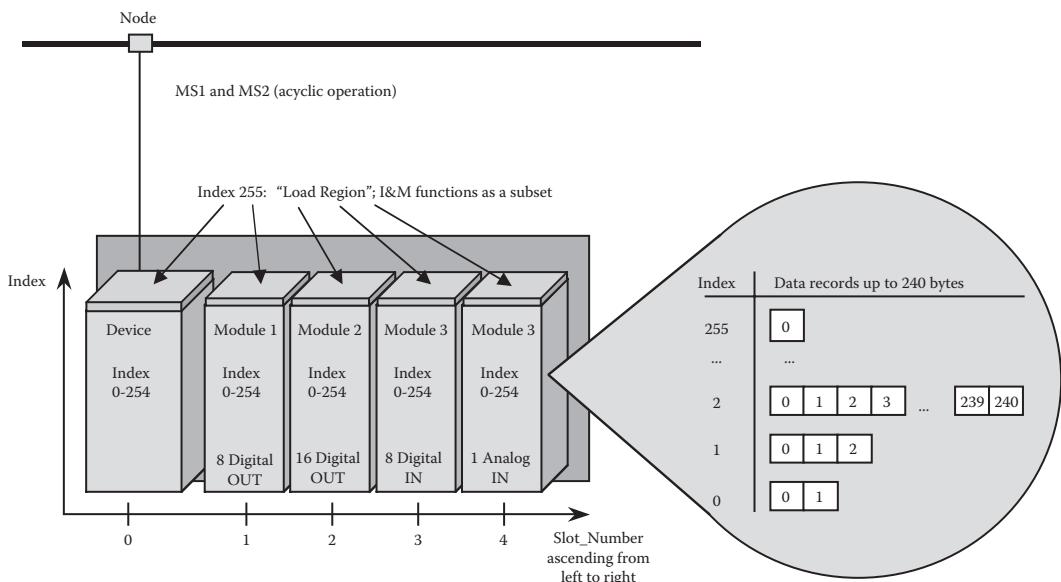

**FIGURE 11.11** Slave-to-slave data exchange.

with numerous masters. This facilitates the diagnosis of faults as well as the chronological planning of events.

*Upload and download* (DP-V2) allows up- and downloading of any amount of data into or from a field device with the help of a few commands. Within IEC 61158, these services are called load region. This enables, for example, programs to be updated or devices replaced without the need for manually loading processes.

*Addressing with slot and index* is used both for cyclic and acyclic communication services (Figure 11.12).

When addressing data, PROFIBUS assumes that the physical structure of the slaves is modular or can be structured internally in logical functional units, the so-called modules (Figure 11.12). The slot number addresses the module, and the index addresses the data records assigned to a module. Each data record

**FIGURE 11.12** Slot/index address model of a slave.

can be up to 244 bytes. The modules begin at slot 1 and are numbered in ascending contiguous sequence. The slot number 0 is for the device itself. Compact devices are regarded as a unit of virtual modules. These can also be addressed with slot number and index.

## 11.4 Application Profiles

---

Profiles are used in automation technology to define specific properties and behavior for devices, device families, or entire systems. Only devices and systems using a vendor-independent profile provide interoperability on a fieldbus, thereby fully exploiting the advantages of a fieldbus. Profiles take into account application and type-specific special features of field devices, controls, and methods of integration (engineering). The meaning of the term *profile* ranges from just a few specifications for a specific device class through comprehensive specifications for applications in a specific industry. The generic term for all profiles is the application profiles.

A distinction is thus drawn between common application profiles with implementation options for different applications (this includes, e.g., the profiles identification and maintenance [I&M] functions, PROFIsafe, redundancy, and time stamp); specific application profiles, which are developed for a specific application such as PROFIdrive, Ident Systems, or PA Devices; and host profiles, which describe specific system performance that is available to field devices.

PROFIBUS offers a wide range of such application profiles, which allow application-oriented implementation.

### 11.4.1 Common Application Profiles

I&M functions are mandatory for all PROFIBUS devices with MS1 and/or MS2 services. The main purpose of the I&M functions described hereinafter is to support the end user during various scenarios of a device's life cycle, be it configuration, commissioning, parameterization, diagnosis, repair, firmware update, asset management, audit trailing, and alike. It is kind of a *type plate* or *boiler plate*. The corresponding parameters all are stored at the same address space within the PROFIBUS slot/index address model.

The *call* mechanism of the load region services [1] opens up an additional subindex address space of 65,535 data records. I&M functions are assigned a space between 65,000 and 65,199 for basic, profile-specific, and manufacturer-specific items. Table 11.4 itemizes the individual parameters.

Nowadays, laptops or engineering tools normally have access to the Internet. Thus, it is quite easy to reference a central database (e.g., on the PROFIBUS web server) and retrieve comprehensive and always actual information, even in a desired language (Figure 11.13).

*PROFIsafe* is a comprehensive, open fieldbus solution for safety-relevant applications without the use of a second relay-based layer or proprietary safety buses. PROFIsafe defines how fail-safe devices (emergency stop pushbuttons, light curtains, level switches, etc.) can communicate over PROFIBUS with fail-safe controllers in such a manner that they can be used for safety-relevant automation tasks up to category 4 compliant with EN954 (ISO 13849) or SIL3 (Safety Integrity Level) according to IEC 61508. It implements safe communications over a profile, that is, over a special PROFIsafe data frame and a special protocol. PROFIsafe is a single-channel software solution, which is implemented in the devices as an additional layer *above* layer 7 (Figure 11.14); the standard PROFIBUS components, such as lines, ASICs, or protocols, remain unchanged. This ensures redundancy mode and retrofit capability. Devices with the PROFIsafe profile can be operated in coexistence with standard devices without restriction on the same bus (cable).

PROFIsafe takes advantage of the acyclic communication (DP-V1) for full maintenance support of the devices and can be used with RS485, fiber optic, or MBP transmission technology. This ensures both fast response times (important for the manufacturing industry) and low power consumption with intrinsically safe operation (important for process automation).

**TABLE 11.4** Basic Identification and Maintenance Functions

I&M Function	Data Format	Notes
MANUFACTURERS	2 Octets	I&M functions are using company IDs instead of names. These IDs are harmonized with the list of the HART Foundation and comprise extensions for additional companies.
ORDER_ID	20 Octets	Order number for a particular device type. For virtual modular devices, the root or highest level of the basic device.
SERIAL_NUMBER	16 Octets	Unique identifier for a particular device (counter).
HARDWARE_REVISION	2 Octets	The content of this parameter characterizes the edition of the hardware only.
SOFTWARE_REVISION	4 Octets	The content of this parameter characterizes the edition of the software or firmware of a device or module. The structure supports coarse and detailed differentiation that may be defined by the manufacturer: Vx.y.z.
REV_COUNTER	2 Octets	Indicates unplugging of modules or write access.
PROFILE_ID	2 Octets	Device or module corresponds to a particular PROFIBUS profile.
PROFILE_SPECIFIC_TYPE	2 Octets	This identifier references a device class defined within a PROFIBUS profile.
IM_VERSION	2 Octets	Version of the I&M functions implemented within a device or module.
IM_SUPPORTED	2 Octets	Directory for the subset of I&M functions implemented within a device or module.
TAG_FUNCTION	32 Octets	User-definable information about the <i>role</i> of the device within a plant facility.
TAG_LOCATION	22 Octets	User-definable information about the <i>location coordinates</i> of the device within a plant facility.
INSTALLATION_DATE	16 Octets	Indicates the date of installation or commissioning of a device or module, e.g., 1995-02-04 16:23.
_DESCRIPTOR	54 Octets	User-defined comments.
SIGNATURE	54 Octets	Allows parameterization tools to store a <i>security code</i> as a reference for a particular parameterization session and audit trail tools to retrieve the code for integrity checks. Used for safety applications according 21 CFR 11 [6] or hazardous machinery (PROFIsafe).

*HART on PROFIBUS DP* integrates Highway Addressable Remote Transducer (HART) protocol devices installed in the field, in existing or new PROFIBUS systems. It includes the benefits of the PROFIBUS communication mechanisms without any changes required for the PROFIBUS protocol and services, the PROFIBUS PDUs or the state machines, and functional characteristics. This profile is implemented in the master and slave above layer 7, thus enabling mapping of the HART client-master-server model on PROFIBUS. The cooperation of the HART Foundation on the specification work ensures complete conformity with the HART specifications.

The HART-client application is integrated in a PROFIBUS master, and the HART master in a PROFIBUS slave, whereby the latter serves as a multiplexer and handles communication to the HART devices (Figure 11.15).

The *time stamp* application profile describes mechanisms as to how to supply certain events and actions with a time stamp, which enables precise time assignment. Precondition is a clock control in the slaves through a clock master via special services. An event can be given a precise system time stamp and read out accordingly. A concept of graded messages is used. The message types are summarized under the term *Alerts* and are divided into high-priority *alarms* (these transmit a diagnostics message) and low-priority *events*. In both cases, the master acyclically reads the time-stamped process values and alarm messages from the alarm and event buffer of the field device (Figure 11.16).

The *slave redundancy* application profile provides a slave redundancy mechanism (Figure 11.17): slave devices contain two different PROFIBUS interfaces that are called primary and backup (slave interface). These may be either in a single device or distributed over two devices.

The devices are equipped with two independent protocol stacks with a special redundancy expansion.

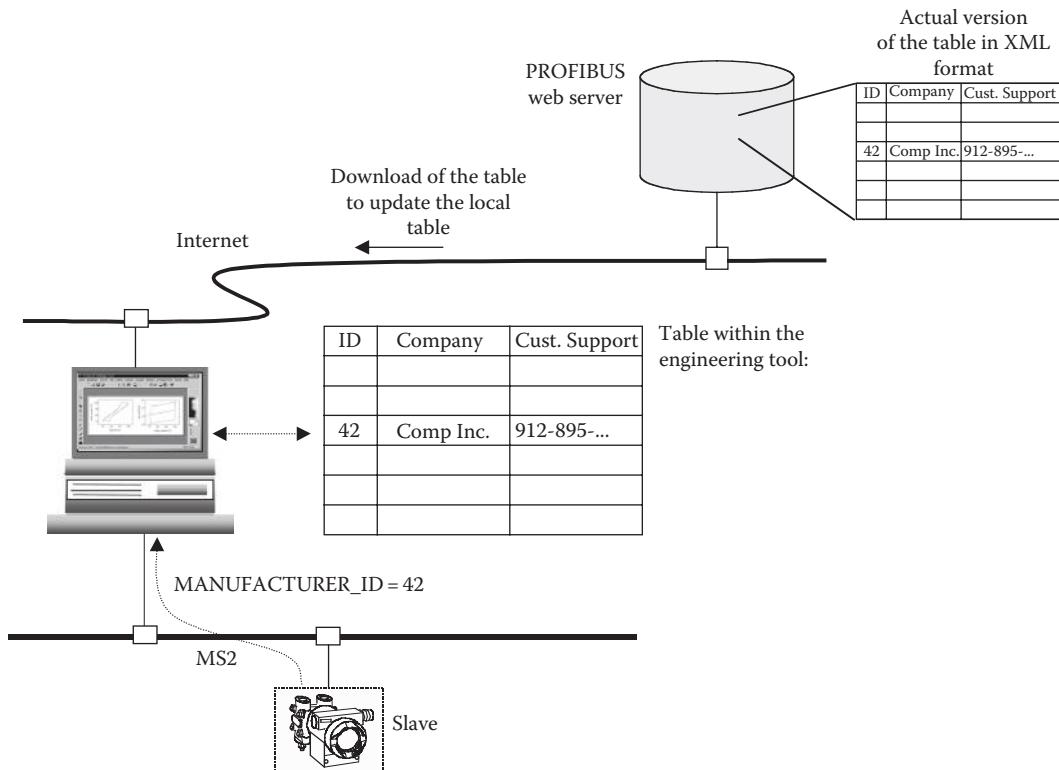

FIGURE 11.13 Referencing IDs via the Internet.

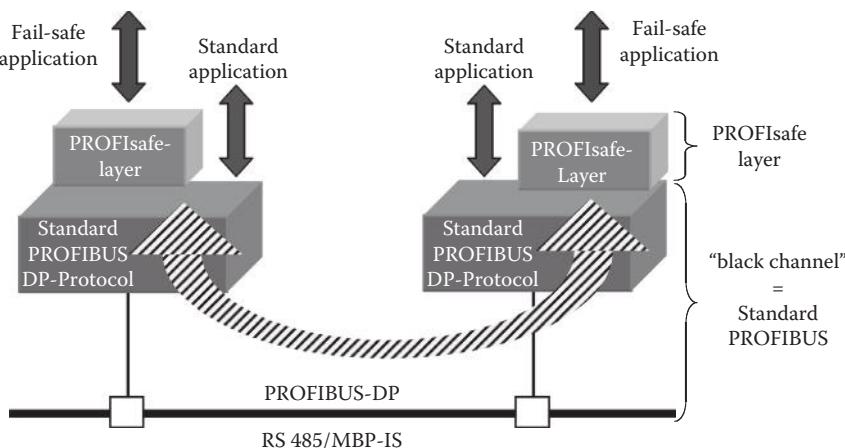

FIGURE 11.14 Safe communication on PROFIBUS DP.

A redundancy communication (RedCom) runs between the protocol stacks, that is, within a device or between two devices. It is independent of PROFIBUS, and its performance capability is largely determined by the redundancy reversing times.

Only one device version is required to implement different redundancy structures, and no additional configuration of the backup slave is necessary. The redundancy of PROFIBUS slave devices provides high availability, short reversing times, no data loss, and ensures fault tolerance.

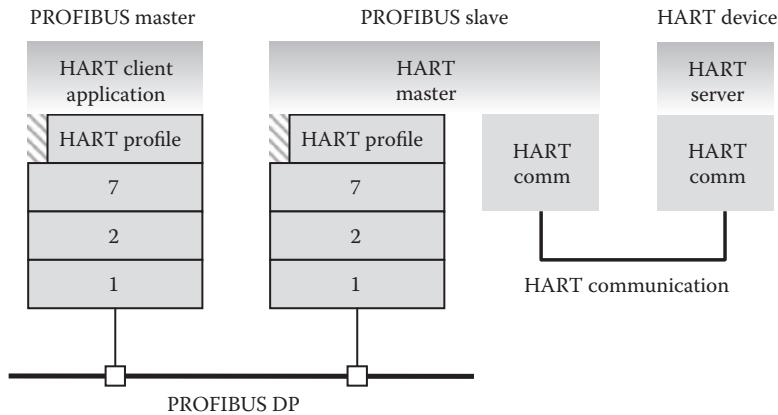

FIGURE 11.15 Operating HART devices over PROFIBUS DP.

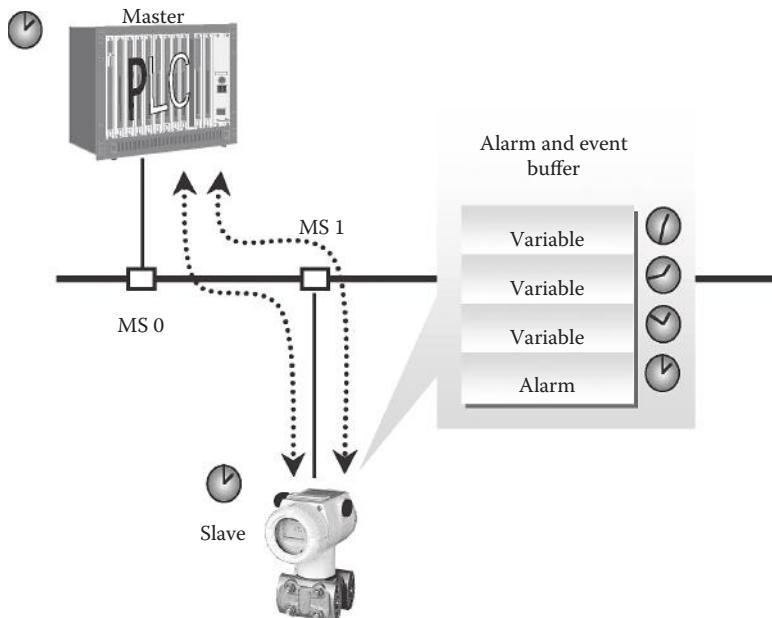

FIGURE 11.16 Time stamping and alarm messages.

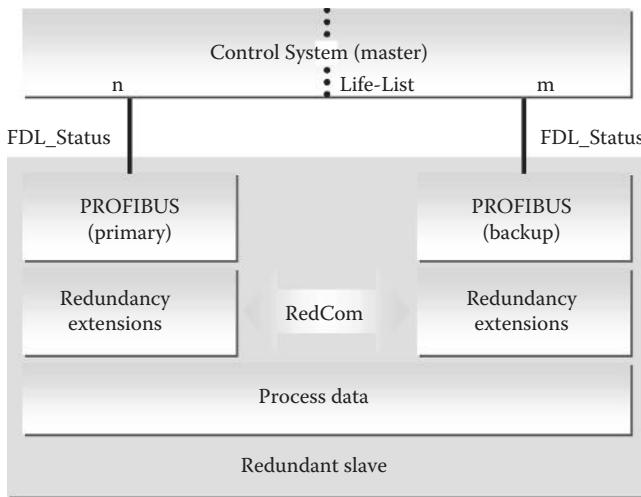

### 11.4.2 Specific Application Profiles

The **PROFIdrive** application profile (standardized in IEC 61800-7) defines device behavior and the access procedure to drive data for electric drives, from simple frequency converters to highly dynamic servo-controls.

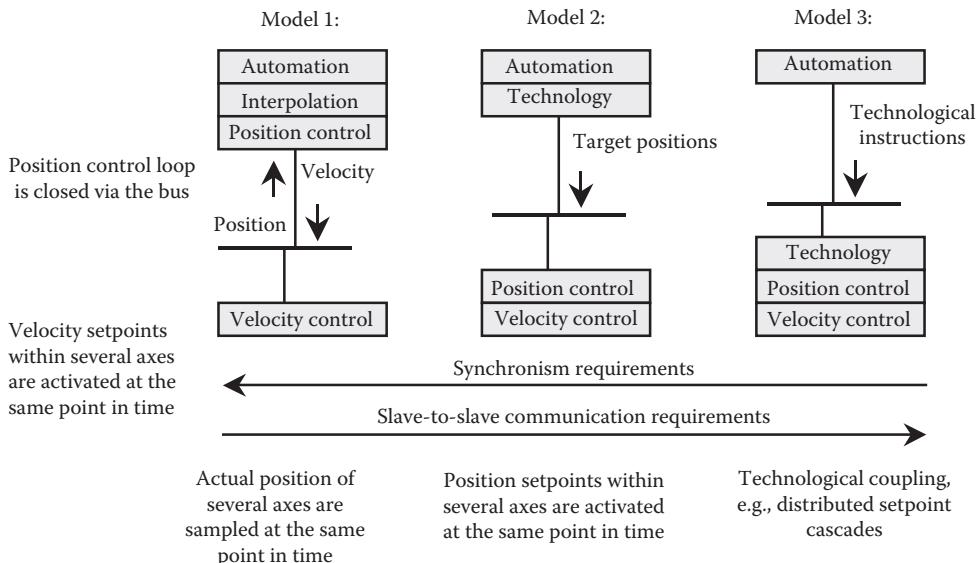

The method of integrating drives in automation solutions is highly dependent on the task of the drives (Figure 11.18). The more drives are acting independently from the central host controllers, the more they require slave-to-slave communication capabilities. On the other hand, the more the central host controllers are taking over the computing tasks, the more synchronization of the involved drives is required (Figure 11.19).

For this reason, PROFIdrive defines six classes covering the majority of applications.

With standard drives (class 1), the drive is controlled by means of a main setpoint value (e.g., rotational speed), whereby the speed control is carried out by the drive controller. In case of standard drives

**FIGURE 11.17** Slave redundancy in PROFIBUS.

**FIGURE 11.18** Different requirements for distributed drive applications.

with a technological function (class 2), the automation process is broken down into several subprocesses, and some of the automation functions are shifted from the central programmable controller to the drive controllers. PROFIBUS serves as the technology interface in this case. Slave-to-slave communication between the individual drive controls is a requirement for this solution.

The positioning drive (class 3) integrates an additional position controller in the drive, thus covering an extremely broad spectrum of applications (e.g., the twisting on and off of bottle tops). The positioning tasks are passed on to the drive controller over PROFIBUS and executed. The central motion control (classes 4 and 5) enables the coordinated motion sequence of multiple drives. The motion is primarily controlled over a Central Numeric Control (CNC). PROFIBUS serves to close the position control loop, as well as synchronize the clock (Figure 11.20).

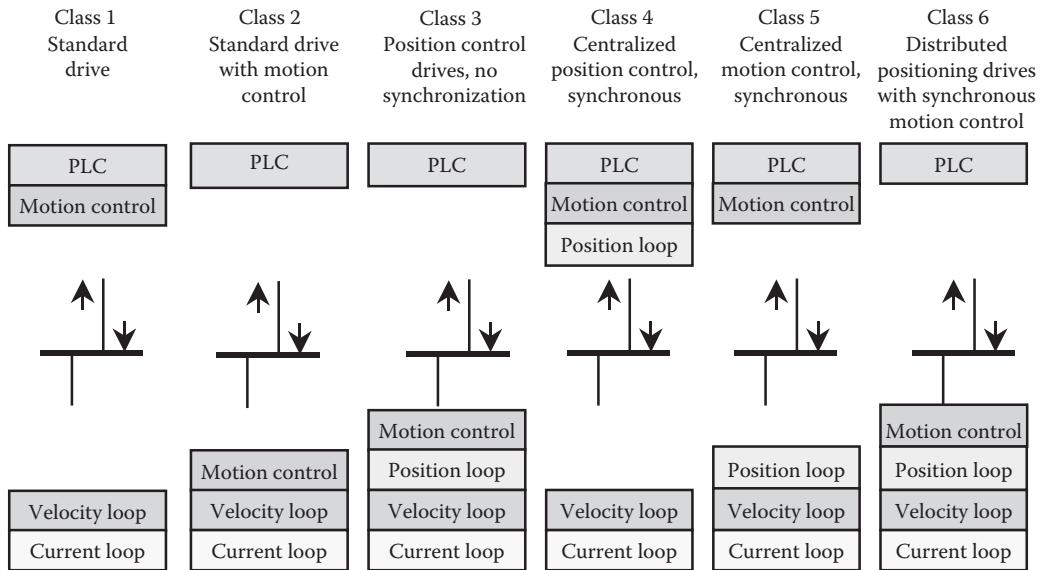

FIGURE 11.19 PROFIdrive defines six application classes.

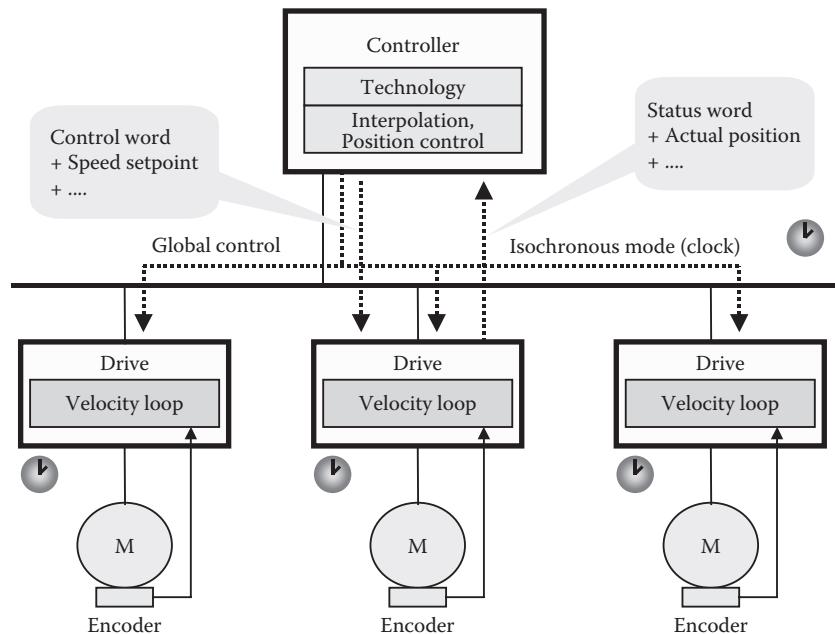

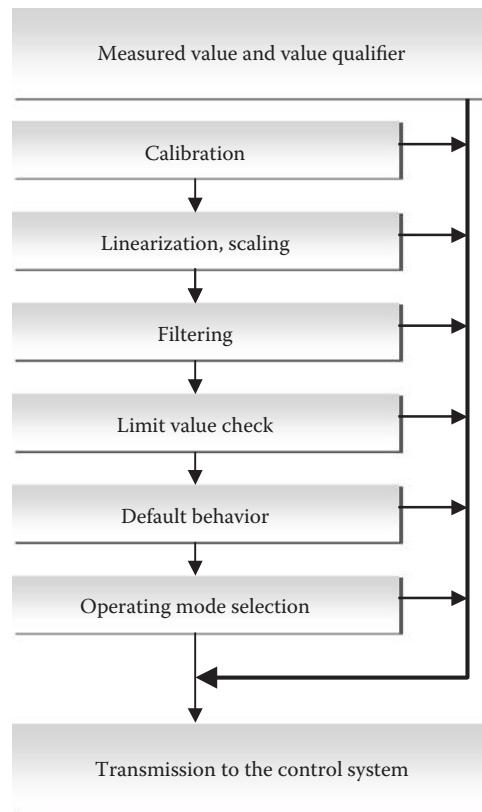

FIGURE 11.20 Positioning with central interpolation and position control.

The position control concept (dynamic servo-control) of this solution also supports extremely sophisticated applications with linear motors. Distributed automation by means of clocked processes and electronic shafts (class 6) can be implemented using slave-to-slave communication and isochronous slaves. Sample applications include *electrical gears*, *curve discs*, and *angular synchronous processes*.

In contrast to other drive profiles, PROFIdrive only defines the access mechanisms to the parameters and a subset of approx. 30 profile parameters, which include fault buffers, drive controllers, device identification, etc.

**FIGURE 11.21** Signal processing defined in profile PA devices.

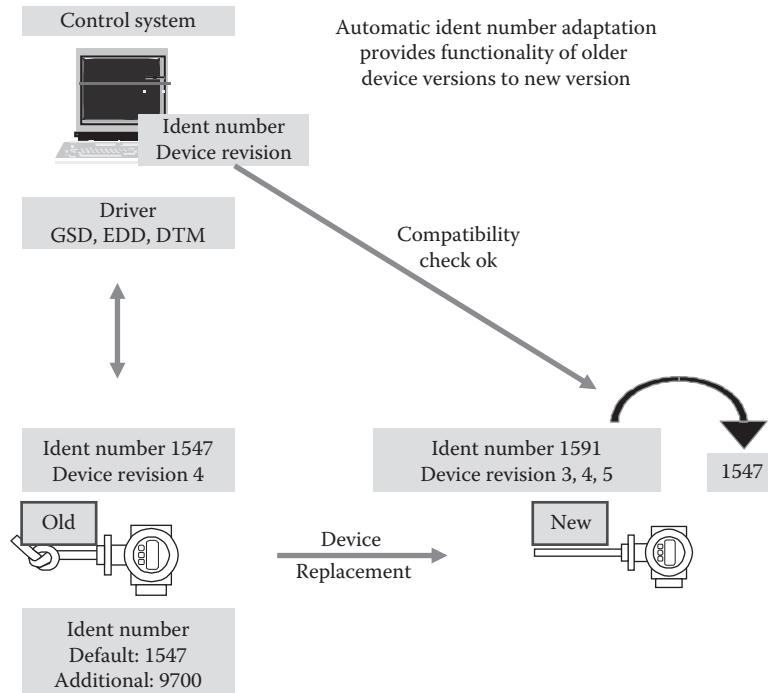

All other parameters (which may number more than 1000 in complex devices) are *manufacturer-specific*, which provide drive manufacturers great flexibility when implementing control functions.

The profile for *PA devices* defines all functions and parameters for different classes of devices for process automation with local intelligence [5,8]. They can execute part of the information processing or even take over the overall functionality of the automation systems. The profile includes all steps of a typical signal flow—from process sensor signals to the preprocessed process value that is communicated to the control system together with a value qualifier (Figure 11.21).

The profile for PA devices is documented in a general model description containing the currently valid specifications for all device types and in device data sheets containing the agreed additional specifications for individual device classes. The profile for PA devices includes device data sheets for quantity measurement of pressure and differential pressure; level; temperature; flow rate; and data sheets for valves, actuators, analyzers, analog, and digital inputs (DIs) and digital outputs (DOs).

The current version 3.02 of the profile provides users with powerful possibilities for operating plants more efficiently. The most important of the functions are described in the following.

*Field device replacement* has been very much simplified and shortened (see Figure 11.22). Once the device has been replaced, the control system detects the device and the device version expected at the bus address based on the message frame of the master. The new device answers with the appropriate Ident Number and is then included in the cyclic communication of the master. The process value is available again immediately after the device start-up. Additional intervention in the control system is not required. User-specific parameters are loaded via the cyclic channel, and the device can be operated as usual by using the abilities of the former profile version. In order to be able to use the new functionality of the new version, the device general station

**FIGURE 11.22** Device replacement with PA Profile Version 3.02.

description (GSD) and the configuration of the device have to be updated. This can be done during the next scheduled plant shutdown, after which all the new functionality of the device is available.

In order to shorten the time required for uploading or downloading the device parameter assignment, the PA Profile Version 3.02 has introduced a solution: by grouping parameter sets, it is now possible to reduce the time required to transfer parameters by a factor of 5–10, thereby achieving the fastest transfer times for a fieldbus in process automation.

*Classification of diagnostic messages* has been structured according to NAMUR Recommendation NE 107. The objective is to lessen the burden on the plant operator by providing only the information that is necessary for reliable process operation. The status that is reported to operators is limited to four categories: *failure*, *function check*, *out of specification*, and *maintenance required*.

In process engineering, it is common to use blocks for describing the characteristics and functions of a measuring point, or manipulating point, at a certain control point and to represent an automation application through a combination of these types of blocks. Therefore, the specification for PA devices uses a *function block model* according to IEC 61804 to represent functional sequences as shown in Figure 11.23. The blocks are implemented by the manufacturers as software in the field devices and, taken as a whole, represent the functionality of the device.

The following three block types are used:

1. A Physical Block (PB) contains the characteristic data of a device, such as device name, manufacturer, version and serial number, etc. There can only be one PB in each device.
2. A Transducer Block (TB) contains all the data required for processing an unconditioned signal delivered from a sensor for passing on to a function block. If no processing is required, the TB can be omitted. Multifunctional devices with two or more sensors have a corresponding number of TBs.
3. A Function Block (FB) contains all data for final processing of a measured value prior to transmission to the control system or for adjusting the parameter before it is finally set. Different FBs are available: Analog Input Block (AI), which delivers the measured value from the sensor/TB to the

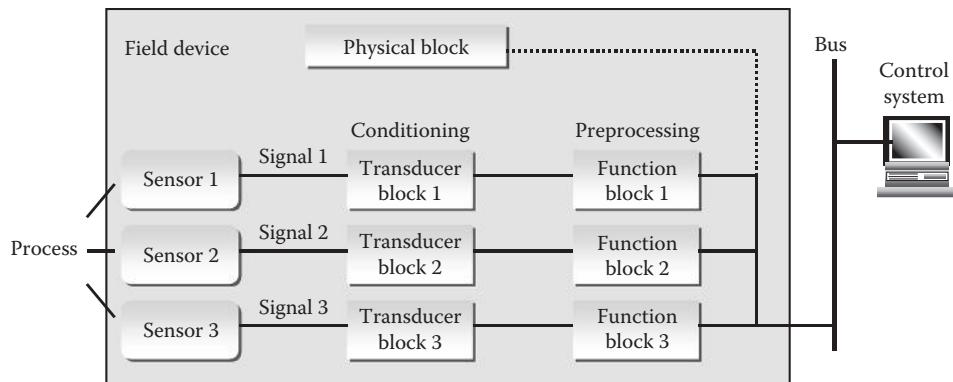

FIGURE 11.23 Block structure of a PA field device.

control system, Analog Output Block (AO), which provides the device with the value specified by the control system, Digital Input (DI), which provides the control system with a digital value from the device, and Digital Output (DO), which provides the device with the value specified by the control system.

The profile for *Ident Systems* defines complete communication and processing models for barcode readers and transponder systems. These are primarily intended for extensive use with the DP-V1 functionality. While the cyclic data transmission channel is used for small data volumes to transfer status/control information, the acyclic channel serves the transmission of large data volumes that result from the information in the barcode reader or transponder. The definition of standard PROXY function blocks [9] according IEC 61131-3 has facilitated the use of these systems and paves the way for the application of open solutions on completion of international standards, such as ISO/IEC 15962 and ISO/IEC18000.

The profile for *weighing and dosage systems* follows similar approaches as the Ident Systems. Communication and processing models are defined for four classes of devices or systems:

1. Simple scale
2. Comfort scale
3. Continuous scale
4. Batch scale

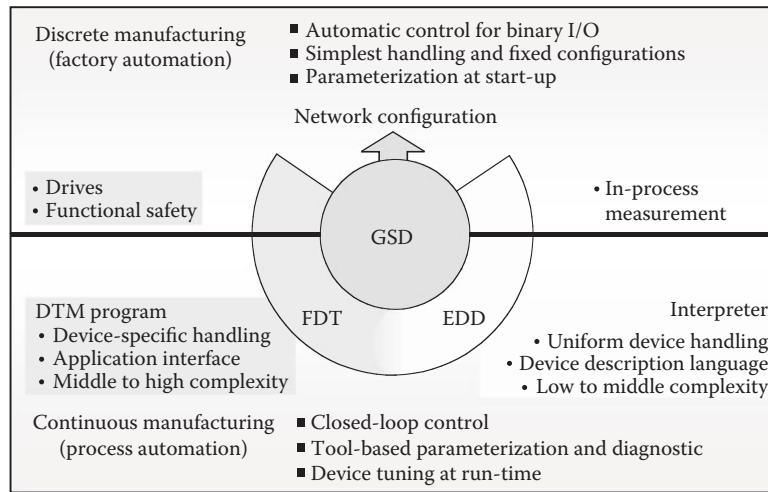

These new types of profiles will dramatically reduce the engineering costs and improve the bidding process during project execution.

### 11.4.3 Host Application Profiles

Application profiles usually define the functionality from the point of view of field devices. The host application profiles specification document defines the necessary functions of the counterpart of the field device, which is the host with its related engineering system. Typically, the host is a PLC or a Distributed Control System (DCS) controller. The host application profiles specification does not describe any new feature. It rather provides an overview of which PROFIBUS/PROFINET functionality on the host side is required for which application profile.

## 11.5 Integration Technologies

Modern field devices in both factory and process automation provide a wide range of information and also execute functions that were previously executed in PLCs and control systems. To execute these tasks, the tools for commissioning, maintenance, engineering, and parameterization of these devices

**FIGURE 11.24** Integration technologies for PROFIBUS DP.

require an exact and complete description of device data and functions, such as the type of application function, configuration parameters, range of values, units of measurement, default values, limit values, identification, etc. The same applies to the controller/control system, whose device-specific parameters and data formats must also be made known (integrated) to ensure error-free data exchange with the field devices.

PROFIBUS has developed a number of methods and tools (integration technologies) for this type of device description, which enable the standardization of device management. The performance range of these tools is optimized to specific tasks (Figure 11.24), which has given rise to the term *scalable device integration*. General Station Description (GSD) and Electronic Device Description (EDD) are both a sort of *electronic device data sheets*, developed with different languages according to the special scope, whilst a Device Type Manager (DTM) is a software component containing specific field device functions for parameterization, configuration, diagnostics, and maintenance, generated by mapping and to be used together with the universal software interface Field Device Tool (FDT), which is able to implement software components.

### 11.5.1 GSD

A GSD is an electronically readable ASCII text file and contains both general and device-specific specifications for communication (GSD) and network configuration. Each of the entries describes a feature that is supported by a device. By means of keywords, a configuration tool reads the device identification (ID number), the adjustable parameters, the corresponding data type, and the permitted limit values for the configuration of the device from the GSD. Some of the keywords are mandatory, for example, Vendor\_Name. Others are optional, for example, Sync\_Mode\_supported. A GSD replaces the previously conventional manuals and supports automatic checks for input errors and data consistency, even during the configuration phase.

Distinction is made between a device GSD (for an individual device only) and profile GSD, which may be used for devices that comply exactly with a profile such as PROFIdrive or PA devices.

GSD for compact devices, whose block configuration is already known on delivery, can be created completely by the device manufacturer. GSD for modular devices, whose block configuration is not yet conclusively specified on delivery, must be configured by the user in accordance with the actual module configuration using the configuration tool.

The device manufacturers are responsible for the scope and quality of the GSD of their devices. Submission of a profile GSD (containing the information from the profile of a device family) or an individual device GSD (device-specific) is essential for certification of a device.

### 11.5.2 EDD

An EDD is, like a GSD, an electronic device data sheet, but developed by using a more powerful and universal language, the electronic device description language (EDDL). An EDD typically describes the application-related parameters and functions of a field device such as configuration parameters, ranges of values, units of measurement, default values, etc. An EDD is a versatile source of information for engineering, commissioning, runtime, asset management, and documentation. It also contains support mechanisms to integrate existing profile descriptions in the device description, allow references to existing objects, access standard dictionaries, and allow assignment of the device description to a device.

An EDD is independent of operating systems and supports the user by its uniform user and operation interface (only one tool, reliable operation, reduced training, and documentation costs) and also the device manufacturer (no specific knowledge required; existing EDDs and libraries can be used).

The EDD concept is suitable for tasks of low to middle complexity.

### 11.5.3 FDT/DTM

A DTM is software that is generated by mapping the specific functions and dialogs of a field device for parameterization, configuration, diagnostics, and maintenance, complete with user interface, in a software component. This component is called DTM and is integrated in the engineering tool or control system over the FDT interface. A DTM uses the routing function of an engineering system for communicating across the hierarchical levels. It works similar to a printer driver, which the printer supplier includes in delivery and must be installed on the PC by the user. The DTM is generated by the device manufacturer and is included in delivery of the device.

DTM generation may be performed using one of the following options:

- Specific programming in a higher programming language
- Reuse of existing components or tools through their encapsulation as DTM
- Generation from an existing device description using a compiler or interpreter
- Use of the DTM toolkit of MS Visual Basic

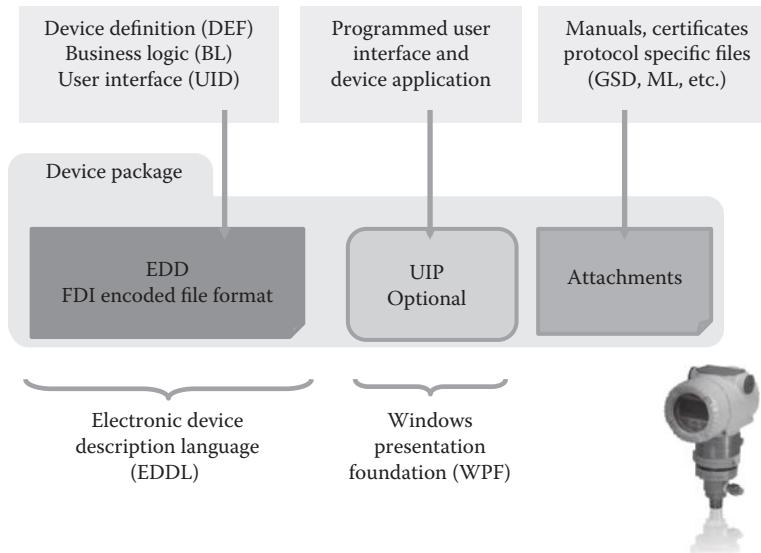

With DTMs, it is possible to obtain direct access to all field devices for planning, diagnostics, and maintenance purposes from a central workstation. The FDT/DTM concept is protocol-independent and, with its mapping of device functions in software components, opens up interesting new user options. The DTM/FDT concept is very flexible, resolves nowadays interface and navigation needs, and is suitable for tasks of middle to high complexity.

### 11.5.4 Field Device Integration

For many years, EDD and FDT/DTM have been the two technologies for managing information from intelligent field devices. Users increasingly asked to form a single, unified solution, which takes account of the various tasks over the entire lifecycle for both simple and complex devices, including configuration, commissioning, diagnosis, and calibration (asset management).

This was how the field device integration (FDI) project was born and supported by the five major automation foundations, including the FDT Group, Fieldbus Foundation, HART Communication Foundation, PI, and OPC Foundation.

The core of FDI technology is the scalable FDI device package (Figure 11.25), which encompasses all features of the electronic description of a field device:

**FIGURE 11.25** Conception of the FDI device package.

The Device Definition (DEF), Business Logic (BL), and User Interface Description (UID) are based on EDDL (IEC 61804-3). The optional User Interface Plug-in (UIP) offers the advantages of freely programmable user interfaces familiar from FDT, based on Windows Presentation Foundation (WPF).

Via the FDI device package, the device manufacturers define which data, functions, and user interfaces have to be represented in the information model of the FDI server.

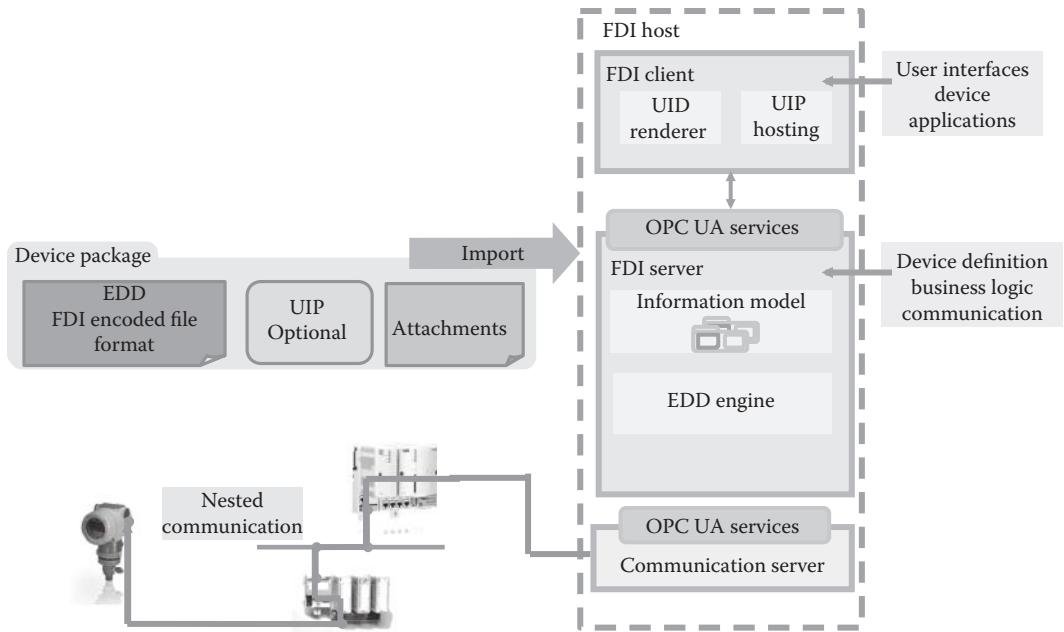

- The DEF describes the field device data and the internal structure (e.g., blocks).
- The BL primarily ensures that the device data remain consistent. The dynamic dependencies, in particular, play a part here.
- UID and UIP define the field device user interfaces.
- Product documentation, protocol-specific files, such as GSD or Common File Format (CFF), etc., will all be added to the FDI package as attachments.

The FDI concept is based on the client-server architecture model. In the architecture of this kind, a server provides services that are accessed by various clients (often distributed).

The FDI architecture is based on the OPC Unified Architecture (OPC UA). The FDI server imports FDI device packages into its internal device catalog (Figure 11.26), which makes version management of FDI packages very easy. The representation of device instances in the FDI server takes place in the information model. The information model maps the communication topology of the automation system by representing the entire communication infrastructure and the field devices as objects. If an FDI client wishes to work with a device, it accesses the information model and, for example, loads the user interface of the device in order to display it on the client side, in a similar manner to a web browser. The FDI server always ensures that the device data remain consistent.

## 11.6 Technical Support

PI maintains more than 50 approved PI competence centers worldwide. These facilities provide users and manufacturers with all kinds of advice and support. As institutions of PI, they are vendor-neutral service providers and adhere to the mutually agreed-upon rules. The PI competence centers are regularly checked for their suitability as part of an individually tailored approval process. More than 25 PI

**FIGURE 11.26** The architecture of an FDI host.

training centers have been set up to establish a uniform global training standard for engineers and technicians. Approval of the training centers and their experts ensures the quality of the training and, thus, of the engineering and installation services for PROFIBUS. Refer to the website for current addresses.

### 11.6.1 Quality Assurance

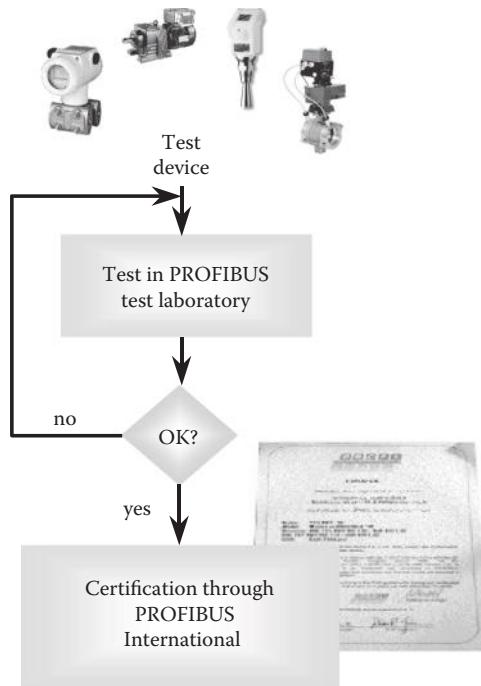

In order for PROFIBUS devices of different types and manufacturers to correctly fulfill tasks in the automation process, it is essential to ensure the error-free exchange of information over the bus. The requirement for this is a standard-compliant implementation of the communications protocol and application profiles by device manufacturers. To ensure that this requirement is fulfilled, the PI has established a quality assurance procedure whereby, on the basis of test reports, certificates are issued to devices that successfully complete the test.

Basis for the certification procedure are the standards ISO 9646 (guides concerning conformance inspection and certification) and EN 45000. The PI has approved manufacturer-independent PI test labs in accordance with the specifications of these standards. Only these test laboratories are authorized to carry out device tests, which form the basis for granting certificates (Figure 11.27).

PI maintains 11 approved PI Test Labs (PITL) worldwide. As institutions of PI, they are vendor-neutral service providers and adhere to the mutually agreed-upon rules. The testing services provided by the PITLs are regularly audited in accordance with a strict accreditation process to ensure that they meet the necessary quality requirements. Refer to the website for current addresses [2].

The test procedure, which is the same for all PI Test Labs, is made up of several parts:

- The GSD/EDD check ensures that the device description files comply with the specification.
- The hardware test tests the electric characteristics of the PROFIBUS interface of the device for compliance with the specifications. This includes terminating resistors, suitability of the implemented drivers and other modules, and the quality of line level.
- The function test examines the bus access and transmission protocol and the functionality of the test device.

**FIGURE 11.27** Certification procedure.

- The conformity test forms the main part of the test. The objective is to test the conformity of the protocol implementation with the standard.
- The interoperability test checks the test device for interoperability with the PROFIBUS devices of other manufacturers in a multivendor plant. This checks that the functionality of the plant is maintained when the test device is added. Operation is also tested with different masters.

Once a device has successfully passed all the tests, the manufacturer can apply for a certificate from PI. Each certified device contains a certification number as a reference.

### 11.6.2 Implementation Support

For the device development or implementation of the PROFIBUS protocol, a broad spectrum of standard components and development tools (PROFIBUS ASICs, PROFIBUS stacks, monitoring, and commissioning tools) as well as services are available that enable device manufacturers to realize cost-effective development. A corresponding overview is available in the product catalog of PI [2].

*PROFIBUS interface modules* are ideal for a low/medium volume of devices to be produced. These credit card size modules implement the entire bus protocol. They are fitted on the master board of the device as an additional module.

*PROFIBUS protocol chips* (single chips, communication chips, and protocol chips) are recommended for an individual implementation in the case of high volume of devices.

The implementation of single-chip ASICs is ideal for simple slaves (I/O devices). All protocol functions already are integrated on the ASIC. No microprocessor or software is required. Only the bus interface driver, the quartz, and the power electronics are required as external components.

For intelligent slaves, parts of the PROFIBUS protocol are implemented on a protocol chip and the remaining protocol parts implemented as software on a microcontroller. In most of the ASICs available on the market, all cyclic protocol parts [4] have been implemented, which are responsible for the transmission of time-critical data.

For complex masters, the time-critical parts of the PROFIBUS protocol are also implemented on a protocol chip and the remaining protocol parts implemented as software on a microcontroller. Various ASICs of different suppliers are currently available for the implementation of complex master devices. They can be operated in combination with many common microprocessors.

An overview for commercially offered PROFIBUS chips and software (PROFIBUS stacks) is available at the PROFIBUS website [2]. For further information, please contact the suppliers directly.

*Modem chips* are available to realize the (low) power consumption, which is required when implementing a bus-powered field device with MBP transmission technology. Only a feed current of 10–15 mA over the bus cable is available for these devices, which must supply the overall device, including the bus interface and the measuring electronics. These modems take the required operating energy for the overall device from the MBP bus connection and make it available as feed voltage for the other electronic components of the device. At the same time, the digital signals of the connected protocol chip are converted into the bus signal of the MBP connection modulated to the energy supply.

## 11.7 Wide Range of Applications

PROFIBUS is the world's most popular fieldbus with an unparalleled wide application field in discrete manufacturing and process control as well as in drive technology and safety applications. Profibus offers a fully integrated platform for discrete and process applications, which is a major benefit in the process industries where upstream, mainstream, and downstream processes have to work together (Figure 11.28).

Industries using PROFIBUS range from critical petrochemical operations and high-volume robotic manufacturing plants, right across the spectrum to food and drink, water and waste water, power and glass, pulp and paper, and many others.

International*

### 12.1 Introduction

---

Automation technology is undergoing continuous change due to the ever-shorter innovation cycles for new products. The use of fieldbus technology in the 1990s has represented a significant innovation. It has enabled the migration of automation systems from centralized to decentralized systems. In this regard, PROFIBUS has set the standard as the market leader for more than 20 years. In today's automation technology, not only fieldbuses but also increasingly Ethernet and information technology (IT), with established standards like TCP/IP and XML, are calling the shots. Integrating IT into automation allows significantly better communication options between automation systems, extensive configuration and diagnostic possibilities, and network-wide service functionality.

PROFINET is the open standard for Industrial Ethernet of PROFIBUS & PROFINET International (PI) that covers all automation technology requirements [1]. With PROFINET, real-time (RT) capable solutions can be implemented for discrete manufacturing and continuous process automation, safety applications, and the entire range of drive technology up to and including isochronous motion control applications.

In addition to the RT capability and utilization of IT, protection of investment also plays an important role with PROFINET. PROFINET enables existing fieldbus systems such as PROFIBUS to be integrated without modifications.

The use of open standards, simple handling ability, and integration into existing plant units has defined PROFINET from the start.

### 12.1.1 Standardization

PROFINET is 100% Ethernet-compatible according to IEEE standards. The standard Ethernet protocol as defined in IEEE 802 was extended only in cases of requirements that could not otherwise be met in a satisfactory manner. PROFINET is standardized in IEC 61158 and IEC 61784 [2]. The mandatory certification test services by authorized PI Test Labs for PROFINET products ensure a high-quality standard.

### 12.1.2 PROFINET at a Glance

The motivation to create PROFINET came from user requirements and the anticipated cost reduction resulting from manufacturer-independent plant-wide engineering.

The PROFINET architecture supports a modular concept that allows users to choose the functionality they require. The functionality differs mainly in terms of the type of data exchange. This distinction is necessary to satisfy the very stringent requirements for data transmission speed that exist for some applications.

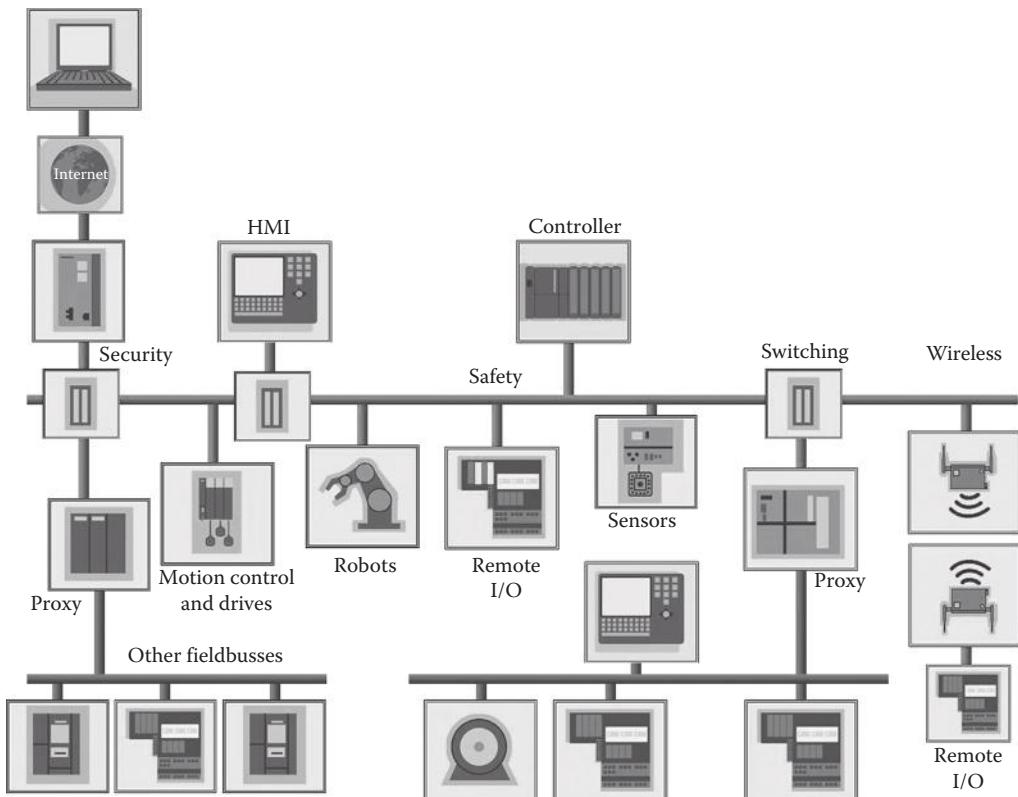

PROFINET defines the following requirements for data communication:

- 100 Mbps data communication with copper or fiber-optic transmission (100 Base TX and 100 Base FX)
- Full duplex transmission
- Switched Ethernet
- Autonegotiation (negotiation of transmission parameters)
- Autocrossover (send and receive cable crossover in the switch)
- Wireless communication based on WLAN and Bluetooth

PROFINET describes an I/O data view of distributed I/O. It includes RT communication and isochronous RT (IRT) communication with distributed I/O. The designations RT and IRT simply refer to the RT properties of communication.

PROFINET uses UDP/IP as the higher-level protocol for demand-oriented data exchange such as parameters, configuration data, and interconnection information. UDP stands for user datagram protocol; it includes the broadcast communication in connection with IP. This satisfies the prerequisites for interfacing the automation levels with other networks (MES and ERP).

In parallel to this UDP/IP communication, cyclic data exchange in PROFINET is based on the scalable RT concept. Based on this concept, PROFINET enables deterministic and isochronous transmission of time-critical process data. Process data and alarms are always transmitted in RT according to the definitions of IEEE and IEC for high-performance data exchange of I/O data. RT communication constitutes the basis for data exchange in PROFINET I/O. RT data are handled with higher priority compared to TCP (UDP)/IP data. This method of data exchange allows bus cycle times in the range of a few hundred milliseconds to be achieved.

**FIGURE 12.1** Example architecture of a PROFINET communication.

Isochronous data exchange with PROFINET is defined in the IRT concept. Here, data exchange cycles are normally in the range of a few tens of microseconds up to 1 ms. IRT communication differs from RT communication mainly in its isochronous behavior, meaning that the bus cycles are started with maximum precision. The start of a bus cycle can deviate by a maximum of 1  $\mu$ s.

### 12.1.2.1 Higher-Level Functions

PROFINET provides many application-driven functions for commissioning and operation. These include visualization of plant topology in conjunction with informative diagnostics and support of convenient plant diagnostics through a combination of basic services available by default in the higher-level controller.

For easy replacement of field devices—when a fault occurs—PROFINET has integrated neighborhood detection functionality. This information can be used to represent the plant topology in a very easy-to-understand graphic display.

The proven PROFIsafe safety technology is also available for PROFINET. The ability to use the same cable for standard and safety-related communication saves on devices, engineering, and setup.

PROFINET integrates automatically reacting redundancy solutions and intelligent diagnostic concepts. Acyclic diagnostic data transmission provides important information regarding the status of the network and devices, including a display of the network topology. The defined concepts for media and system redundancy guarantee a smooth changeover from one communication path to another in the event of an error. Both features significantly increase plant availability.

### 12.1.2.2 Network Installation

PROFINET network installations are oriented toward specific requirements for Ethernet networks in industrial environments. The installation guideline provides plant construction engineers and plant operators with simple rules for installing Ethernet networks and associated cabling. This guideline provides device manufacturers with clear specifications for device interfaces.

### 12.1.2.3 Web Integration

PROFINET is based on Ethernet and supports TCP/IP. This enables the use of web technologies for accessing an integrated web server in a field device, among other things. Depending on the specific device implementation, diagnostics and other information can be easily called up using a standard web browser, even across network boundaries. Thus, an engineering system is no longer necessary for simple diagnostics. PROFINET itself does not define any specific contents or formats. Rather, it allows an open and free implementation.

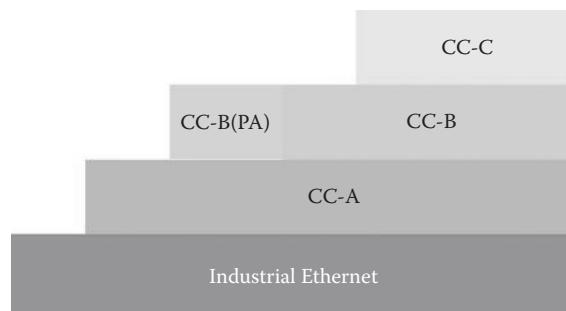

### 12.1.2.4 Fieldbus Integration

In addition, PROFINET plays an important role when it comes to investment protection. PROFINET enables a seamless integration of existing fieldbus systems like PROFIBUS without changes to existing devices. That means that the investments of plant operators, machine and plant manufacturers, and device manufacturers are all protected.

## 12.1.3 Conformance Classes

The scope of functions supported by PROFINET I/O is clearly divided into conformance classes (CCs). These provide a practical summary of the various minimum properties. There are three CCs that build upon one another and are oriented to typical applications (Figure 12.2).

CC-A provides basic functions for PROFINET I/O with RT communication. All IT services can be used without restriction. Typical applications are found, for example, in building automation. Wireless communication is possible only in this class. CC-B extends the concept to include network diagnostics via IT mechanisms as well as topology information. The system redundancy function important for continuous process automation is contained in an extended version of CC-B named CC-B (PA). CC-C describes the basic functions for devices with hardware-supported bandwidth reservation and synchronization (IRT communication) and is thus the basis for isochronous applications.

**FIGURE 12.2** Structure of conformance classes.

## 12.2 PROFINET Basics

PROFINET I/O follows the provider/consumer model for data exchange. Configuring a PROFINET I/O system has the same look and feel as in PROFIBUS. The following device classes are defined for PROFINET I/O:

*I/O-Controller:* This is typically the programmable logic controller (PLC) on which the automation program runs. This is comparable to a class 1 master in PROFIBUS. The I/O-Controller provides output data to the configured I/O-Devices in its role as provider and is the consumer of input data of I/O-Devices.

*I/O-Device:* An I/O-Device is a distributed I/O field device that is connected to one or more I/O-Controllers via PROFINET I/O. It is comparable to the function of a slave in PROFIBUS. The I/O-Device is the provider of input data and the consumer of output data.

*I/O-Supervisor:* This can be a programming device, personal computer (PC), or human machine interface (HMI) device for commissioning or diagnostic purposes and corresponds to a class 2 master in PROFIBUS.

A plant unit has at least one I/O-Controller and one or more I/O-Devices. I/O-Supervisors are usually integrated only temporarily for commissioning or troubleshooting purposes.

### 12.2.1 Device Model of an I/O-Device

The device model describes all field devices in terms of their possible technical and functional features. It is specified by the device access point (DAP) and the defined modules for a particular device family. A DAP is the access point for communication with the Ethernet interface and the processing program. A variety of I/O modules can be assigned to it in order to manage the actual process data communication.

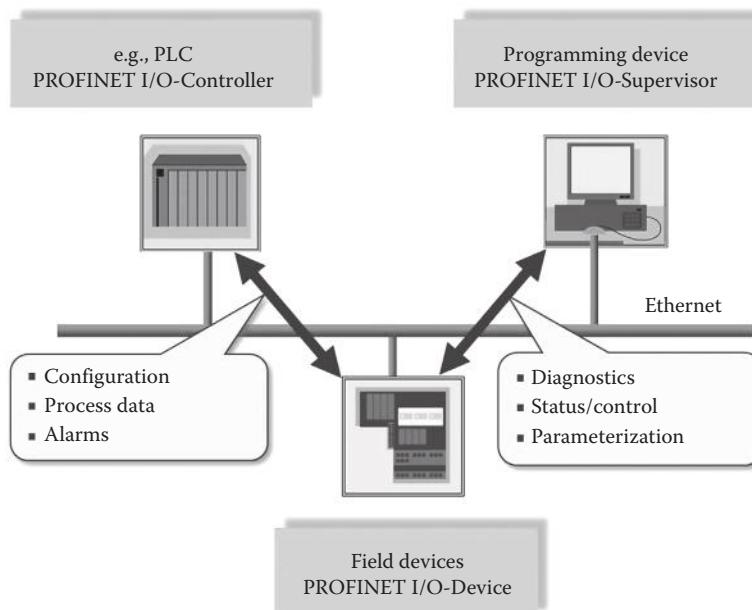

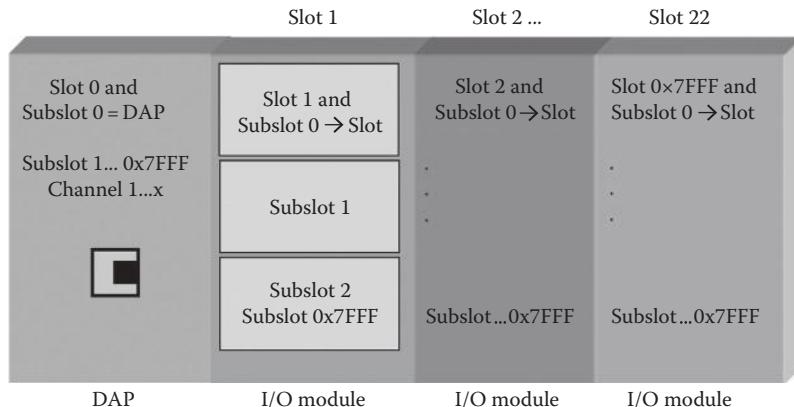

FIGURE 12.3 Communication paths for PROFINET I/O.

**FIGURE 12.4** Addressing of I/O data in PROFINET I/O based on slots and subslots.

The following structures are standardized for an I/O-Device:

- The slot designates the place where an I/O module is inserted in a modular I/O field device. The configured modules containing one or more subslots for data exchange are addressed on the basis of different slots.
- Within a slot, the subslots represent the actual interface to the process (inputs/outputs). The granularity of a subslot (bitwise, byte-wise, or word-wise division of I/O data) is determined by the manufacturer. The data content of a subslot is always accompanied by status information, from which the validity of the data can be derived.
- The index specifies the data within a slot/subslot that can be read or written acyclically via read/write services. For example, parameters can be written to a module or manufacturer-specific module data can be read out on the basis of an index.

Cyclic I/O data are addressed by specifying the slot/subslot combination. These can be freely defined by the manufacturer. For acyclic data communication via read/write services, an application can specify the data to be addressed using slot, subslot, and index (Figure 12.4).

To avoid competing accesses in the definition of user profiles (e.g., for PROFIdrive, weighing and dosing, etc.), the application process identifier/instance (API) is defined as an additional addressing level.

PROFINET differentiates between compact field devices, in which the degree of expansion is already specified in the as-delivered condition and cannot be changed by the user, and modular field devices, in which the degree of expansion can be customized for a specific application when the system is configured.

## 12.2.2 Device Descriptions

All field devices are described in terms of their available technical and functional properties in an XML-based general station description file (GSD) to be created by the field device developer. It contains among other things a representation of the device model that is reproduced by the DAP and the defined modules for a particular device family. The GSD files of the field devices to be configured are required for system engineering. It contains all data relevant for engineering as well as for data exchange with the field device.

The GSD contains all necessary information:

- Properties of the I/O-Device (e.g., communication parameters)
- Insertable modules (number of type)

- Configuration data for individual modules (e.g., 4–20 mA analog input)
- Parameters of modules
- Error texts for diagnostics (e.g., wire break, short circuit)

Because XML is an open, widespread, and accepted standard for describing data, appropriate tools and derived properties are automatically available, including

- Creation and validation through a standard tool
- Foreign language integration
- Hierarchical structuring

The GSD structure corresponds to ISO 15745 and consists of a header, the device description in the application layer (e.g., configuration data and module parameters), and the communication properties description in the transport layer.

### 12.2.3 Communication Relations

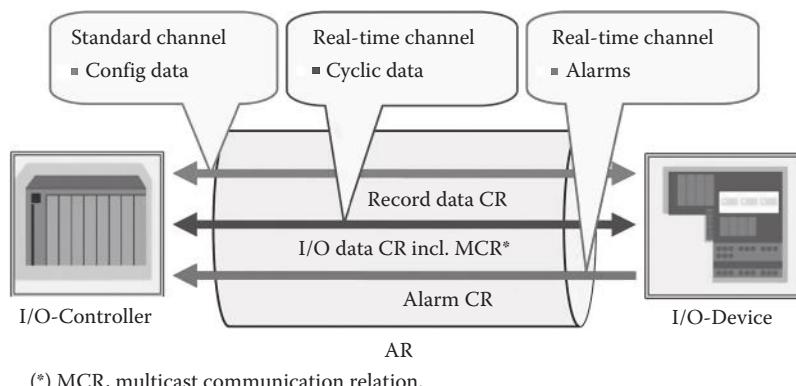

To establish communication between the I/O-Controller and an I/O-Device, the communication paths must be established. These are set up by the I/O-Controller during system start-up based on the configuration data in the engineering system. This specifies the data exchange explicitly.

Every data exchange is embedded into an application relation (AR) (Figure 12.5). Within the AR, communication relations (CRs) specify the data explicitly. As a result, all data for the device modeling, including the general communication parameters, are downloaded to the I/O-Device. An I/O-Device can have multiple ARs established from different I/O-Controllers.

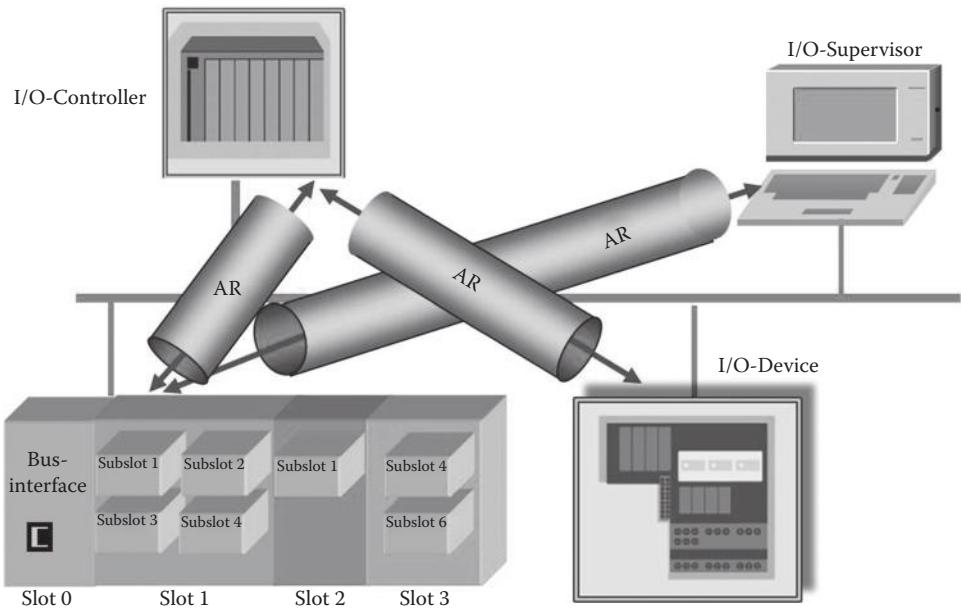

The communication channels for cyclic data exchange (I/O data CR), acyclic data exchange (record data CR), and alarms (alarm CR) are set up simultaneously.

Multiple I/O-Controllers can be used in a PROFINET system (Figure 12.6). If these I/O-Controllers are to be able to access the same data in the I/O-Devices, this must be specified when configuring (shared devices, shared inputs).

An I/O-Controller can establish one AR each with multiple I/O-Devices. Within an AR, several 10 Communication Relations (10 CR) and APIs can be used for data exchange. This can be useful, for example, if more than one user profile (PROFIdrive, Encoder, etc.) is involved in the communication and different subslots are required. The specified APIs serve to differentiate the data communication within an I/OCR.

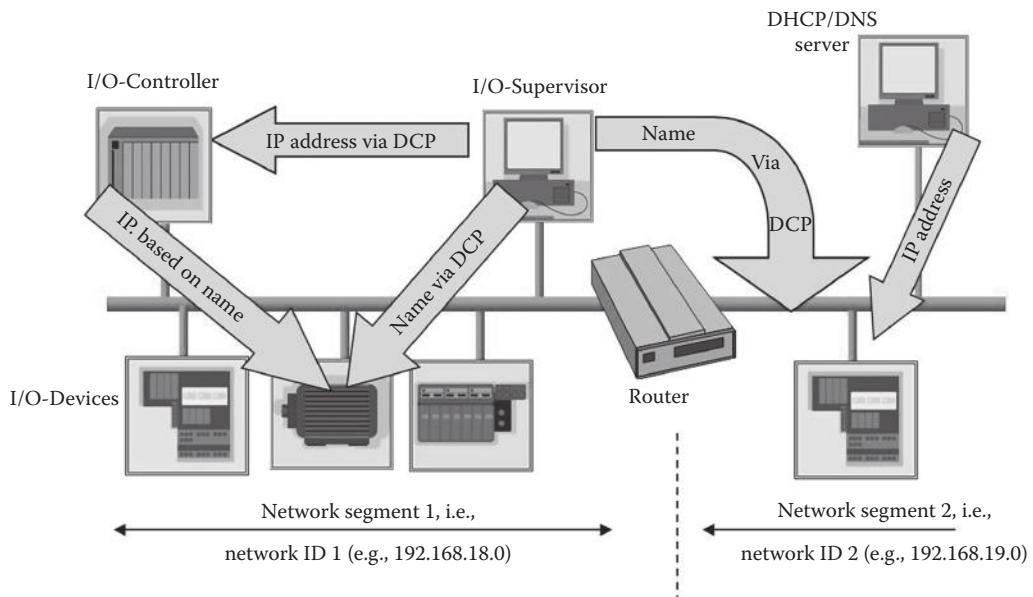

**FIGURE 12.5** Application relations and communication relations.

**FIGURE 12.6** A field device can be accessed by multiple application relations.

#### 12.2.4 Addressing

In PROFINET I/O, each field device has a symbolic name that uniquely identifies the field device within a PROFINET I/O system. This name is used for assigning the IP address and the MAC address. The dynamic configuration protocol (DCP) integrated in every I/O-Device is used for this purpose. Figure 12.7 shows a network that comprises two subnets. These are represented by the different network IDs (subnet mask).

**FIGURE 12.7** Example of a PROFINET network consisting of two subnets.

MAC address and OUI (organizationally unique identifier)

Each PROFINET device is addressed based on MAC address. This address is unique worldwide. The company code (bits 47 to 24) can be obtained free of charge from the IEEE Standards Department. This part is called the OUI (organizationally unique identifier).

PI offers MAC addresses to device manufacturers that do not want to apply for their own OUI, in other words, a fixed OUI and the manufacturer-specific portion (bits 23 to 0). This service allows components to acquire MAC addresses from the PI Support Center. The assignment can be completed in 4 K-ranges.

The OUI of PI is 00-0E-CF and is structured as shown in the table. The OUI can be used for up to 16,777,214 products.

Bit significance 47 to 24						Bit significance 23 to 0					
0	0	0	E	C	F	X	X	X	X	X	X
Company code→OUI						Consecutive number					

FIGURE 12.8 OUI for PROFINET.

After the system is configured, the engineering tool loads all information required for data exchange to the I/O-Controller, including the IP addresses of the connected I/O-Devices. Based on the name (and the associated MAC address), an I/O-Controller can recognize the configured field devices and assign them the specified IP addresses using the DCP (address resolution). Alternatively, addressing can be performed via a DHCP server.

Following address resolution, the system powers up, and parameters are transmitted to the I/O-Devices. The system is then available for productive data traffic.

Optionally, the name can also be automatically assigned to the I/O-Device by means of a specified topology based on neighborhood detection.

A PROFINET I/O-Device is addressed for direct data exchange by its MAC address (see Figure 12.8).

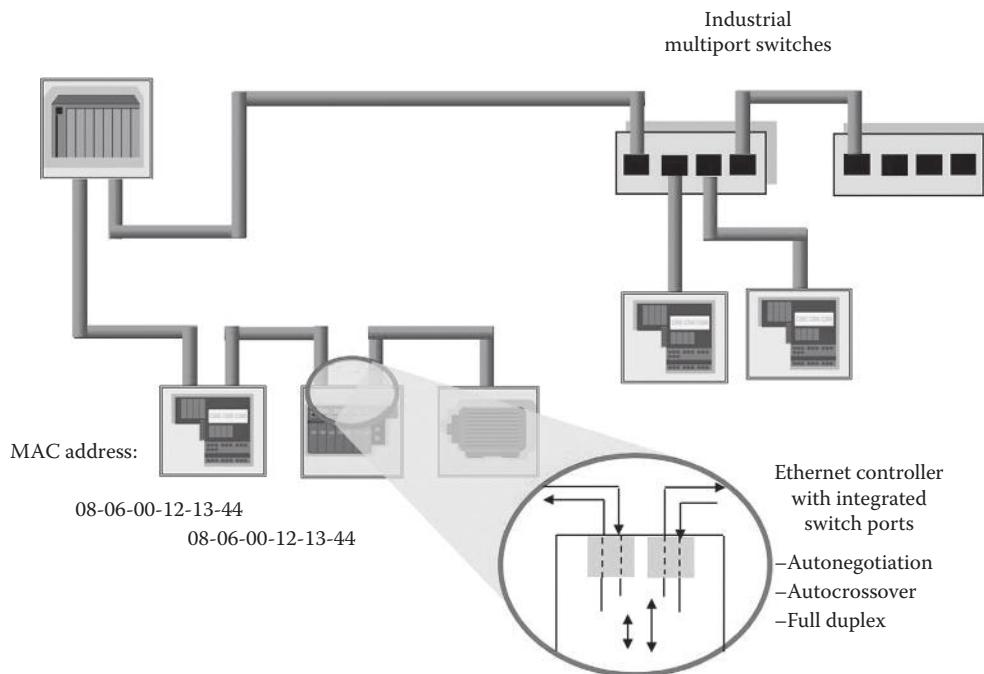

PROFINET I/O field devices are always connected via switches as network components (Figure 12.9). This takes the form of a star topology with separate multiport switches or a line topology with switches integrated in the field device (two ports occupied).

PROFINET transmits some message frames (e.g., for synchronization and neighborhood detection) using the MAC address of the respective port instead of the device MAC address. For this reason, each switch port in a field device requires a separate port MAC address. Therefore, a two-port field device has three MAC addresses in the as-delivered condition. However, these port MAC addresses are not visible to users. Because the field devices are connected via switches, PROFINET always sees only point-to-point connections (same as Ethernet). That is, if the connection between two field devices in a line is interrupted, the field devices located after the interruption are no longer accessible. If increased availability is required, provision must be made for redundant communication paths when planning the system, and field devices/switches that support the redundancy concept of PROFINET must be used.

PROFINET-suitable switches must support *autonegotiation* (negotiation of transmission parameters) and *autocrossover* (crossing of send and receive lines in the switch). As a result, communication can be established autonomously.

## 12.2.5 Configuration and Data Exchange

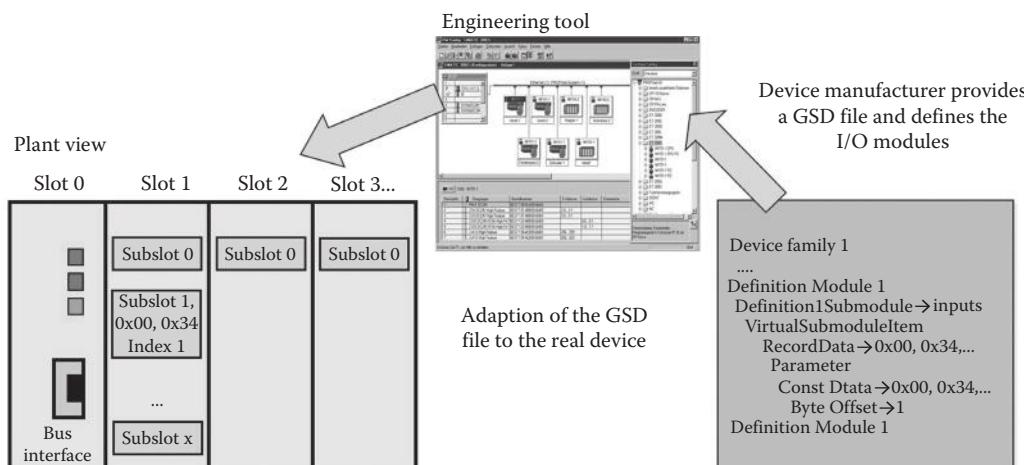

Each I/O-Controller manufacturer also provides an engineering tool for configuring a PROFINET system.

**FIGURE 12.9** Usage of switches.

During system engineering, the configuring engineer joins together the modules/submodules of an I/O-Device defined in the GSD file in order to map them to the real system and to assign them to slots/subslots. The configuring engineer configures the real system symbolically in the engineering tool. Figure 12.10 shows the relationship between the GSD definitions, configuration, and real plant view.

After completion of system engineering, the configuring engineer downloads the system data to the I/O-Controller, which also contains the system-specific application. As a result, an I/O-Controller has all the information needed for addressing the I/O-Devices and for data exchange.

**FIGURE 12.10** Assignment of definitions in the GSD file to I/O-Devices when configuring the system.

Before an I/O-Controller can perform data exchange with the I/O-Devices, these must be assigned an IP address based on their configured name. This must take place prior to system power-up. The I/O-Controller performs this automatically using the DCP.

After a start-up/restart, an I/O-Controller always initiates system power-up based on the configuration data without any intervention by the user. During system power-up, an I/O-Controller establishes an explicitly specified CR and AR with an I/O-Device. This specifies the cyclic I/O data, the alarms, the exchange of acyclic read/write services, and the expected modules/submodules. After successful system power-up, the exchange of cyclic process data, alarms, and acyclic data traffic can occur.

### 12.2.6 Diagnostics

PROFINET I/O supports a multilevel diagnostic concept that enables efficient fault localization and correction. When a fault occurs, the faulty I/O-Device generates a diagnostic alarm to the I/O-Controller. This alarm triggers a call in the PLC program to the appropriate program routine in order to be able to respond to the fault. If a device or module defect requires a complete replacement of the device or module, the I/O-Controller automatically performs a parameter assignment and configuration of the new device or module.

The diagnostic information is structured hierarchically:

- Slot number (module)
- Channel number
- Channel type (input/output)
- Coded fault cause (e.g., wire break, short circuit)
- Additional manufacturer-specific information

When an error occurs in a channel, the I/O-Device generates a diagnostic alarm to the I/O-Controller. This alarm triggers a call in the control program to the appropriate fault routine. After processing of the fault routine, the I/O-Controller acknowledges the fault to the I/O-Device. This acknowledgment mechanism ensures that a sequential fault processing is possible in the I/O-Controller.

## 12.3 Principles of PROFINET Communication

---

Standard Ethernet communication via TCP/IP or UDP/IP communication is sufficient for data communication in some cases. In industrial automation, however, requirements regarding time behavior and isochronous operation exist that cannot be fully satisfied using the TCP/IP or UDP/IP channel.

A scalable RT concept is the solution for this. With RT, this concept can be realized with standard network components, such as switches and standard Ethernet controllers. RT communication takes place without TCP/IP information.

The transmission of RT data is based on cyclical data exchange using a provider/consumer model. The communication mechanisms of layer 2 (according to the ISO/OSI model) are sufficient for this. For optimal processing of RT frames within an I/O-Device, the VLAN tag according to IEEE 802.1Q (prioritization of data frames) has been supplemented with a special Ethertype that enables fast channelization of these PROFINET frames in the higher-level software of the field device. Ethertypes are allocated by IEEE and are therefore an unambiguous criterion for differentiation among Ethernet protocols. Ethertype 0x8892 is specified in IEEE and is used for fast data exchange in PROFINET I/O.

PROFINET I/O provides protocol definitions for the following services:

- Address resolution for field devices
- Cyclic transmission of I/O data on RT basis
- Acyclic transmission of alarms to be acknowledged

- Acyclic transmission of data (parameters, detailed diagnostics, I&M data, information functions, etc.) on an as-needed basis
- Redundancy mode for RT frames

The combination of these communication services in the higher-level controller makes it possible to implement convenient system diagnostics, topology detection, and device replacement, among other things.

Many communication services in PROFINET occur in RT.

PROFINET provides scalable Ethernet-based communication. The following three performance levels are differentiated:

1. UDP/IP for data that are not time critical, such as parameter assignment and configuration data
2. RT for time-critical process data in standard application in the area of discrete manufacturing and continuous process automation
3. IRT for particularly challenging application requirements, such as those for motion control

These three PROFINET communication performance levels cover the entire spectrum of automation applications in their overall diversity. The PROFINET communication standard is characterized by the following in particular:

- Coexisting utilization of RT and TCP-based IT communication on one line
- Uniform RT protocol for communication between the controller and the distributed field devices for all applications
- Scalable RT communication from performant to high-performant and isochronous mode

Scalability and a uniform communication basis represent two of the major strengths of PROFINET. They guarantee continuity to the corporate management level and fast response times in the automation process.

### 12.3.1 Standard Communication with UDP

PROFINET uses Ethernet and UDP with IP as the basis for communication. TCP/UDP with IP is a de facto standard with respect to communication protocols in the IT area. However, for interoperability (i.e., the interaction between applications), establishment of a common communication channel over the field devices, based on TCP/UDP, is insufficient. TCP or UDP represent only the foundation on which Ethernet devices can exchange data via a transport channel in local and distributed networks. Therefore, additional specifications and protocols beyond TCP/UDP—the so-called application protocols—are required. Interoperability is guaranteed only if the same application protocol is used on the devices. Typical application protocols are SMTP (for e-mail), FTP (for file transfer), and HTTP (used on the Internet).

### 12.3.2 Real-Time Communication

To enable enhanced scaling of communication options and, thus, also of determinism in PROFINET I/O, RT classes have been defined for data exchange. From the user perspective, these classes involve unsynchronized and synchronized communication. The details are managed by the field devices themselves.

RT frames are automatically prioritized in PROFINET compared to UDP/IP frames. This is necessary in order to prioritize the transmission of data in switches to prevent RT frames from being delayed by UDP/IP frames.

RT applications in discrete manufacturing automation require update, or response times, in the range of 5–10 ms. The update time refers to the time that elapses when a variable is generated by an application in a device, then sent to a peer device via the communication system, and then received updated by the application. For devices, the implementation of an RT communication causes only a small load on the processor so that execution of the user program continues to take precedence. From experience,

in the case of Fast Ethernet (100 Mb/s Ethernet), the transmission rate on the line in proportion to the execution in the devices can be disregarded. Most of the time is consumed in the application. The time it takes to provide data to the application of the provider is not influenced by the communication. This also applies to processing of data received in the consumer. As a result, noteworthy improvements in update rates and thus the RT performance can be obtained primarily through proper optimization of the communication stack in the provider and the consumer. In order to satisfy RT demands in automation, PROFINET uses an optimized RT communication channel.

Motion control applications require update rates in the range of 1 ms along with a jitter for consecutive update cycles of 1  $\mu$ s for cases involving up to 100 stations. To satisfy these requirements, PROFINET defines the IRT time slot-controlled transmission process on layer 2 for Fast Ethernet. That means every device knows exactly in which time slot it is allowed to send data over the bus. Through synchronization of the devices involved (network components and PROFINET devices) with the accuracy indicated earlier, a time slot can be specified during which data critical for the automation task are transferred. The communication cycle is split into a deterministic part and an open part. The cyclic RT message frames are dispatched in the deterministic channel, while the RT and UDP/IP message frames are transported in the open channel. The process is comparable to the traffic on a highway where the left lane is reserved for time-critical traffic (IRT traffic) and the remaining traffic elements (RT and UDP/IP traffic) are prevented from switching to this lane. Even if there is traffic jam in the right lane, the time-critical traffic is not impacted.

Isochronous data transmission is realized based on hardware, for example, using application specific integrated circuits (ASICs). Such an ASIC covers the cycle synchronization and time slot reservation functionality for the RT data. Realization in hardware ensures the accuracy requirements to be achieved within the order of magnitude required. Furthermore, the processor in the PROFINET device is relieved from communication tasks. The resulting additional runtime can be made available for automation tasks.

## 12.4 Conformance Classes and Their Functions

PROFINET I/O is a performance-optimized communication system. It encompasses a broad scope of functions to meet the requirements of all industrial applications. However, the complete scope of functions is not required in every application. For this reason, PROFINET I/O offers scalability with regard to the functionality supported by the particular application.

PI has classified the scope of functions in PROFINET I/O into three CCs. The minimum requirements for these three CCs (CC-A, CC-B, and CC-C) have been defined from the perspective of the plant operator. They enable plant operators to easily select field devices and bus components with explicitly defined minimum properties [3].

### 12.4.1 Basic Functions of Conformance Class A

The basic functions of CC-A include cyclic exchange of I/O data with RT properties, acyclic data communication for reading and writing of demand-oriented data (parameters and diagnostics), including the identification and maintenance (I&M) function for reading out device information, and a flexible alarm model for signaling device and network errors with three alarm levels (maintenance required, urgent maintenance required, and diagnostics) (Table 12.1).

**TABLE 12.1** List of Basic Functions

Requirement	Technical Function/Solution
Cyclic data exchange	PROFINET with RT communication
Acyclic parameter data/device identification (HW/FW)	Read Record/Write Record I&M
Device/ network diagnostics (alarms)	Diagnostics and maintenance

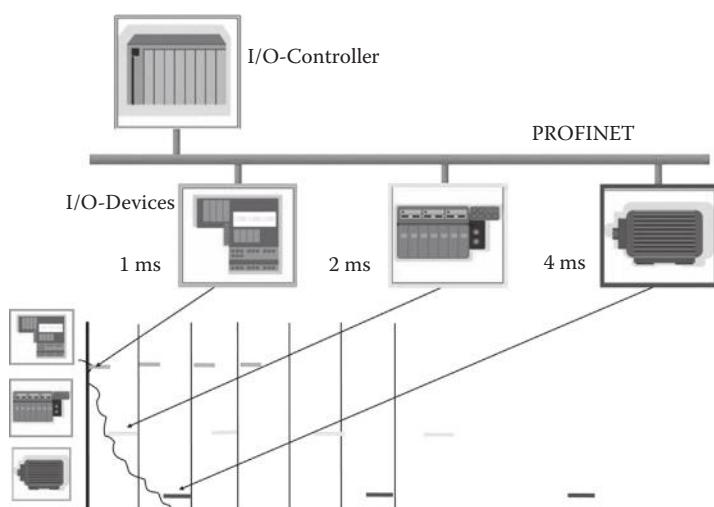

### 12.4.1.1 Cyclic Data Exchange

Cyclic I/O data are transmitted via the *I/O Data CR* unacknowledged as RT data between provider and consumer in an assignable time base. The cycle time can be specified individually for connections to the individual devices and are thus adapted to the requirements of the application. Likewise, different cycle times can be selected for the input and output data, within the range of 250 µs to 512 ms. The connection is monitored using a time monitoring setting that is derived from a multiple of the cycle time. During data transmission in the frame, the data of a subslot are followed by a provider status. This status information is evaluated by the respective consumer of the I/O data. As a result, it can evaluate the validity of the data from the cyclic data exchange alone. In addition, the consumer statuses for the opposite direction are transmitted. The data in the message frames are followed by accompanying information that provides information about the data's validity, the redundancy, and the diagnostic status (data status and transfer status). The cycle information (cycle counter) of the provider is also specified so that its update rate can be determined easily. Failure of cyclic data to arrive is monitored by the respective consumer in the CR. If the configured data fail to arrive within the monitoring time, the consumer sends an error message to the application. The cyclic data exchange can be realized with standard network components, such as switches and standard Ethernet controllers and takes place directly on layer 2 with Ethertype 0x8892 and without any UDP/IP information. For optimized processing of cyclic data within a network component, the VLAN tag according to IEEE802.1Q is additionally used with a high priority.

### 12.4.1.2 Acyclic Parameter Data

Acyclic data exchange can be used for parameter assignment or configuration of I/O-Devices or reading out status information using the *record data CR*. This is accomplished with read/write frames using standard IT services via UDP/IP, in which the different data records are distinguished by their index. In addition to the data records available for use by device manufacturers, the following system data records are also specially defined:

- Diagnostic information on the network and device diagnostics can be read out by the user from any device at any time.
- Error log entries (alarms and error messages), which can be used to determine detailed timing information about events within an I/O-Device.
- I&M information.

**FIGURE 12.11** Real-time communication with cycle time monitoring.

The ability to read out identification information from a field device is very helpful for maintenance purposes. For example, this allows inferences to be drawn in response to incorrect behavior or regarding unsupported functionality in a field device. This information is specified in the I&M data structures. The I&M functions are subdivided into five different blocks (IM0... IM4) and can be addressed separately using their index. Every I/O-Device must support the IM0 function with information about hardware and firmware versions. The I&M specification titled *Identification & Maintenance Functions* can be downloaded from the PI website [4].

#### 12.4.1.3 Device/Network Diagnostics

A status-based maintenance approach is currently gaining relevance for operation and maintenance. It is based on the capability of devices and components to determine their status and to communicate this using agreed mechanisms. A system for reliable signaling of alarms and status messages by the I/O-Device to the I/O-Controller was defined for PROFINET I/O for this purpose. This alarm concept covers both system-defined events (such as removal and insertion of modules) and signaling of faults that were detected in the utilized controller technology (e.g., defective load voltage or wire break). This is based on a state model that defines *good* and *defective* status as well as the *maintenance required* and *maintenance demanded* prewarning levels. A typical example for this is the loss of media redundancy, which signals *maintenance required*, but because of its redundancy, the media is still fully functional.

Diagnostic alarms must be used if the error or event occurs within an I/O-Device or in conjunction with the connected components. They can signal an incoming or outgoing fault status. In addition, the user can define corresponding process alarms for messages from the process, for example, limit temperature exceeded. In this case, the I/O-Device may still be operable. These process alarms can be assigned different priorities than the diagnostic alarms.

#### 12.4.2 Network Diagnostics and Management of Conformance Class B

CC-B expands devices to include functions for additional network diagnostics and for topology detection. PROFINET uses simple network management protocol (SNMP) for this. Portions of management information base 2 (MIB2) and lower link discovery protocol-MIB (LLDP-EXT MIB) are integrated into devices. In parallel to SNMP, all diagnostics and topology information can also be called up from the physical device object (PDEV) using acyclic PROFINET services.

##### 12.4.2.1 Network Management Protocol

In existing networks, SNMP has established itself as the de facto standard for maintenance and monitoring of network components and their functions. SNMP can read access network components, in order to read out statistical data pertaining to the network as well as port-specific data and information for neighborhood detection. In order to monitor PROFINET devices with an established management system, implementation of SNMP is mandatory for devices of CCs B and C.

##### 12.4.2.2 Neighborhood Detection

Automation systems can be configured flexibly in a line, star, or tree structure. To compare the specified and actual topologies, that is, to determine which field devices are connected to which switch port and to identify the respective port neighbor, LLDP according to IEEE 802.1AB was applied in PROFINET I/O. PROFINET field devices exchange existing addressing information with connected neighbor devices via each switch port. The neighbor devices are thereby unambiguously identified, and their physical location is determined (e.g., in Figure 12.12: the delta device is connected to port 003 of switch 1 via port 001).

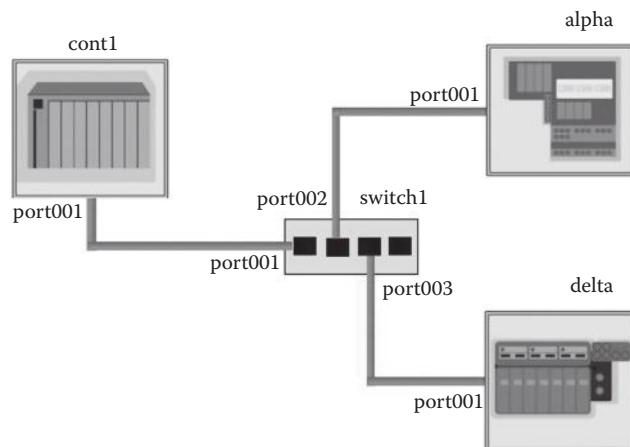

FIGURE 12.12 Example for neighbors.

#### 12.4.2.3 Representation of the Topology

A plant owner can use a suitable tool to graphically display a plant topology and port-granular diagnostics (Figure 12.13). The information found during neighborhood detection is collected using the SNMP protocol. This provides the plant operator a quick overview of the plant status.

#### 12.4.2.4 Device Replacement

If a field device fails in a known topology, it is possible to check whether the replacement device has been reconnected in the proper position. It is even possible to replace devices without the use of an engineering tool: when replaced, a device at a given position in the topology receives the same name and parameters as its predecessor (Figure 12.14).

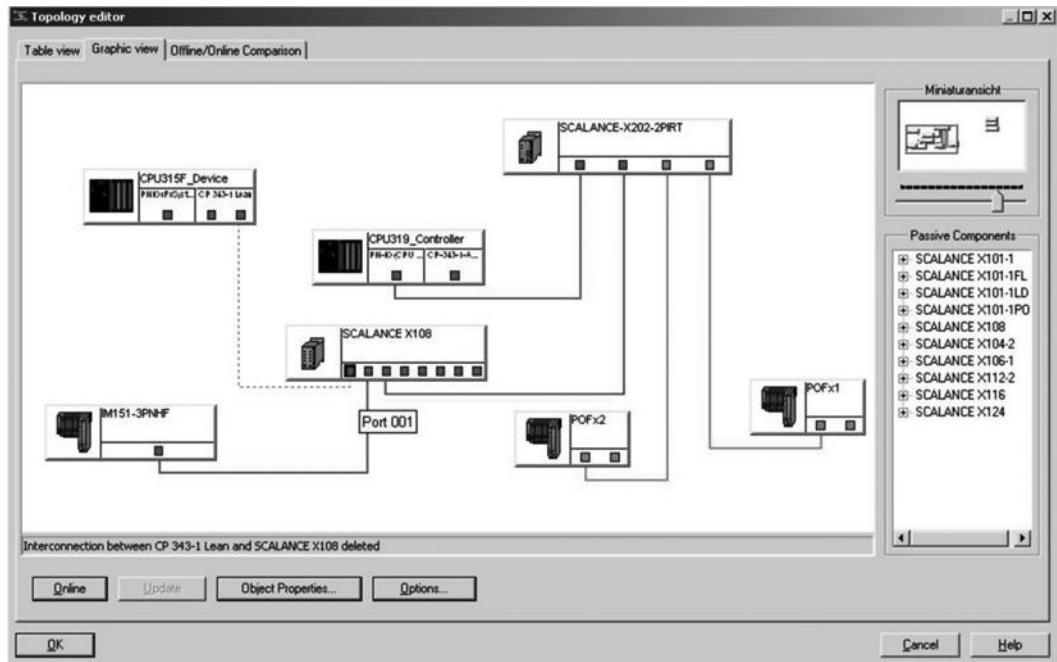

FIGURE 12.13 Example of a topology plan.

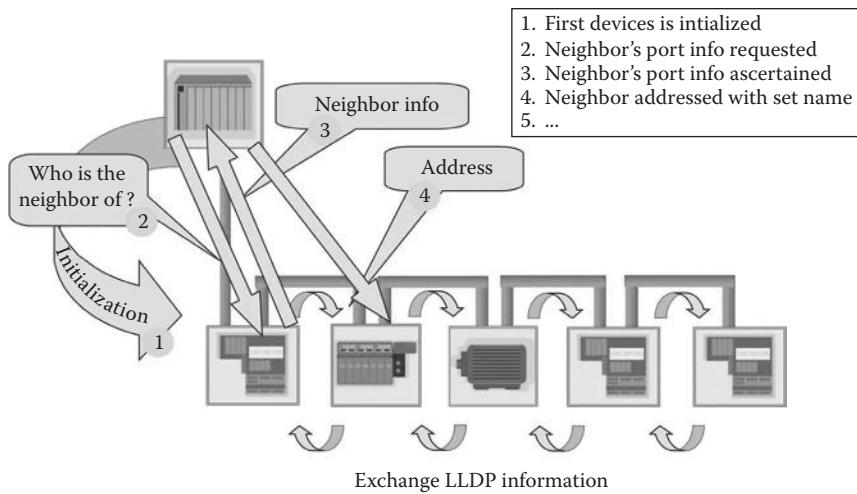

FIGURE 12.14 Device replacement procedure.

#### 12.4.2.5 Integration of Network Diagnostics into the I/O System Diagnostics

A switch must also be configured as a PROFINET I/O-Device and signal the detected network errors of a lower-level Ethernet line directly to the I/O-Controller. Acting as an I/O-Device, this type of switch can signal faults and specific operating modes to its I/O-Controller by transmitting acyclic alarms using the *alarm CR*. In this way, the network diagnostics can be integrated into the I/O system diagnostics (Figure 12.15).

#### 12.4.3 Isochronous Real-Time with Conformance Class C

CC-C includes all necessary network-wide synchronization functions for applications with the most stringent requirements for deterministic behavior. Networks based on CC-C enable applications having

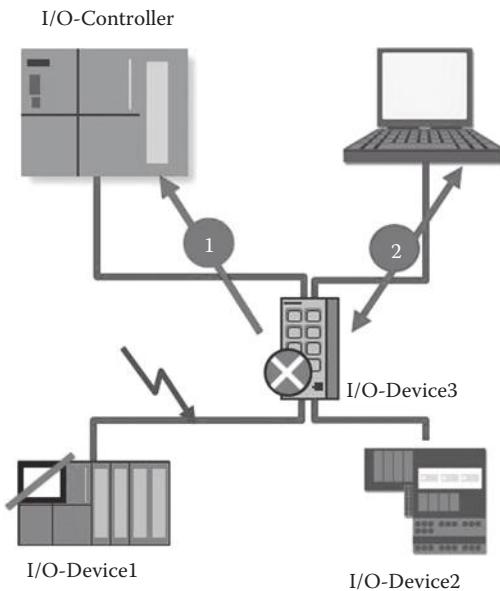

FIGURE 12.15 Integration of network diagnostics into I/O system diagnostics.

a jitter of less than 1  $\mu\text{s}$ . Cyclic data packets are transferred as synchronized packets on a reserved bandwidth. All other packets, such as packets for diagnostics or TCP/IP, share the rest of the Ethernet bandwidth. By default, the minimum update rate is defined at 250  $\mu\text{s}$  in CC-C. For maximum control performance, this can be reduced to as low as 31.25  $\mu\text{s}$ , depending on the hardware used. In order to expand data volumes when cycle times are set at less than 250  $\mu\text{s}$ , a message frame optimization method (dynamic frame packing, DFP) is incorporated. With this method, nodes that are wired together in a line structure are addressed with one message frame. In addition, for cycle times less than 250  $\mu\text{s}$ , the TCP/IP communication is fragmented and transmitted in smaller packets.

#### 12.4.3.1 Synchronized Communication

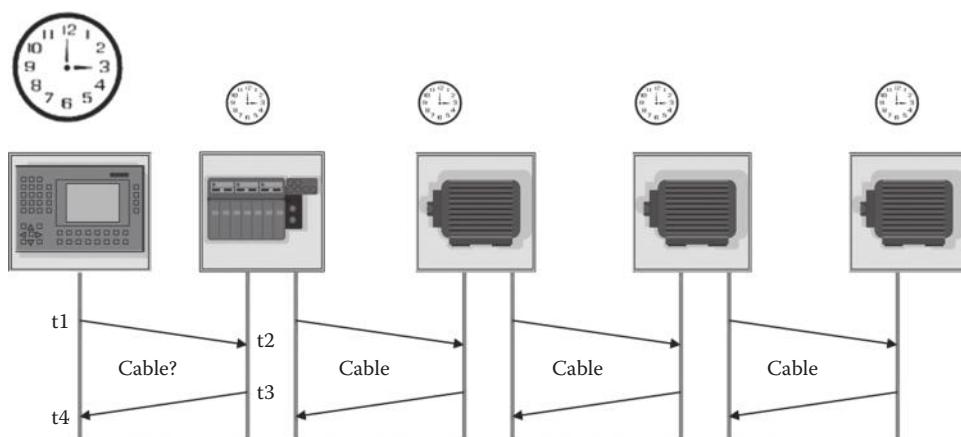

In order for the bus cycles to run synchronously (at the same time) with a maximum deviation of 1  $\mu\text{s}$ , all devices involved in the synchronous communication must have a common clock. A clock master uses synchronization frames to synchronize all local clock pulse generators of devices within a clock system (IRT domain) to the same clock (Figure 12.16). For this purpose, all of the devices involved in this type of clock system must be connected directly to one another, without crossing through any nonsynchronized devices. Multiple independent clock systems can be defined in one network.

To achieve the desired accuracy for the synchronization and synchronous operation, the runtime on each connecting cable must be measured with defined Ethernet message frames and figured into the synchronization. Special hardware precautions must be taken for implementing this clock synchronization. The bus cycle is divided into different intervals for synchronized communication (Figure 12.17). First, the synchronous data are transmitted in the real-time phase. This phase is protected from delays caused by other data and allows a high level of determinism. In the subsequent open phase, all other data are transmitted according to IEEE 802 and the specified priorities.

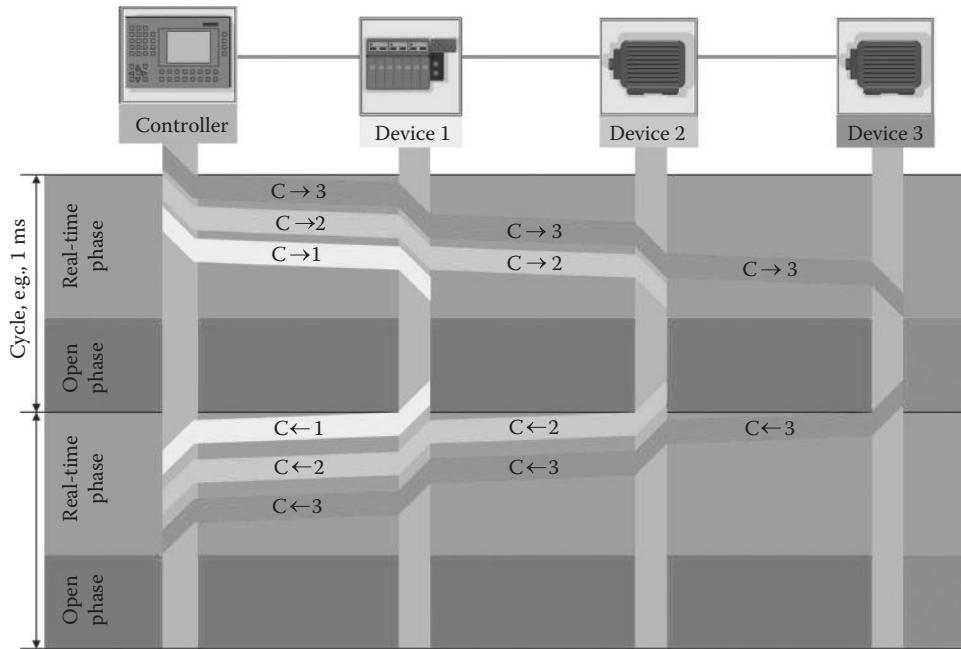

The division of the individual intervals can vary. If forwarding of the data before the start of the next reserved interval is not assured, these frames are stored temporarily and sent in the next open phase.

#### 12.4.3.2 Mixed Operation

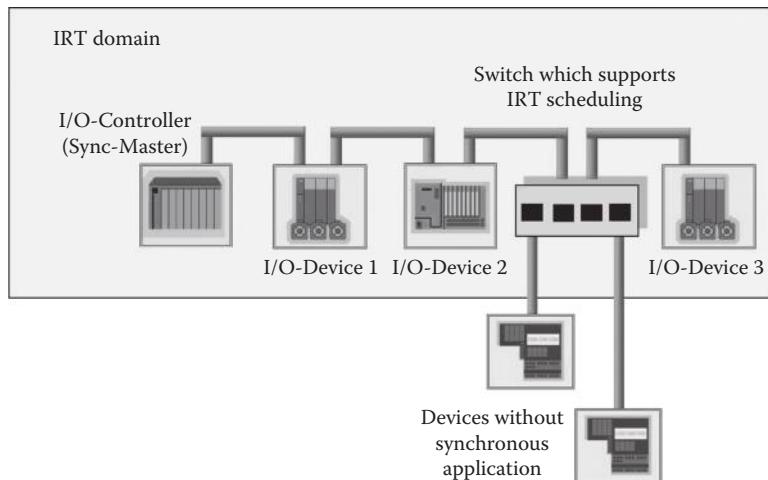

A combination of synchronous and asynchronous communication within an automation system is possible, if certain preconditions are met. A mixed operation is shown in Figure 12.18. In this example, a synchronizable switch has been integrated in the field device for devices 1–3. This enables the runtime to be determined and precise synchronization of the clock system to be maintained. The other two devices are connected via a standard Ethernet port and thus communicate asynchronously. The switch ensures that this communication occurs only during the open phase.

**FIGURE 12.16** Synchronization of clock pulse generators within an IRT domain by the clock master.

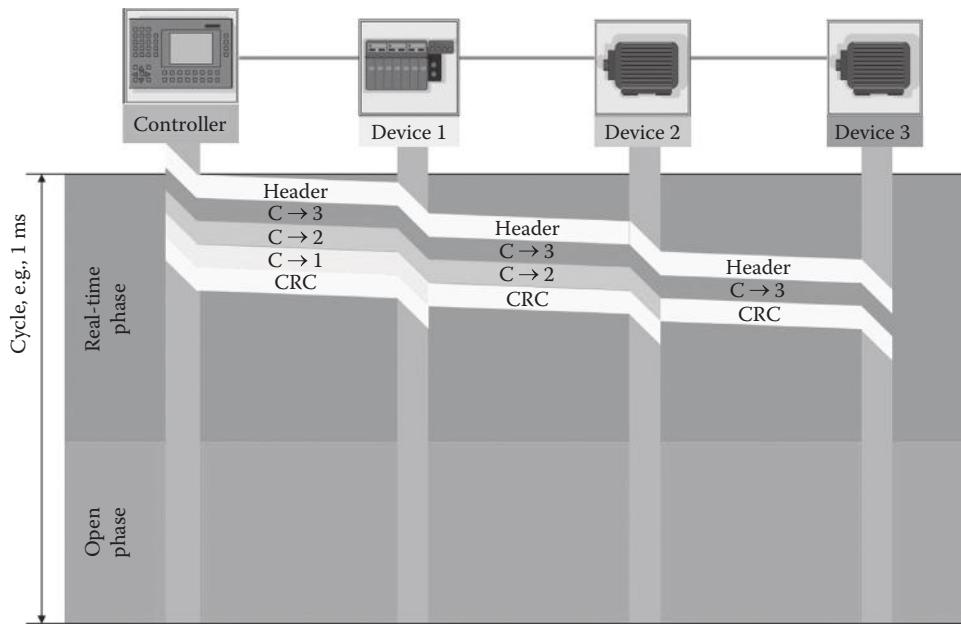

**FIGURE 12.17** IRT communication divides the bus cycle into a reserved interval (real-time phase) and an open interval (open phase).

**FIGURE 12.18** Mixed operation of synchronized and unsynchronized applications.

#### 12.4.3.3 Optimized IRT Mode

When the time ratios are subject to stringent requirements, the efficiency of the topology-oriented synchronized communication can be optimized using DFP (Figure 12.19). For a line structure, the synchronous data of several devices are optionally combined into one Ethernet frame. The individual cyclic RT data can be extracted for each node. Because the data from the field devices to the controller are also strictly synchronized, these data can be assembled by the switch in a single Ethernet frame. Ideally, only one frame is then transmitted for all the field devices in the real-time phase. This frame is disassembled or assembled in the corresponding switch, if required. This DFP technology is optional for systems with

**FIGURE 12.19** Packing of individual message frames into a group message frame.

stringent requirements. The functionalities of other intervals are retained; that is, a mixed operation is also possible here. To achieve short cycle times of up to 31.25 µs, however, the open phase must also be sharply reduced. To accomplish this, the standard Ethernet frames for the application are disassembled transparently into smaller fragments, transmitted in small pieces, and reassembled.

## 12.5 Optional Functions

Additionally, PROFINET provides a large number of optional functions that are not included in devices by default by way of CCs (Table 12.2). If additional functions are to be used, this must be checked on a case-by-case basis using the device properties (data sheet, manuals, and GSD file).

### 12.5.1 Multiple Access to Field Devices

The innovative starting point for shared devices is the parallel and independent access of two different controllers to the same device. In the case of a shared device, the user configures a fixed assignment of the various I/O modules used in a device to a selected controller. One possible application of a shared device is in fail-safe applications in which a fail-safe CPU controls the safe portion of the device and a

**TABLE 12.2** List of Possible Optional Functions

Requirement	Technical Function/Solution
Multiple access to inputs by various controllers	Shared input
Distribution of device functions to various controllers	Shared device
Extended device identification	Identification & Maintenance IM1-4
Automatic parameter assignment of devices using parameter sets	Individual parameter server
Configuration changes during operation	Configuration in Run (CiR)
Time stamping of I/O data	Time sync
Fast restart after voltage recovery	Fast start-up (FSU)
Higher availability through ring redundancy	MRP/MRPD
Call of a device-specific engineering tool	Tool Calling Interface (TCI)

standard controller controls the standard I/O within the same station. In the safety scenario, the F-CPU uses the fail-safe portion to safely switch off the supply voltage of the outputs.

In the case of a shared input, there is parallel access to the same input by two different controllers. Thus, an input signal that must be processed in two different controllers of a plant does not have to be wired twice or transferred via CPU–CPU communication.

### 12.5.2 Extended Device Identification

Further information for standardized and simplified I&M is defined in additional I&M data records. I&M1–4 (Table 12.3) contain plant-specific information, such as installation location and date, and are created during configuration and written to the device.

### 12.5.3 Individual Parameter Server

The individual parameter server functionality is available for backing up and reloading of other optional individual parameters of a field device (Figure 12.20). The basic parameter assignment of a field device is carried out using the parameters defined in the GSD file for the field device. A GSD file contains module parameters for I/O modules, among other things. These are stored as static parameters and can be loaded from the I/O-Controller to an I/O-Device during system power-up. For some field devices, it is either impossible or inappropriate to initialize parameters using the GSD approach due to the quantities, the user guidance, or the security requirements involved. Such data for specific devices and technologies are referred to as individual parameters (iPar). Often, they can be specified only during commissioning. If such a field device fails and is replaced, these parameters must also be reloaded to the new field device without the need for an additional tool. The individual parameter server provides plant operators a convenient and uniform solution for this.

TABLE 12.3 Extended Device Identification

IM1	TAG_FUNCTION	Plant designation
	TAG_LOCATION	Location designation
IM2	INSTALLATION_DATE	Installation date
IM3	_DESCRIPTOR	Comments
IM4	SIGNATURE	Signature

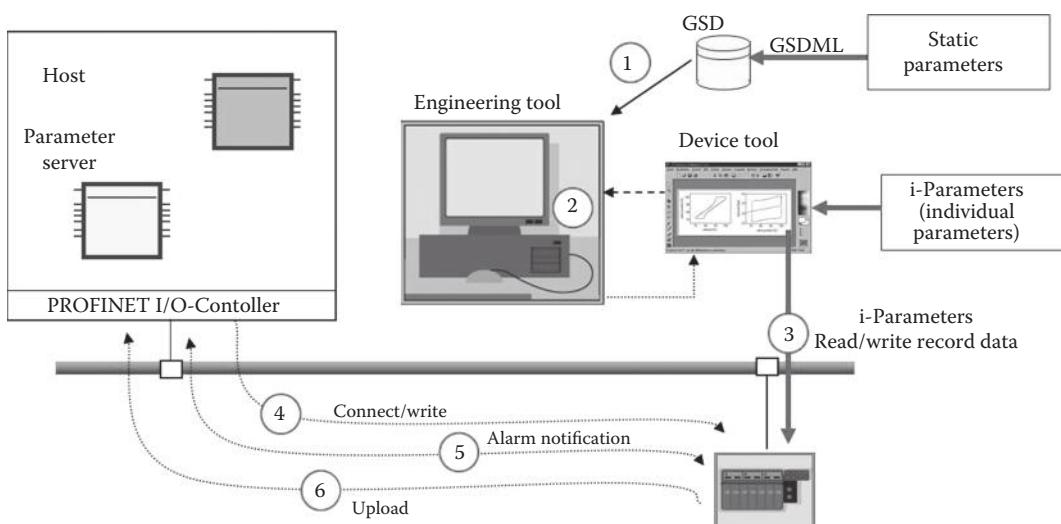

FIGURE 12.20 Automatic reload backed-up data during device replacement using a parameter server.

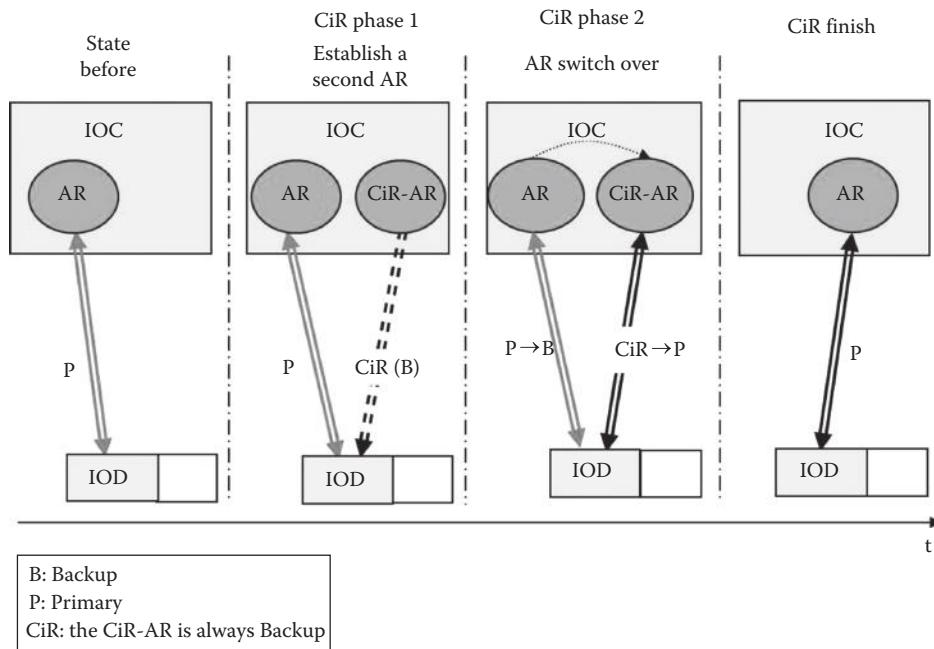

FIGURE 12.21 Configuration changes without plant interruption thanks to redundant connection.

#### 12.5.4 Configuration in Run

Like redundancy, uninterrupted plant operation—including when reconfiguring devices and networks and when inserting, removing, or replacing devices or individual modules—plays an important role in process automation (Figure 12.21). All of these *configuration in run* measures (CiR) are carried out in PROFINET bumpless and without adversely affecting network communication. This ensures that plant repairs, modifications, or expansions can be performed without a plant shutdown in continuous production processes, as well.

#### 12.5.5 Time Stamping

In large plants, the ability to assign alarms and status messages to a sequence of events is often required. For this purpose, an optional time stamping of these messages is possible in PROFINET I/O. In order to time stamp data and alarms, the relevant field devices must have the same time of day. To accomplish this, a master clock and the time synchronization protocol are used to set the clocks to the same time.

#### 12.5.6 Fast Restart

Fast start-up defines an optimized system power-up in which data exchange begins much faster starting with the second power-up since many parameters are already stored in the field devices. This optional path can be used in parallel to standard power-up (which is still used after a power on and during the first power-up or reset). It must be possible to store communication parameters retentively for this.

#### 12.5.7 High Availability

Chaining of multiport switches allows the star topology widely used in Ethernet to be effectively combined with a line structure. This combination is especially well suited for control cabinet connections, that is, line connection between control cabinets and star connection to process-level field device. If the connection

between two field devices in a line is interrupted, the field devices located after the interruption are no longer accessible. If increased availability is required, provision must be made for redundant communication paths when planning the system, and field devices/switches that support the redundancy concept of PROFINET must be used. The line can be closed to form a ring to easily provide a redundant communication path. In the event of an error, the connection to all nodes is ensured via the alternative connection (the other direction of the ring line). This achieves a tolerance for one fault. Organizational measures must be taken to ensure that this fault is eliminated before a second error occurs. PROFINET has two mechanisms for setting up ring-shaped media redundancy, depending on the requirements:

#### 12.5.7.1 Media Redundancy Protocol

The media redundancy protocol (MRP) according to IEC 62439 describes PROFINET redundancy with a typical reconfiguring time of <200 ms for communication paths with TCP/IP and RT frames after a fault. Error-free operation of an automation system involves a media redundancy manager and several media redundancy clients arranged in a ring.

The task of a media redundancy manager is to check the functional capability of the configured ring structure. This is done by sending out cyclic test frames. As long as it receives all of its test frames back, the ring structure is intact. As a result of this behavior, a media redundancy manager prevents frames from circulating and converts a ring structure into a line structure. A media redundancy client is a switch that acts only as a *passer* of frames and generally does not assume an active role. It must have two switch ports in order to connect to other media redundancy clients or the media redundancy manager in a single ring.

#### 12.5.7.2 Media Redundancy for Planned Duplication

IEC 61158 describes the redundancy concept media redundancy for planned duplication (MRPD) for topology-optimized IRT communication, which enables smooth switchover from one communication path to another in the event of a fault. During system power-up, the I/O-Controller loads the data of the communication paths for both communication channels (directions) in a communication ring to the individual nodes. Thus, it is immaterial which node fails because the loaded *schedule* for both paths is available in the field devices and is monitored and adhered to without exception. Loading of the *schedule* alone is sufficient to exclude frames from circulating in this variant, because the destination ports are explicitly defined.

## 12.6 Integration of Fieldbus Systems

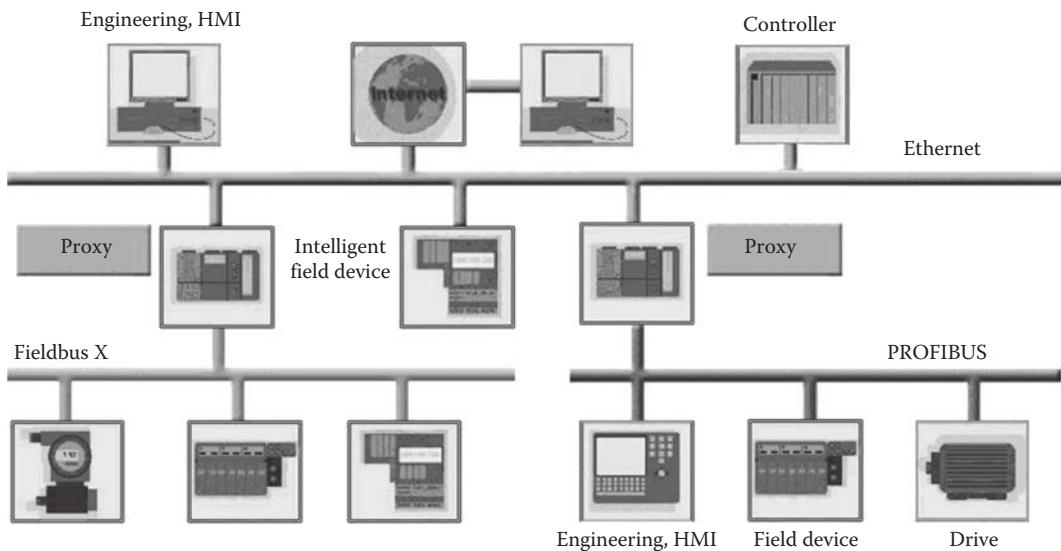

---

PROFINET specifies a model for integrating existing PROFIBUS and other fieldbus systems such as INTERBUS and DeviceNet (Figure 12.22).

This means that any combination of fieldbus and PROFINET-based subsystems can be configured. Thus, a smooth technology transition is possible from fieldbus-based systems to PROFINET. The following requirements are taken into consideration here:

- Plant owners would like the ability to easily integrate existing installations into a newly installed PROFINET system.
- Plant and machine manufacturers would like the ability to use their proven and familiar devices without any modifications for PROFINET automation projects, as well.
- Device manufacturers would like the ability to integrate their existing field devices into PROFINET systems without the need for costly modifications.

Fieldbus solutions can be easily and seamlessly integrated into a PROFINET system using proxies and gateways. The proxy acts as a representative of the fieldbus devices on the Ethernet. It integrates the nodes connected to a lower-level fieldbus system into the higher-level PROFINET system. As a result, the advantages of fieldbuses, such as high dynamic response, pinpoint diagnostics, and automatic system configuration without settings on devices, can be utilized in the PROFINET world, as well. These advantages simplify planning through the use of known sequences. Likewise, commissioning and operation

**FIGURE 12.22** Integration of fieldbus systems is easy with PROFINET.

are made easier through the comprehensive diagnostics properties of the fieldbus system. Devices and software tools are also supported in the accustomed manner and integrated into the handling of the PROFINET system.

## 12.7 Application Profiles

By default, PROFINET transfers the specified data transparently. It is up to the user to interpret the sent or received data in the user program of a PC-based solution or PLC. Application profiles are specifications for particular properties, performance characteristics, and behavior of devices and systems that are developed jointly by manufacturers and users. The term *profile* can apply to a few specifications for a particular device class or a comprehensive set of specifications for applications in a particular industry sector. In general, two groups of application profiles are distinguished:

- General application profiles that can be used for different applications (examples of these include the profiles PROFIsafe and PROFIdirect)
- Specific application profiles that are each developed for a specific type of application, such as PROFIdrive or devices for process automation

These application profiles are specified by PI based on market demand and are available on the PI website.

### 12.7.1 PROFIsafe

The PROFIsafe designation refers to a protocol defined in IEC 61784-3-3 for implementation of functional safety (fail-safe) and approved by IFA and TÜV. PROFIsafe can be used with PROFIBUS and PROFINET alike. The use of PROFIsafe enables elements of a fail-safe controller to be transferred directly to the process control on the same network. The need for additional wiring is eliminated.

### 12.7.2 PROFIdrive

The PROFIdrive designation refers to the specification of a standardized drive interface for PROFIBUS and PROFINET. This application-oriented profile, which has been standardized in IEC 61800-7, contains

standard definitions (syntax and semantics) for communication between drives and automation systems, thus assuring vendor neutrality, interoperability, and investment protection. The PROFIdrive application profile provides the foundation for almost every drive task in the field of industrial automation engineering. It defines the device behavior and the procedure for accessing drive data of electric drives and also optimally integrates the additional PROFIsafe and PROFIenergy profiles.

### 12.7.3 PROFIenergy

The high cost of energy and compliance with legal obligations are compelling industry to engage in energy conservation. Recent trends toward the use of efficient drives and optimized production processes have been accompanied by significant energy savings. However, in today's plants and production units, it is common for numerous energy-consuming loads to continue running during pauses. PROFIenergy addresses this situation [5]. PROFIenergy enables an active and effective energy management. By purposefully switching off unneeded consumers and/or adapting parameters such as clock rates to the production rate, energy demand and, thus, energy costs can be drastically reduced. In doing so, the power consumption of automation components such as robots and laser cutting machines or other subsystems used in production industries is controlled using PROFIenergy commands. PROFINET nodes in which PROFIenergy functionality is implemented can use the commands to react flexibly to idle times. In this way, individual devices or unneeded portions of a machine can be shut down during short pauses, while a whole plant can be shut down in an orderly manner during long pauses. In addition, PROFIenergy can help optimize a plant's production on the basis of its energy consumption.

## 12.8 PROFINET for Process Automation

---

Compared with discrete manufacturing automation, continuous process automation has a few special characteristics that contribute to defining the use of automation to a large extent. Plants can have a service life of many decades. This gives rise to a requirement, on the part of plant operators, for older and newer technologies to coexist in such a way that they are functionally compatible. In addition, requirements for the reliability of process plants, particularly in continuous processes, are often considerably greater. As a result of these two factors, investment decisions regarding new technologies are significantly more conservative in process automation than in discrete manufacturing automation. For optimal use of PROFINET in all sectors of continuous process automation, PI has created a requirements catalog in collaboration with users. In this manner, it is ensured that plant owners can rely on a future-proof system based on PROFIBUS today and can change to PROFINET at any time. The requirements mainly include the functions for cyclic and acyclic data exchange, integration of fieldbuses (PROFIBUS PA, HART, and FF), integration and parameter assignment of devices including configuration in Run, diagnostics and maintenance, redundancy, and time stamping.

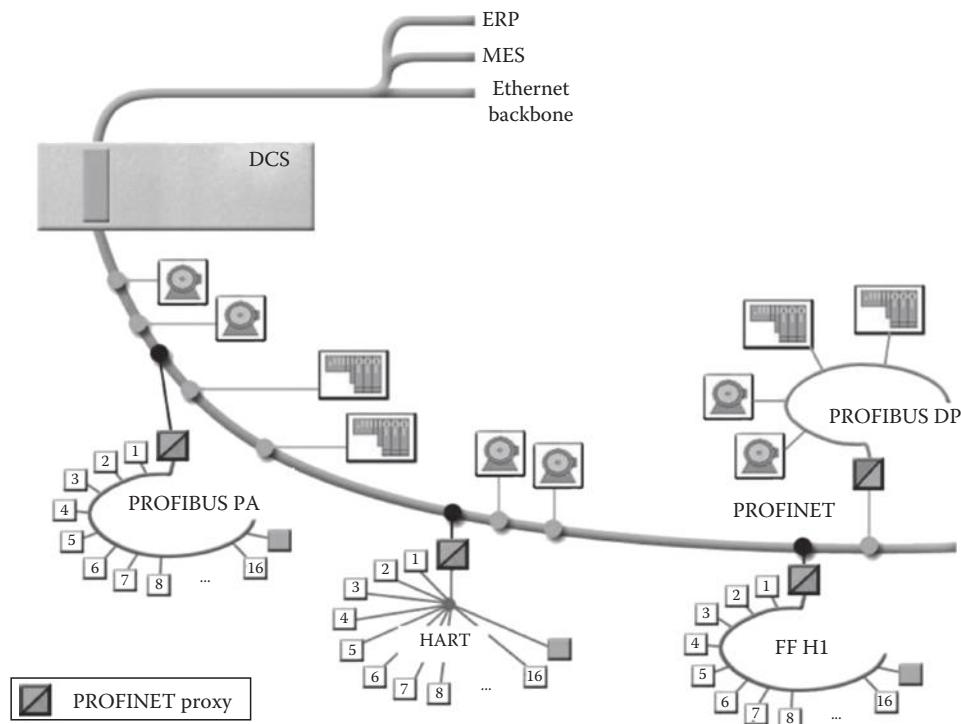

The energy-limited bus feed of devices in hazardous areas on Ethernet has not been formulated as a requirement as there is already an ideal, proven solution with PROFINET for PA. In addition, proven, field-tested Ethernet solutions currently do not exist for this.

## 12.9 Installation Technology for PROFINET

---

In addition to the described functions, PROFINET defines the passive infrastructure components (cabling, connectors) [6]. Communication may take place on copper or fiber-optic cables. In a CC-A network, communication is also allowed over wireless transmission systems (Bluetooth and WLAN) (Table 12.1).

The cabling guide defines for all CCs, a two-pair cable according to IEC 61784-5-3. The use of four-pair cables is also allowed for transmission systems with Gigabit cabling requirements. For a CA-A network, complete networking with active and passive components according to ISO/IEC-24702 is

**FIGURE 12.23** Example architecture for use of PROFINET in process automation.

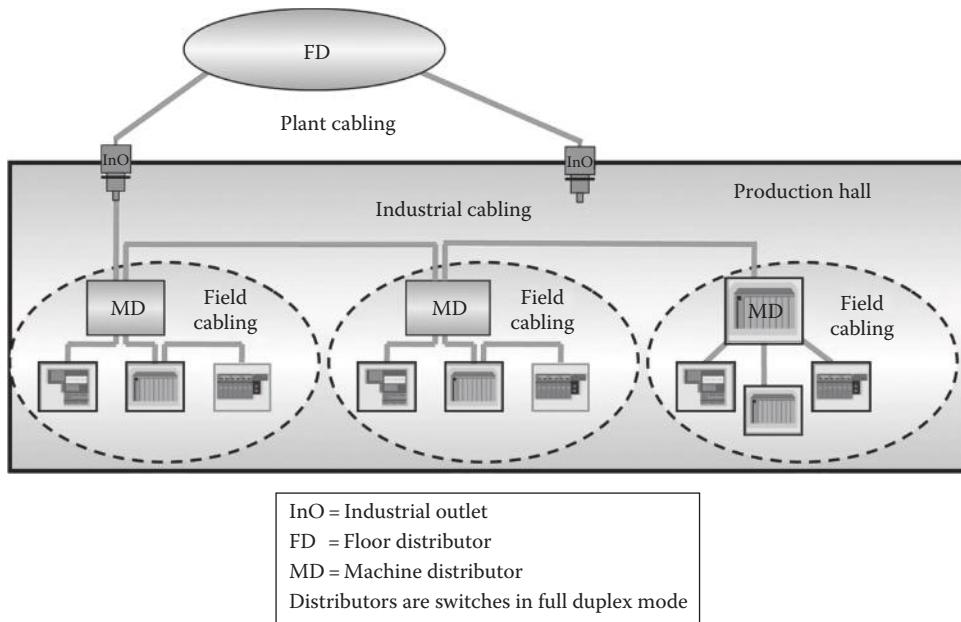

**TABLE 12.4** Network Installation for Different Conformance Classes

Network Cabling and Infrastructure Components	Solution	Conformance Class
Passive network components (connector, cable)	RJ45, M12	A, B, C
Copper and fiber-optic transmission systems	TX, FX, LX	A, B, C
Wireless connections	WLAN, Bluetooth	A
IT switch	With VLAN tag according to IEEE 802.x	A
Switch with device function	PROFINET with RT	B
Switch with device function and bandwidth reservation	PROFINET with IRT	C

allowed, taking into consideration the CC-A cabling guide. Likewise, active infrastructure components (e.g., switches) according to IEEE 801.x can be used if they support the VLAN tag with prioritization. Easy-to-understand and systematically structured instructions have been prepared to enable problem-free planning, installation, and commissioning of PROFINET I/O. These are available to any interested party on the PI website. These manuals should be consulted for further information.

### 12.9.1 Network Configuration

The connection of PROFINET I/O field devices occurs exclusively with switches as network components. Switches typically integrated in the field device are used for this (with two ports assigned). PROFINET-suitable switches must support *autonegotiation* (negotiation of transmission parameters)

**FIGURE 12.24** Ethernet networks in industrial environments often have line topology.

and *autocrossover* (autonomous crossing of send and receive lines). As a result, communication can be established autonomously, and fabrication of the transmission cable is uniform: only 1:1 wired cables can be used.

PROFINET supports the following topologies for Ethernet communication:

- Line topology, which primarily connects terminals with integrated switches in the field (Figure 12.24).
- Star topology, which requires a central switch located preferably in the control cabinet.
- Ring topology, in which a line is closed to form a ring in order to achieve media redundancy.
- Tree topology, in which the topologies indicated earlier are combined.

### 12.9.2 Cables for PROFINET

The maximum segment length for electrical data transmission with copper cables between two nodes (field devices or switches) is 100 m. The copper cables are designed uniformly in AWG 22. The installation guide defines different cable types, whose range has been optimally adapted to general requirements for industry. Sufficient system reserves allow industry-compatible installation with no limitation on transmission distance. The PROFINET cables conform to the cable types used in industry:

- PROFINET Type A: Standard permanently routed cable, no movement after installation
- PROFINET Type B: Standard flexible cable, occasional movement or vibration
- PROFINET Type C: Special applications: for example, highly flexible, constant movement (trailing cable or torsion)

Due to their electrical isolation, the use of fiber-optic cables for data transmission is especially suitable if equipotential bonding between individual areas of the plant is difficult to establish. Optical fibers also offer advantages over copper in the case of extreme EMC requirements. For fiber-optic transmission, the use of 1 mm polymer optic fibers (POFs) is supported, whose handling conforms optimally to industrial requirements.

### 12.9.3 Plug Connectors

PROFINET has divided the environmental conditions into just two classes. This eliminates unnecessary complexity and allows for the specific requirements of automation. The PROFINET environmental classes for automation applications are subdivided into one class *inside* protected environments, such as in a control cabinet, and one class *outside* of control cabinets for applications located directly in the field (Figure 17.25).

The selection of suitable PROFINET plug connectors accords with the application. If the emphasis is on a universal network that is to be office-compatible, electrical data transmission is via RJ 45, which is prescribed universally for *inside* environmental conditions. For the *outside* environment, a push-pull plug connector has been developed that is also fitted with the RJ 45 connector for electrical data transmission. The M12 connector is also specified for PROFINET.

For optical data transmission with POFs, the SC-RJ plug connector, which is based on the SC plug connector, is specified. The SC-RJ is used both in the *inside* environment and in connection with the push-pull housing in the *outside* environment. An optical plug connector is available for the M12 family and can be used for PROFINET and the 1 mm POF transmission.

At the same time, the plug connectors are also specified for the power supply, depending on the topology and the supply voltage. Besides the push-pull plug connector, a 7/8" plug connector, a hybrid plug connector, or an M12 plug connector can also be used. The difference between these connectors lies in their connectable cross sections and, thus, their maximum amperages.

### 12.9.4 Security

For networking within a larger production facility or over the Internet, PROFINET relies on a phased security concept. It recommends a security concept optimized for the specific application case, with one or more upstream security zones. On the one hand, this unburdens the PROFINET devices, and on the other, it allows the security concept to be optimized to changing security requirements in a consistent automation engineering solution.

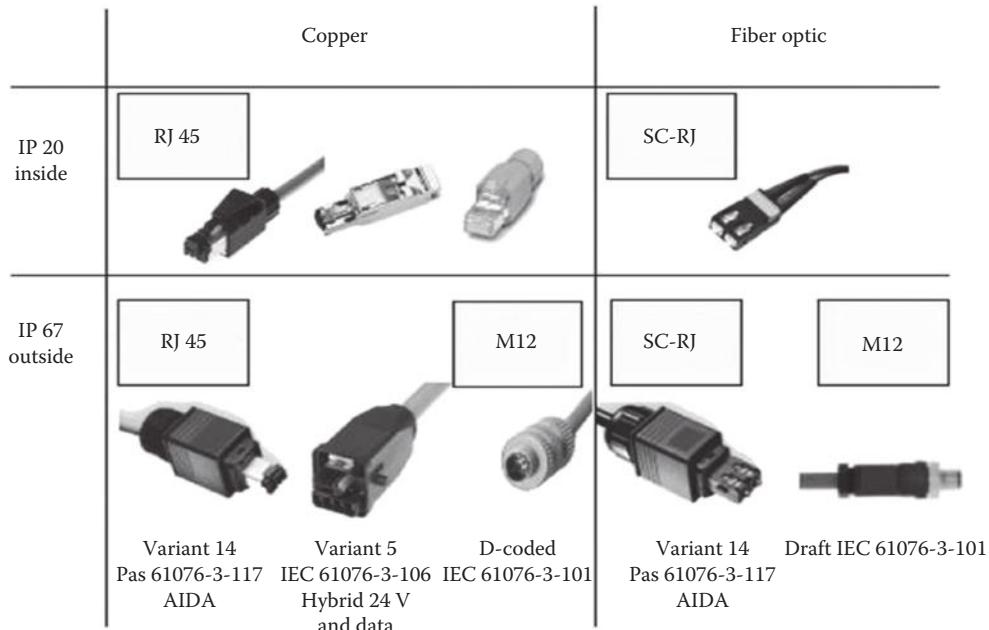

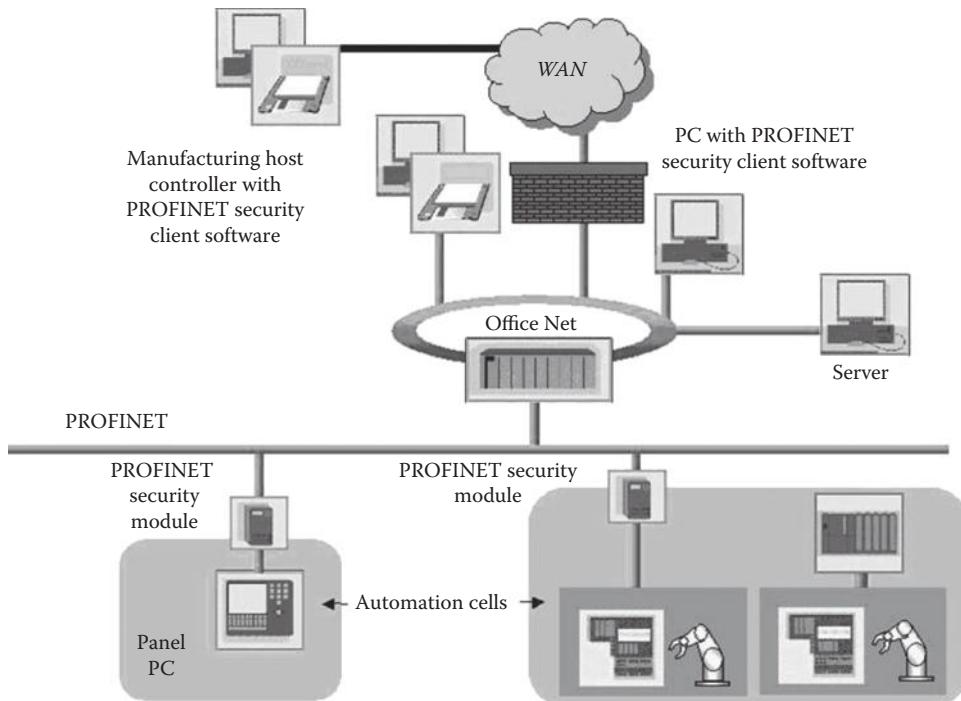

FIGURE 12.25 PROFINET offers a range of industrial connectors.

**FIGURE 12.26** Segmented automation network.

The security concept provides for protection of both individual devices and whole networks from unauthorized access. In addition, there are security modules that will allow networks to be segmented and, thus, also separated and protected from the safety standpoint. Only uniquely identified and authorized messages will be allowed to reach devices within such segments from outside (Figure 12.26).

## 12.10 Technical Support

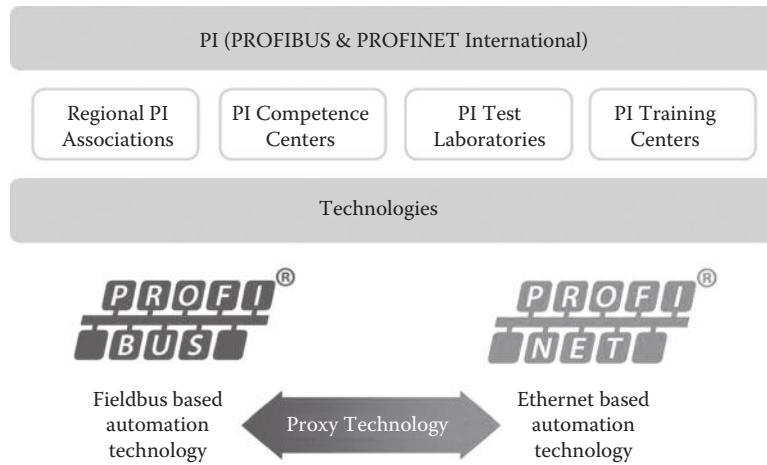

As far as maintenance, ongoing development, and market penetration are concerned, open technologies need a company-independent institution that can serve as a working platform. This is performed for PROFINET (as well as for PROFIBUS) by PI. With its 27 regional PI associations and approximately 1400 members, PI is represented on every continent and is the world's largest interest group for the industrial communications field.

Technology development takes place in the context of approx. 40 working groups with input from more than 500 experts mostly from engineering departments of member companies.

Optimal support by PI is key means for rapid dissemination of PROFINET in the market. In order to guarantee this, a powerful offer of services and products has been established.

PI maintains more than 50 approved PI competence centers worldwide. These facilities provide users and manufacturers with all kinds of advice and support. As institutions of PI, they are vendor-neutral service providers and adhere to the mutually agreed-upon rules. The PI competence centers are regularly checked for their suitability as part of an individually tailored approval process. More than 25 PI training centers have been set up to establish a uniform global training standard for engineers and technicians. Approval of the training centers and their experts ensures the quality of the training and thus of the engineering and installation services for PROFINET.

PI maintains 11 approved PI test labs (PITLs) worldwide. As institutions of PI, they are vendor-neutral service providers and adhere to the mutually agreed-upon rules. The testing services provided by the

**FIGURE 12.27** Structure of PROFIBUS & PROFINET International (PI).

PITLs are regularly audited in accordance with a strict accreditation process to ensure that they meet the necessary quality requirements. Refer to the website for current addresses [2]. Current information on PI and the PROFIBUS and PROFINET technologies is available on the PI website [www.profibus.com](http://www.profibus.com) or [www.profinet.com](http://www.profinet.com). This includes, for example, an online product guide, a glossary, a variety of web-based training content, and the download area containing specifications, profiles, installation guidelines, and other documents.

### 12.10.1 Technology Development

Device manufacturers that want to develop an interface for PROFINET I/O have the choice of developing field devices based on existing Ethernet controllers. Alternatively, member companies of PI offer many options for efficient implementation of a PROFINET I/O interface. To make the development of a PROFINET I/O interface easier for device manufacturers, the PI competence center and member companies offer PROFINET I/O basic technology (enabling technology). Consulting services and special developer training programs are also available. Before starting a PROFINET I/O development project, device manufacturers should always perform an analysis to determine whether internal development of a PROFINET I/O device is cost-effective or whether the use of a ready-made communication module will satisfy their requirements. More detailed information on this topic can be found in the brochure *PROFINET Technology—The easy way to PROFINET* [7], which can be downloaded from the PI website.

### 12.10.2 Tools for Product Development

Device manufacturers are assisted by software tools when developing and checking their products. These tools are provided to members of PI at no additional charge. A GSD editor assists the manufacturer when creating the GSD file for its product. This GSD editor can be used to create the proper files and check them. Likewise, PROFINET tester software is available for testing PROFINET functionalities. The current version supports the testing of all CCs as well as IRT functions. The additional security tester allows testing for secure function of a field device, including under load conditions. For detailed analysis, the Wireshark freeware tools can be used for problem-free interpretation of individual PROFINET frames since the decoding of PROFINET is already included in the standard version.

### 12.10.3 Certification Test

A certification test is a standardized test procedure that is performed by specialists whose knowledge is kept up to date at all times and who are able to interpret the relevant standards unequivocally. The test scope is described in binding terms in a test specification for each laboratory. The tests are implemented as so-called black box tests in which the tester is the first real user. All the defined test cases that are run through in a certification test are field-oriented and reflect industrial requirements. This affords all users the maximum possible security for use of the field device in a system. In very many cases, the dynamic behavior of a system can be simulated in the test laboratory. PI awards the certificate to the manufacturer based on the test report from an accredited test lab. A product must have this certificate in order to use the PROFINET designation. For the plant manufacturer/owner, the use of certified products means time savings during commissioning and stable behavior during the entire service life. They therefore require certificates from their suppliers for the field devices used, in accordance with the utilized CC.

PI supports more than 10 accredited PITLs worldwide for the certification of products with a PROFIBUS or PROFINET interface. As institutions of PI, they are independent service providers and adhere to the mutually agreed regulations. The testing services provided by the PITLs are regularly audited in accordance with a strict accreditation process to ensure that they meet the necessary quality requirements. A list of the current addresses can be found on the website.

## Abbreviations

AR	Application relation
ASIC	Application specific integrated circuit
CR	Communication relation
DAP	Device access point (This access point allows addressing an I/O-Device as a whole. It is the representative of the device)
GSD	General station description (electronically readable data sheet)
HMI	Human machine interface
I&M	Identification and maintenance
IEC	International Electrotechnical Commission
I/O	Input/output
IP	Internet protocol: the protocol that ensures the transfer of data in the Internet from end node to end node
IRT	Isochronous real time or clocked real time
ISO/OSI	International Standards Organization/Open Systems Interconnection (Reference Model)
LAN	Local area network
LLDP	Lower link discovery protocol
MAC	Media access control
MIB	Management information base
MRP	Media redundancy protocol
MRPD	Media redundancy for planned duplication
OUI	Organizationally unique identifier
PROFIBUS	Process fieldbus (fieldbus developed by PI)
PDEV	Physical device object
PDU	Protocol data unit
PI	PROFIBUS & PROFINET International
PLC	Programmable logic controller
RT	Real time
SNMP	Simple network management protocol

TCP	Transmission control protocol: superimposed protocol of IP to ensure secure data exchange and flow control
UDP	User datagram protocol (unsecured data frame)
VLAN	Virtual local area network
XML	Extensible Markup Language: standardized descriptive language that can be interpreted by almost all parsers
WLAN	Wireless LAN

This chapter describes the Sercos automation bus, an international standard (IEC61784/61158/61800) for communication between digital motion controls, drives, I/O, sensors, and ancillary devices. It includes definitions, a description of Sercos communication methodology, an introduction to Sercos hardware, a discussion of speed considerations, information on conformance testing, and information on available development tools. A number of real-world applications are presented, and a list of sources for additional information is provided.

There have been three generations of the Sercos automation bus. The latest generation, industrial Ethernet-based Sercos III is described first, followed by Sercos I/II, the original fiber-optic-based versions of Sercos.

---

## 13.1 Description

### 13.1.1 Introduction

SERCOS is an acronym for *SErial Realtime COmmunications System*, a digital automation bus that interconnects motion controls, drives, I/O, sensors, and ancillary devices such as cameras and weighing stations. It is an open controller-to-intelligent digital device interface, designed for high-speed serial communication of standardized closed-loop data in real time (RT). Sercos I and II transmit data over a noise-immune fiber-optic cable, while Sercos III transmits data over a standard CAT5 Ethernet cable and optionally over a fiber-optic cable.

The Sercos automation bus was created in the 1980s by the German ZVEI and VDW organizations to specify a digital open interface that would ease the transition from analog to digital drive technology. It was originally intended to be a drive interface and, in its beginnings, was mainly used for advanced machine tool applications. It has become a universal machine control interface, accepted worldwide in a myriad of industries. Sercos not only is an RT communication system but also offers more than 700 standardized parameters that describe the interplay of drives, controls, and ancillary devices in terms independent of any manufacturer. It offers advanced motion control and I/O capabilities for electronics, pneumatics, and hydraulics.

Sercos offers short data update times and low communication jitter for any kind of automation applications, including—but not limited to—high-performance multiaxis machine control systems. Like most digital buses, Sercos greatly reduces connectivity problems in control systems. It can connect up to 254 slave devices (drives, I/O, ancillary devices) to a control using one fiber-optic cable ring (Sercos I/II) or up to 511 on a single Ethernet cable (Sercos III), compared to a traditional analog servo system with eight axes of motion that may require over 100 wires between the drive and the control. This reduces system cost, eliminates many types of noise problems, and helps machine designers get motion control systems up and running quickly.

### 13.1.2 Three Generations of Sercos

There have been three Sercos generations (see Table 13.1). The first two generations utilized an application-specific integrated circuit (ASIC) as a hardware processing platform, fiber-optic transmitters/receivers, and a fiber-optic cable as the transmission medium.

- The first generation (Sercos I, now obsolete) operated at 2 and 4 Mbps, using the Sercon410B ASIC and fiber-optic cabling. The Sercon410B is no longer produced.
- The second generation (Sercos II) operates at 2/4/8/16 Mbps, using the Sercon816 ASIC and fiber-optic cabling.
- The third generation (Sercos III) operates at up to 100 Mbps utilizing a field-programmable gate array (FPGA), an ASIC, or a general-purpose communication controller (GPCC) and is based on standard Ethernet hardware. It links the high-performance of Sercos II with industrial Ethernet, combining the determinism of the original Sercos with the high bandwidth of industrial Ethernet for the best of both worlds. Sercos III maintains backward compatibility with previous versions in regard to profiles, synchronization, and message structures. It retains the set of more than 700 standard parameters that describe all aspects of RT motion and I/O control.

Dozens of manufacturers worldwide offer both Sercos II and Sercos III products, with hundreds of thousands of systems installed. Several manufacturers offer Sercos hardware and software development tools.

### 13.1.3 Sercos Is an International Standard

The Sercos automation bus is described in a set of standard specifications that may be incorporated into any company's products, with each control and slave device maintaining its own functions and features. Because it is internationally standardized (IEC61784/61158/61800), it allows any manufacturer's

**TABLE 13.1** Three Generations of Sercos

	Sercos I	Sercos II	Sercos III
Date implemented	1987	1999	2005
Physical media	Fiber optics	Fiber optics	Ethernet (twisted-pair copper or Fiber optics)
Network topology	Ring	Ring	Line or ring
Transmission speed (Mbps)	2/4	2/4/8/16	100
Cycle time (μs)	Configurable, min. 62.5	Configurable, min. 62.5	Configurable, min. 31.25
Jitter (μs)	<1	<1	<1

Number of masters	1 per ring	1 per ring	1 per ring/line
Number of nodes	254 per ring, multiple rings possible	254 per ring, multiple rings possible	511 per ring/line, multiple rings/lines possible

Sercos-compatible digital control to talk to any other Sercos-compatible digital servo drive, digital spindle drive, pneumatic or hydraulic system, digital I/O, sensors, and ancillary devices over a well-defined fiber-optic link (Sercos I/II) or standard Ethernet technology (Sercos III). Controls and slave devices conforming to the standard comply with a standard medium for transmission, topology, connection techniques, signal levels, message (telegram) structures, timing, and data formats.

### 13.1.4 How Sercos Works

Sercos II operates at 2/4/8/16 Mbps, using the Sercon816 ASIC. Sercos III operates at up to 100 Mbps, using an FPGA or a GPCC and standard industrial Ethernet hardware.

ASIC-, FPGA-, or GPCC-based Sercos controllers are normally integrated into master motion controls as well as drives, amplifiers, and I/O modules and other devices (e.g., camera systems). They simplify the task of the designer by automatically handling most Sercos communication functions.

A set of over 700 standard software functions (called IDNs) defines standard motion, I/O, and control functions. In addition, the interface allows for manufacturer-specific IDNs, which can be used to define unique functions, not addressed by the standard IDN set.

In a Sercos system, all control loops may be closed in the slave device (e.g., servo loop of a servo drive device). This reduces the computational load on the machine controller, allowing it to control and synchronize more devices (e.g., motion axes and distributed I/Os) than it otherwise could. In addition, closing all the control loops in the slave device reduces the effect of the transport delay between the control system and the slave devices.

### 13.1.5 Sercos Functions

- Sercos exchanges data between control and slave devices, such as drives, I/Os, and encoders, transmitting command and actual values with extremely short cycle times.

- It guarantees an exact synchronization of all connected Sercos devices for precise data exchange in distributed measurement systems or for precise coordinated moves with as many axes as required.
- It includes mechanisms (service channel and unified communication channel [UCC]) for non-cyclic data transmission, used for the display and input of control internal parameters, data, and diagnostics. Device parameters can be downloaded and uploaded for storage via the service channel and the UCC.
- The bus enables the use of controls, drives, I/Os, and other slave devices from different manufacturers in a system, by standardizing all data, parameters, commands, and feedbacks exchanged between all connected Sercos devices.

### 13.1.6 Ideal for Distributed Multiaxis Control Systems

Sercos is a foundation for building distributed multiaxis control systems for a myriad of applications. Distributed control improves machine flexibility by moving processing power and decision making from the computer numerical control (CNC) or motion control down into the drives and sensors. These devices then become intelligent building blocks that can easily be added to a machine or production line without major changes in hardware and software.

Sercos is well suited for distributed control because it allows placement of axis-dependent control functions, such as loop closures, interpolation, and registration in the drives, not in the motion controller. Thus, motion controllers can concentrate on motion control profiles and tool paths independent of the axes. In operation, the control issues a position command to the drive, which then closes its own loops and microinterpolates its trajectory, based on previously downloaded parameters. Sercos also integrates input/output functions such as limit switches, pushbuttons, and various sensors.

### 13.1.7 Advantages

Sercos provides machine manufacturers with the flexibility to configure multivendor control systems with plug and play interoperability. Even more importantly, Sercos has facilitated great advances in machine productivity. A prominent US food manufacturer states as follows: "Our Sercos applications play an important role in our plan for a dynamic enterprise that can flexibly adapt manufacturing for every new product size, shape and packaging configuration. Along with this flexibility, we have realized incredible timesaving advantages – faster delivery, faster installation, faster setup, faster product changeover, and faster production speeds" (Campbell 1999).

Sercos allows manufacturers to create intelligent digital drives with vastly improved capabilities and flexibility. A single drive can be designed to handle multiple motors, such as permanent magnet servomotors, high horsepower induction servomotors (vector drives), and linear motors, with the configuration set up parametrically. Sercos is also used with stepper motors, pneumatic and hydraulic drives, I/O systems, and other devices.

## 13.2 Features and Operation of Sercos III

---

### 13.2.1 Introduction

The third generation of Sercos (Sercos III) is an evolution of Sercos I and II (IEC/EN 61491), based on standard Industrial Ethernet. Work began in 2003, with vendors releasing the first products supporting it in 2005. The well-known and proven Sercos mechanisms (as described in Section 13.3, Features and Operation of Sercos I/II) such as motion control profiles, the telegram structure, and the hardware synchronization have been mapped to the Ethernet standard. To ensure hard RT requirements despite the nondeterministic nature of Ethernet, Sercos III uses an RT channel in parallel to a UCC. In the collision-free RT channel, the Sercos-specific frames are transmitted using the EtherType 0x88CD.

The high protocol efficiency in this channel ensures best performance even with a high number of devices connected and rather small amount of data per device. The UCC can be configured in parallel to this RT channel. In it, any standard Ethernet telegrams (EtherType <> 0x88CD) or IP-based protocols like TCP/IP or UDP/IP can be transmitted.

### 13.2.2 Why Ethernet?

The increasing number of control components, actuators, and sensors in industrial automation adds to the complexity of control networks. The future of industrial communication lies in cost-effective integration of these automation components in low-cost Ethernet networks, which have been engineered to suit the needs of industrial automation.

Specialized fieldbus systems were used initially for simplified networking. Fast Ethernet technology replaces these systems and offers a number of advantages:

- Recognized, future-proof technology
- Data throughput 10–100 times faster than fieldbus solutions
- No need for expensive, proprietary technology
- Use of standard components, for example, CAT5e copper cable with double shielding, connectors, and controllers, such as FPGAs, all produced in large volumes
- Consistent IT implementations stretching from the office to the field level (Figure 13.1)

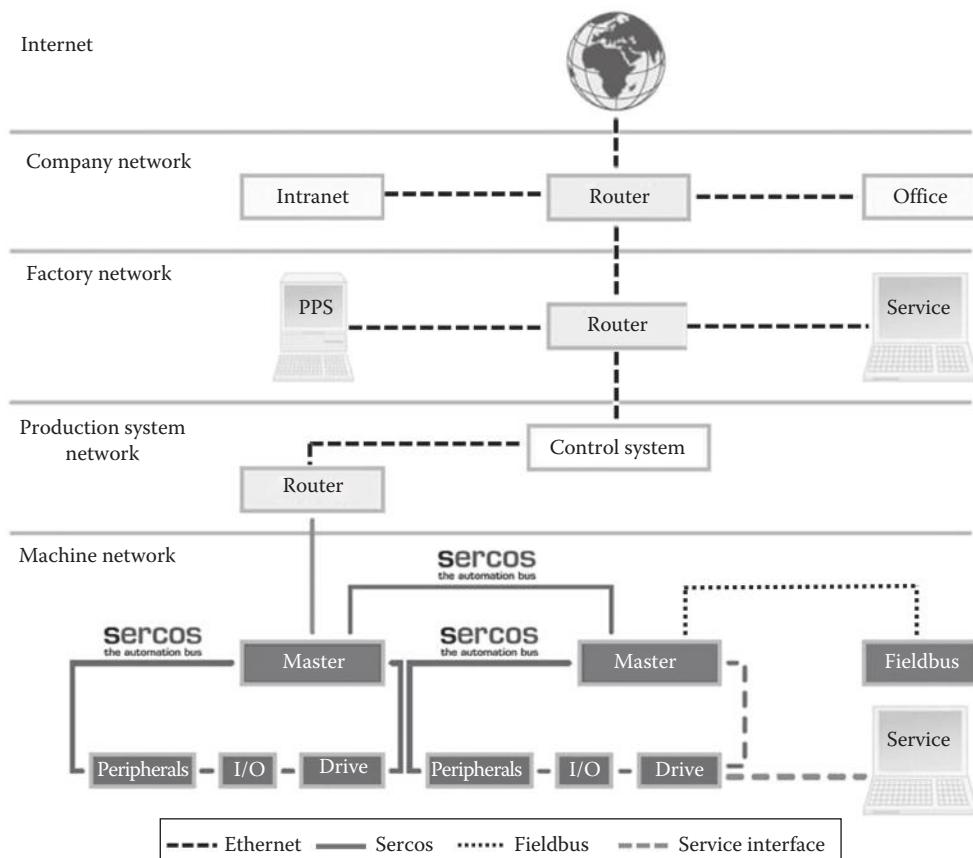

FIGURE 13.1 Ethernet—consistent from the office to the field level.

- Flexible, compatible automation systems based on a global standard
- Supports worldwide networking for diagnostics and maintenance

Ethernet technology combines the peripherals, drives, safety functionality, and office communications in a common medium providing a simple, cost-effective, powerful solution.

### 13.2.3 Advantages of Sercos III

The evolutionary concept of Sercos III maintains all the proven advantages of previous Sercos versions and at the same time offers a range of new features that allow for a substantially increased number of possible applications. Advantages include the following:

- Protection of investment due to high compatibility with previous Sercos generations (ring topology, profiles, telegram structures, and synchronization)
- Reduction of hardware costs
- Reduced cycle times down to 31.25 µs
- Simultaneous transmission of any Ethernet protocols (e.g., UDP/IP and TCP/IP) over the same cable
- Direct cross communication (CC) between slaves
- Synchronization of several control systems, that is, machine segments
- Transfer of safety-relevant data
- Fault tolerance in case of a cable break

### 13.2.4 How Sercos III Communicates

#### 13.2.4.1 Physical Layer and Data Link Layer

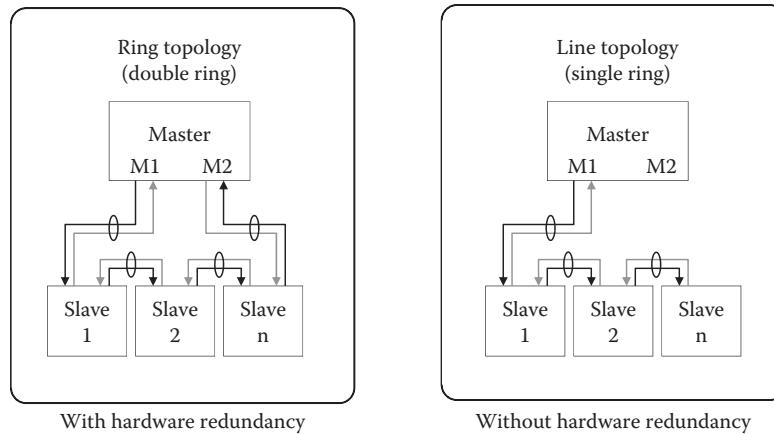

Sercos III supports standard IEEE 802.3 & ISO/IEC 8802-3 100Base-TX or 100Base-FX (100 Mbit/s baseband) full duplex physical layer (PHY) entities. Standard 802.3-compliant media access controller (MAC) sublayers are used. Autonegotiation must be enabled on each PHY, but only 100 Mbit full duplex is supported. Auto (MAU [media attachment unit]-embedded) crossover is specified between the two physical medium attachment (PMA) units present with a duplex port. These two units are referred to as the primary channel and secondary channel in the Sercos III specification. Dual interfaces are required (two duplex interfaces per device). Within the Sercos III specification, the dual interfaces are referred to as P1 and P2 (Ports 1 and 2). All Sercos III frames use EtherType 0x88CD. For bandwidth optimization, the Sercos III frames are transmitted as broadcast frames that are shared between all Sercos III nodes connected to the network.

The basis of Sercos communication is a time slot protocol with a cyclic transmission of telegrams using a master-slave principle. A central master sends master data telegrams (MDTs) to the subordinate slaves. They can contain command values and timing data. The slaves send process data from the field, for example, actual values, to the master via the acknowledge telegrams (ATs). In Sercos III, the ATs are also used for direct data exchange between slave devices (direct CC).

Various measures ensure that Sercos III uses the 100 Mbps bandwidth of fast Ethernet as efficiently as possible. First, the RT frames are shared by multiple network nodes (collective frames), which reduces the overhead significantly. Second, by omitting network infrastructure components such as switches or hubs and by processing the RT frames *on-the-fly*, the frame runtimes through the network are minimized.

#### 13.2.4.2 Network Topologies

Sercos III defines two basic topologies: ring and line topology. Due to the full-duplex characteristics, the physical ring is a logical double ring structure and the physical line is a logical ring structure (Figure 13.2).

**FIGURE 13.2** Sercos III ring and line topology.

A line topology is the simpler of the two possible arrangements and provides no redundancy. However, this configuration saves the cost of one cable. In it, only one of the two interfaces on the master is used. Telegrams are issued out of the transmit PMA on the master's active port. Either port on the master may be the active one. Sercos III determines this during phase-up (initialization). The first slave receives the telegrams on the connected interface's receive PMA, modifies them as required, and issues them out on the transmit PMA of the second interface. Each cascading slave does likewise until the last slave in the line is reached. That slave, detecting no Sercos III connection on its second port, folds the telegram back on the receiving interface's transmit port. The telegram then makes its way through each slave back to the master. Note the last slave also emits all Sercos III telegrams on its second port, even though no Sercos III connection is detected. This is for snooping and ring closures (see later), as well as hot-plugging. Keep in mind that since the Ethernet destination field in all Sercos III telegrams is the broadcast address of 0xFFFF FFFF FFFF (all 1s), all telegrams issued from this open port will be seen by other devices as broadcast telegrams. This behavior is by design and cannot be disabled. To avoid taxing networks attached to an open Sercos port, an IP switch can be used, or alternately a managed Ethernet switch programmed to block broadcast telegrams received from the Sercos port can be used.

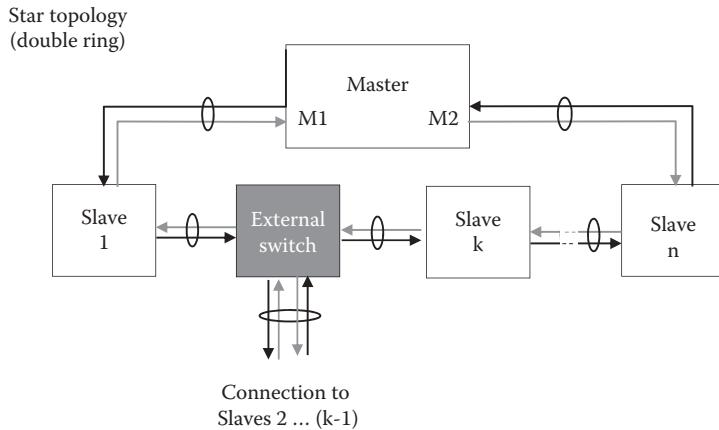

A ring topology simply closes the network by attaching the unused (second) port on the last device in a ring back to the second port on the master. When the Sercos III master senses that a ring exists, it sets up two counter-rotating telegrams. The same data are issued simultaneously out of the transmit PMAs of both ports on the master. From there, both telegrams are managed essentially identically as they make their way through each slave, ending back at the opposite port on the master they were emitted from. Advantages to this topology include tighter synchronization as well as automatic infrastructure redundancy (see later).

No hubs or switches are required for the ring or line topology. This significantly reduces cabling efforts and installation costs.

With both the line or ring structure, Sercos III operates in a *circular* approach. All telegrams leave the master and return there. As with any network that operates in this manner, modified structures can be constructed to appear as a tree or star network, utilizing hardware that manages the branches, but the structure is still circular in nature. The principle of a star topology is shown in Figure 13.3.

### 13.2.4.3 Network Installation

The installation of a Sercos III network is very simple and does not require any specific network configuration procedures. All nodes are simply connected by patch cables or crossover cables.

**FIGURE 13.3** Sercos III star topology with external switch.

The Ethernet ports of the devices are interchangeable and can even be used to connect standard Ethernet nodes (e.g., laptops) to a Sercos RT network. In this case, full Ethernet and IP connectivity is provided, without affecting the RT behavior of a Sercos III network when in online mode or without requiring active Sercos III communication (off-line mode). In such an off-line mode, standard Ethernet devices, such as a laptop, can still communicate to Sercos devices for diagnostics and up/downloading data.

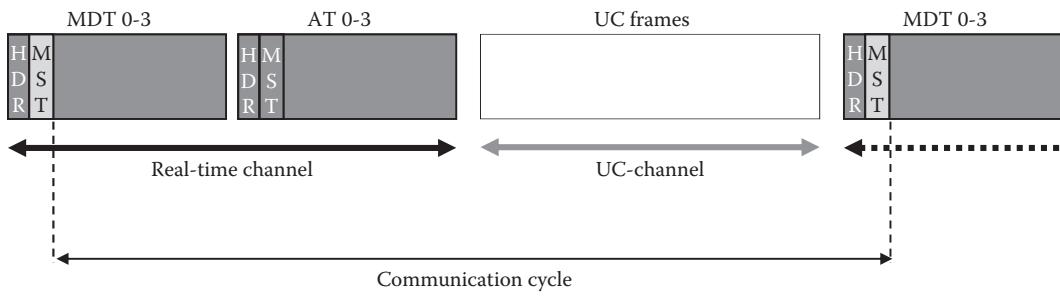

Sercos III uses a component-based approach for the connection between Sercos III devices. Defined cables and connectors are combined and used to connect the automation devices in a machine or system. The total length of the cabling channel as well as the number of transitions between cable and connectors is considered. The result is transmission lines that fulfill the requirements for the Sercos III cabling with a distinct reserve—without the necessity to perform extensive planning, calculations, and measurements. The Sercos organizations offer a free Installation and Planning Guide to make this process easy and trouble-free.

#### 13.2.4.4 Sercos III Cycle

Just as with Sercos I/II, the communication of Sercos III occurs in strict cyclic intervals. A cycle time is chosen by the user for a given application. Cycle times are 31.25, 62.5, 125, 250 µs, and multiples of 250 µs up to a maximum value of 65 ms.

In Sercos III, a communication cycle is divided into two channels via a time slot technique (Figure 13.4). In the RT channel, the collective telegrams specified by Sercos III are transmitted as a broadcast and processed *on-the-fly* by the slave devices. For this purpose, two types of telegrams are used: MDTs and ATs. After all MDTs and ATs are transmitted, Sercos III nodes allow the remaining time in the cycle to be used as a UCC. In this channel, any other Ethernet frames (e.g., IP protocol frames) can be sent as single telegrams to any device in the network. The cycle times as well as the partitioning of the bandwidth of 100 Mbps Ethernet into the Sercos RT and UCCs can be adjusted to the specific requirements of the application.

The network remains available to UCC traffic until the next cycle begins, at which time the Sercos III nodes close the nodes to UCC traffic again. Sercos III is purposely designed to provide open access at all ports for other protocols between cyclic RT messages. No tunneling is required. This provides the advantage that any Sercos III node is available, whether Sercos III is in cyclic mode or not, to use other protocols, such as TCP/IP, without any additional hardware to process tunneling. Sercos nodes are specified to provide a store-and-forward method of buffering non-Sercos messages should they be received at a node while cyclic communication is active.

**FIGURE 13.4** Sercos III communication cycle.

#### 13.2.4.5 UC Channel

The time between the end of the transmission of all Sercos III RT cyclic telegrams and the beginning of the next communication cycle is defined as the Sercos III Unified Communication Channel. During this time period, the Sercos network is opened to allow transmission of Ethernet-compliant frames for other services and protocols. For example,

- Web servers can be embedded in Sercos III-compliant devices to respond to standard Hypertext Transfer Protocol messages received via the UCC.
- Frames from other Fieldbus standards that conform to Ethernet frame formatting may be transmitted across a Sercos III network.

Every Sercos III-compliant node must support the passing of UC frames through its Sercos III interface. Whether a Sercos III node actively makes use of the UC feature is determined by the feature set of the product. If, for example, the device has an embedded web server, it could make its IP address available for access by other devices.

A Sercos III network will always pass UC frames, even when cyclic operation has not been initialized. This means that devices always have access to the network for UC messages, as long as the ports are powered.

Sercos III does not define whether a port should operate in cut-through switching or store-and-forward mode when handling UC frames. There are Sercos III products currently on the market that support both modes. Likewise, Sercos III does not define whether a port should intelligently process UC telegrams, such as learn the network topology. The time allotted for UC traffic is dictated by the amount of data transmitted during the RT portion of the cycle. In real-world applications, there is a significant amount of bandwidth available for UC frames. For example, in a typical application with eight axes of motion and a cycle rate of 250 µs, the equivalent of 85 Mbit/s is available for UC use. This amount of time means the UC frames in this example can be as long as the maximum defined for Ethernet (maximum transmission unit [MTU] = 1500). Using the same example of eight axes, but with a cycle time of 62.5 µs, the effective bandwidth available for UC frames would be 40 Mbit/s, and the MTU would be reduced to 325. As with any network where time on the bus is shared, MTU values should be configured to ensure reliable communication. Properly configured Sercos networks will set the Sercos parameter *Requested MTU* (S-0-1027.0.1) to the recommended MTU value, which can then be read by other devices to match their MTU settings. Regardless of the value of this parameter, a Sercos node will allow non-Sercos traffic to pass for the entire UCC time period (i.e., telegrams longer than the MTU setting are not discarded by the Sercos stack). Sercos parameter S-0-1027.0.1 is set by default to 576, the minimum value called out in RFC 791 (request for comment, Internet Protocol).\*

\* See <http://tools.ietf.org/html/rfc791>.

UC frames may enter a Sercos III network only through a Sercos III-compliant port. This can be achieved in two different ways. One is to employ the unused Sercos III port at the end of a Sercos III network configured in line topology. In a network configured in ring topology, the ring can be temporarily broken at any point to also attach a device. Since the redundancy feature of Sercos III will reconfigure the network in a bump-less manner (responding in less than one cycle), no disruption of network transmission will occur. The ring can again be closed after the access is no longer required. If access is desired in the middle of a line topology (where no free ports are available), or it is undesirable to break a ring topology for extended periods of time, the Sercos III specification permits the use of a device called an *IP Switch* that can be used to provide access to the UCC anywhere along the network. IP switches supply two Sercos III-compliant ports and one or more ports for UCC access.

Commercially available IP switches block the transmission of Sercos III broadcast telegrams out of their non-Sercos III port(s) to prevent flooding of non-Sercos III networks with Sercos III cyclic data.

#### 13.2.4.6 Telegram Format and Telegram Types

All Sercos III telegrams conform to the IEEE 802.3 & ISO/IEC 8802-3 MAC (media access control) frame format with an EtherType of 0x88CD. Combined frames are used for the optimization of the bandwidth. The MST (synchronization signal) and MDT are combined in a block of a maximum of four Ethernet frames. The ATs are also combined in a block of a maximum of four Ethernet frames. The Sercos III header includes control and status information, which is required for the use of the network and the different devices. Furthermore, the synchronization is derived from the Sercos III header. Subsequent to the Sercos III header, a variable data field follows, which contains the RT data of the Sercos III devices (Figure 13.5).

- Destination address: The destination address for all Sercos III telegrams is always 0xFFFF FFFF FFFF (all 1s), which is defined as a broadcast address for Ethernet telegrams. This is because all telegrams are issued by the master and are intended for all slaves on the network.
- Source address: The source address for all Sercos III telegrams is the MAC address of the master, as it issues all telegrams.
- Ethernet type: A unique EtherType value has been assigned via the IEEE EtherType Field Registration Authority for Sercos III (0x88CD).
- Sercos III header: The beginning of the Ethernet-defined data field always begins with a Sercos III header, which contains control and status information unique to Sercos.
- Sercos III data field: The Sercos III header is followed by the Sercos III data field, which contains a configurable set of variables defined for each device in the network.

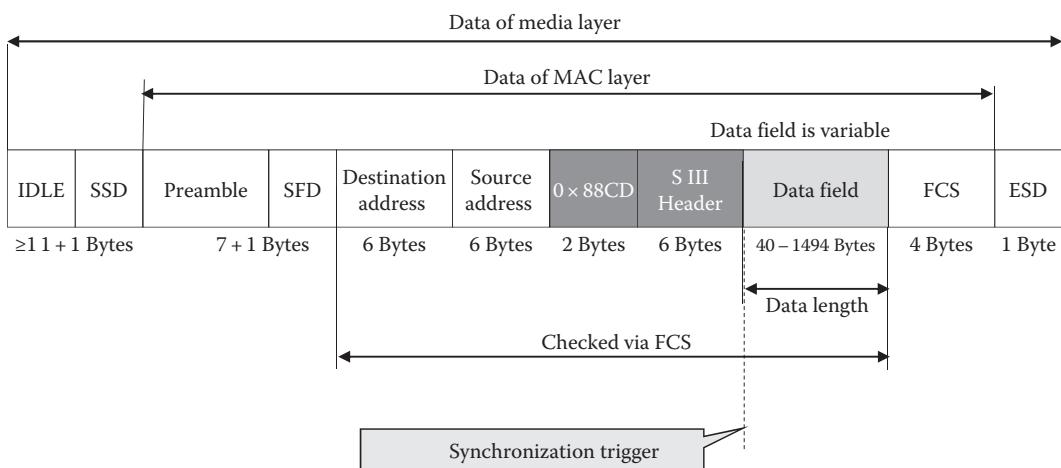

FIGURE 13.5 Sercos III telegram structure.

Two main types of telegrams are used within the Sercos III Cycle: the MDT and the AT. Both telegram types are issued by the master (control). The MDT contains information provided by the master to slaves. It is filled by the master and read by slaves. The AT is issued by the master, but actually populated by each slave with their appropriate response data (feedback values, input states, etc.). More than one slave uses the same AT, filling in its predetermined area in the AT telegram, updating checksums, and then passing the telegram to the next device. This method reduces the impact of the Ethernet frame overhead on the performance of the network without compromising IEEE 802.3 & ISO/IEC 8802-3. The amount of data sent from the master to slaves, as well as the sum of the data returned by the slaves, may exceed the 802.3-specified maximum 1500-byte data field size. To comply with this limit, Sercos III may use more than one MDT telegram in a cycle, as well as more than one AT telegram (up to four in each case). Sercos III specifies that no data are overwritten (destroyed) during a transmission. Every slave on a network may access input and output data for every other slave on the network.

#### 13.2.4.7 Synchronization

There are different ways to achieve synchronicity and simultaneity in distributed systems. Most RT Ethernet systems rely on time synchronization to create a common time basis for the whole network, which is independent of runtimes and runtime fluctuations on the communication medium. The procedure used by Sercos is based on sending a synchronization signal (MST), which is cyclically received and evaluated by all nodes in the network. To ensure optimum synchronization, the signal must be sent and received in a fixed time grid with a minimum of deviation in time. In general, a synchronization accuracy of less than 1 µs is sufficient to realize an adequate machining accuracy for highly dynamic and highly precise production machines and machining systems. It is possible, for example, to achieve a printing accuracy of 10 µm in a shaftless printing press with synchronized single drives and a printing speed of 10 m/s.

In a Sercos III network, the master only has to only measure the ring delay and transmit this value together with a configuration-optimized threshold to all connected devices. Thus, it is possible to prevent a shifting of the synchronization times or the need for reconfiguration of the threshold value when additional devices are added to a Sercos III network in cyclic RT operation (i.e., *hot-plugging*).

The synchronization method ensures that a cyclic and simultaneous synchronization of all connected devices is guaranteed in Sercos III networks, independent of the topology and the number of nodes. Its accuracy remains unchanged even if changes to the topology occur (e.g., redundancy, hot-plugging). The method itself is fast, robust, and easy to apply. On both the master and slave sides, Sercos III controllers can be used, which not only support the fast processing of the RT telegrams and the ring redundancy but also provide an error- and jitter-free synchronization signal. With the described method, Sercos III achieves a synchronization accuracy of less than 20 ns and simultaneity of less than 100 ns. As single Sercos III networks can be combined in interconnected networks on the basis of the controller-to-controller (C2C) profile, it is possible to implement fully synchronized network structures without any restrictions in terms of synchronization performance.

#### 13.2.4.8 Identification Numbers

The identification numbers (IDNs) of Sercos III are based on the IDN concept of Sercos I/II (as described in Section 13.3.2.6).

However, the IDN signification area is extended from 16 bits (Sercos I/II) to 32 bits in Sercos III. This was done in order to expand the parameter area, to allow the logical grouping of IDNs that are used for the same purpose and to enable instances of the same functions with same base data block number (Figure 13.6).

For the 32 bit IDNs in Sercos III, the following symbolic notation of IDNs is used: <IDN>.<SI>.<SE>

- Structure element (SE). The SE is used to address the elements. Consequently, up to 256 elements are possible. The SEs from 1 to 127 are predetermined and the remaining up to 255 are manufacturer specific.

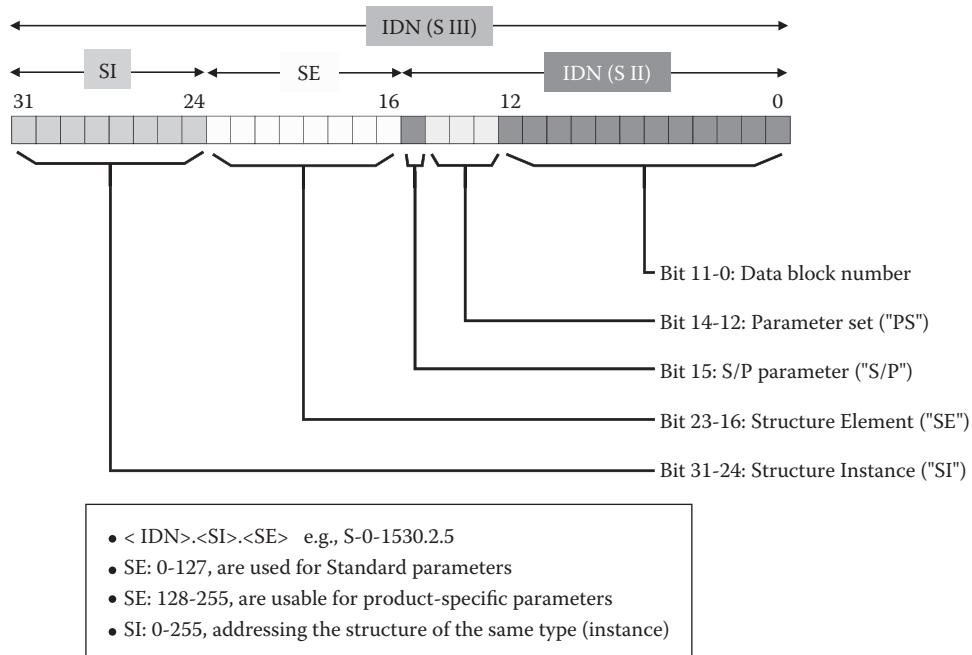

FIGURE 13.6 Structure of 32-bit IDN numbers.

- Structure instance (SI). This serves to address the structure of the same type within one subdevice. So 255 instances of the same structure are possible in one subdevice.

All parameters that were moved from Sercos II are maintained. The upper 16 bits of the IDN are set to zero while the lower 16 bits correspond to the known Sercos II addressing. This has an impact on all IDNs, in which data of type *IDN* are incorporated, because they must use 4 byte values instead of 2 byte values.

An example for the new 32-Bit IDN structure is the electronic label, S-0-1300, which is a group of different IDNs related to the electronic label of a device.

The IDNs S-0-1300.x.x are encompassed by the term *electronic label*. They are used by a master or a configurator device to identify Sercos III devices. Because of this, the two IDNs S-0-1300.x.03 (vendor code) and S-0-1300.x.05 (vendor device ID) are mandatory and must be present in every Sercos III device. All other IDNs in the following list are optional and can be used by a manufacturer to assign additional information to a device.

The SI 0 of all *electronic label* IDNs (e.g., S-0-1300.0.01 for the component name) assigns the physical device that contains the Sercos III Interface itself. The other SIs can be assigned to any component of the device (e.g., modules linked to an internal interface) according to the manufacturer's requirements.

- S-0-1300.x.01 component name (optional)
- S-0-1300.x.02 vendor name (optional)
- S-0-1300.x.03 vendor code (mandatory)
- S-0-1300.x.04 device name (optional)
- S-0-1300.x.05 vendor device ID (mandatory)
- S-0-1300.x.06 connected to subdevice (optional)
- S-0-1300.x.07 function revision (optional)
- S-0-1300.x.08 hardware revision (optional)
- S-0-1300.x.09 software revision (optional)
- S-0-1300.x.10 firmware loader revision (optional)

- S-0-1300.x.11 order number (optional)
- S-0-1300.x.12 serial number (optional)
- S-0-1300.x.13 manufacturing date (optional)
- S-0-1300.x.14 QA date (optional)
- S-0-1300.x.20 operational hours (optional)
- S-0-1300.x.21 service date (optional)
- S-0-1300.x.22 calibration date (optional)
- S-0-1300.x.23 calibration due date (optional)

### 13.2.4.9 Communication Phases

The Sercos communication is divided into five communication phases (CP0 through CP4) and the NRT (non-RT) state:

- After a Sercos III device has been powered up, internal checks are completed, and it is determined to be error-free, it operates in non-RT state (NRT state).
- Initialization of a Sercos III network always begins with CP0.
- CP0 is used for recognizing the participating slaves.
- CP1 is used to configure the slave devices for noncyclic communication.
- CP2 is used to configure the slave devices for cyclic communication and for parameter setting in the slave via noncyclic communication.
- CP3 is used to further configure the slave devices, the cyclic communication already running but not used.
- In CP4, the initialization process is complete, and the Sercos III network is in normal (cyclic) operation.

It is also possible to enter CP0 from any higher phase. All other phases can be entered only in ascending order when leaving the previous phase.

The master initiates a specific CP by setting the MDT phase in the Sercos III header. The slaves follow accordingly. Only in the case of a communication error do the slaves switch to the NRT state (Figure 13.7).

### 13.2.4.10 Communication Services

The Sercos III communication connects all participants in a network. Because of this, it is possible that any device can communicate with any other. A connection determines which devices communicate with each other. The Sercos III network supports the application data exchange between the master and all slaves, and between the slaves in both directions (direct CC). Not all devices need to communicate with each other; therefore, the application data exchange between the devices is configured via connections. These logical connections are based on a producer–consumer model. That means, for each transmission of application data, one connection is required (Figure 13.8).

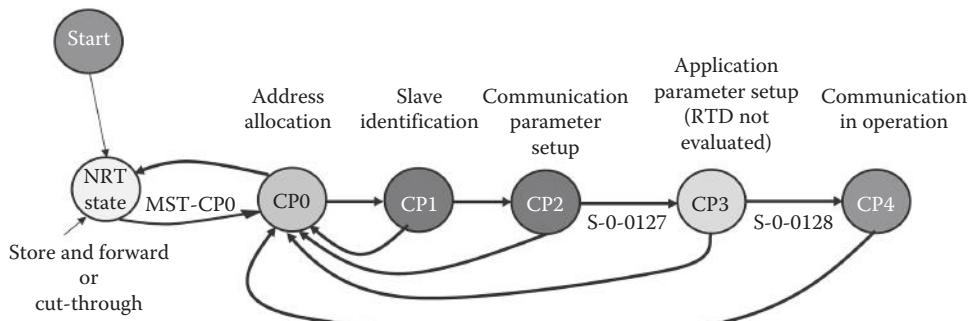

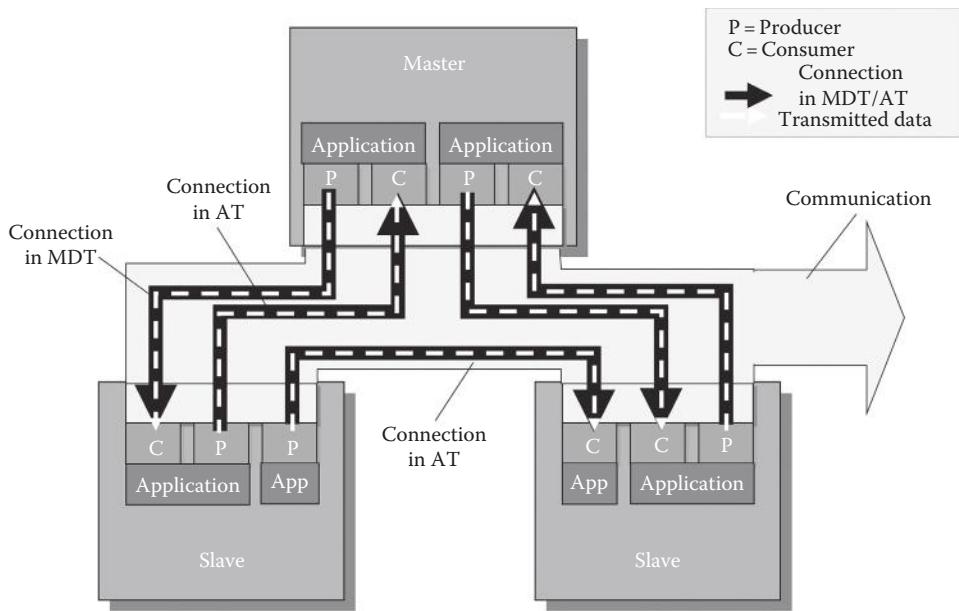

FIGURE 13.7 Communication phases of a Sercos III network.

**FIGURE 13.8** Sercos III communication model based on connections.

In addition to the cyclic RT data transmission, additional services are available:

The *service channel* allows high level, non-time-critical data transfers without disturbing the synchronous transfer of data. For example, items such as communication settings, parameters, or diagnostic information do not need to be transmitted repeatedly, so it is not necessary to impact loop performance by setting aside bandwidth for them. The service channel is part of the protocol in the RT channel and is identical to the service channel of Sercos I/II.

The *Sercos Messaging Protocol (SMP)* is used to transmit services and data within a cyclically configured data container with a fixed length. Both cyclic and acyclic fragmented data can be transmitted via a cyclic Sercos data container within the RT channel. Data packets with low priority can be interrupted by packets with higher priority. Thus, an efficient multiplexing of several logical communication channels within a single data container is possible.

The *S/IP protocol* enables direct communication as well as uniform data exchange between devices, without a Sercos III master or a subsidiary Sercos III communication being necessary. Even in cyclic RT operation, the S/IP protocol can still be used. In this case, the S/IP telegrams are transferred into the UCC of Sercos III, without having a negative influence on the RT behavior of the network. S/IP provides services to read and write parameters of a device, including the possibility of combining several tasks and sending them to the final device for processing. Furthermore, apart from fixed, preset, standardized protocol services, manufacturer-specific services can also be added, which makes Sercos III particularly flexible for users and developers.

#### 13.2.4.11 Addressing

Sercos III devices must support Ethernet's MAC addressing, plus the Sercos III addressing. Other addressing schemes are optional.

Each Sercos III device contains a numeric address used by other devices on the Sercos III network to exchange data. The address may be any whole integer from 1 to 511. The topology address is new in Sercos III and is necessary for the communication of the master in CP1 and CP2 with all slaves in the ring. By means of this topology address, it is possible to also communicate with slaves that do not have

a Sercos address. The topology address also makes it possible to recognize which slaves in the ring use the same Sercos address and, if needed, to change a present Sercos address. The topology address is determined by the slave in CP0 out of the physical topology (cabling). In CP1 and CP2, defined offsets in the frames are assigned to each topology address for the necessary data fields (SVC, C-Dev, and S-Dev). Sercos III does not use an IP address for its own operation. Whether a device contains an IP address or not is dependent on its support of other specifications, either independent (exclusive) of Sercos III operation or via the UCC portion of the cycle.

### 13.2.5 Sercos III Features

#### 13.2.5.1 Redundancy and Hot-Plugging

When a ring network is employed, Sercos III provides for automatic infrastructure redundancy. If any interconnection point in the ring ceases to function, the associated Sercos III nodes will detect a ring break and loop back the end nodes, effectively operating as two lines rather than one ring. The operation is *bump-less*, as the detection and recovery time for such a break is less than 25 µs, which is less than the minimum Sercos III cycle time. Sercos III can also recover from ring breaks and *heal* with no interruption in operation. Since Sercos III telegrams continue to be emitted by transmit PMAs on unconnected ports, and receive PMAs on unconnected ports continue to monitor for incoming data, when a Sercos III port recognizes that a ring has been physically reclosed, it will reactivate the counter-rotating telegrams to functionally close the rings again. This operation is also bump-less.

Another feature of Sercos III is hot-plugging and hot-swapping, which is the ability to add devices to an active network or to replace devices. Using the features described for redundancy, a network can detect when a new device is attached to an active network. Processes exist that configure the new device and announce its availability to the master control. After that, the master control can select to make use of the new device based on the application currently running.

#### 13.2.5.2 Direct Cross Communication

Because of the unidirectional communication of the fiber-optic ring, a direct communication between the slaves was not possible with the first and second Sercos generations. However, because of the full duplex characteristic of Ethernet, Sercos III supports this direct CC feature, which is advantageous for several motion control applications (see Figure 13.9). The direct CC supports the data exchange between

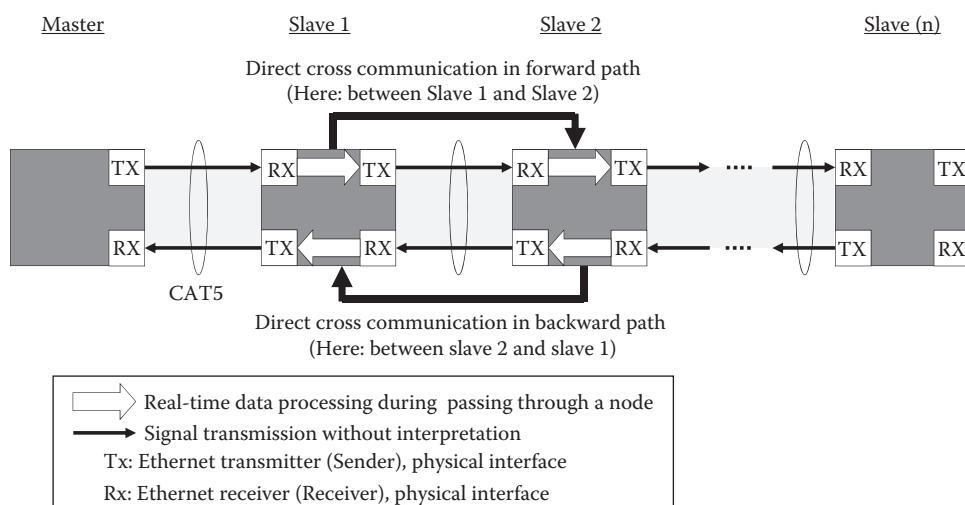

FIGURE 13.9 Direct cross communication between Sercos III slaves.

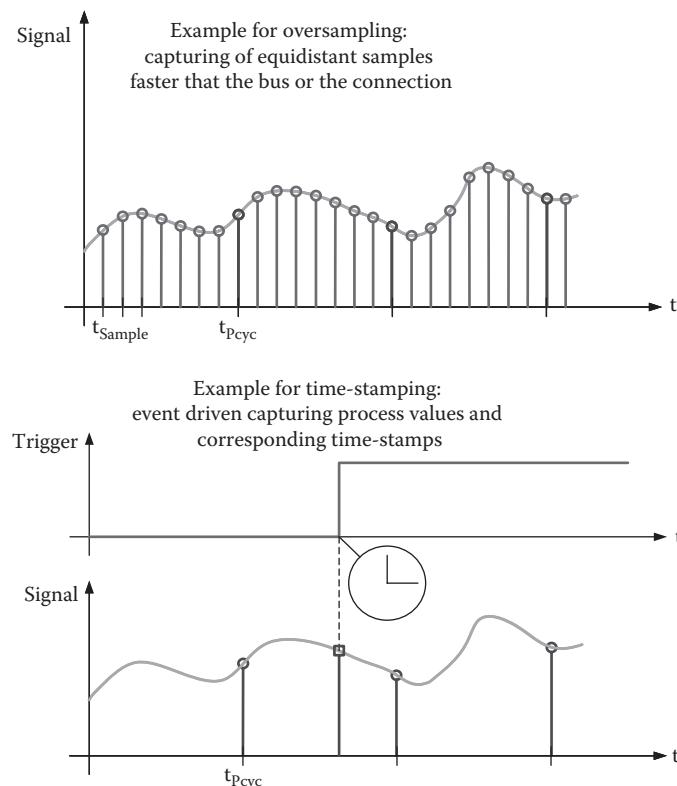

any two nodes within one communication cycle. This has the advantage that data—even in case of longer cycle times—can always be transferred between slaves within one communication cycle. This results in a minimum delay time. In addition, the central master does not need to be involved to copy and retransmit data in a separate communication cycle. As all devices are synchronized with each other, all target values are activated synchronously and simultaneously, and the actual values across the entire network are collected synchronously and simultaneously (related to the same communication cycle).

Communication and synchronization between multiple motion controls also is supported by Sercos III. Several machine modules in modular and networked machines and systems can be synchronized with each other, and RT data can be exchanged between the controls. For this, a dedicated communication profile (C2C) was developed as an extension to the basic Sercos III communication protocol.

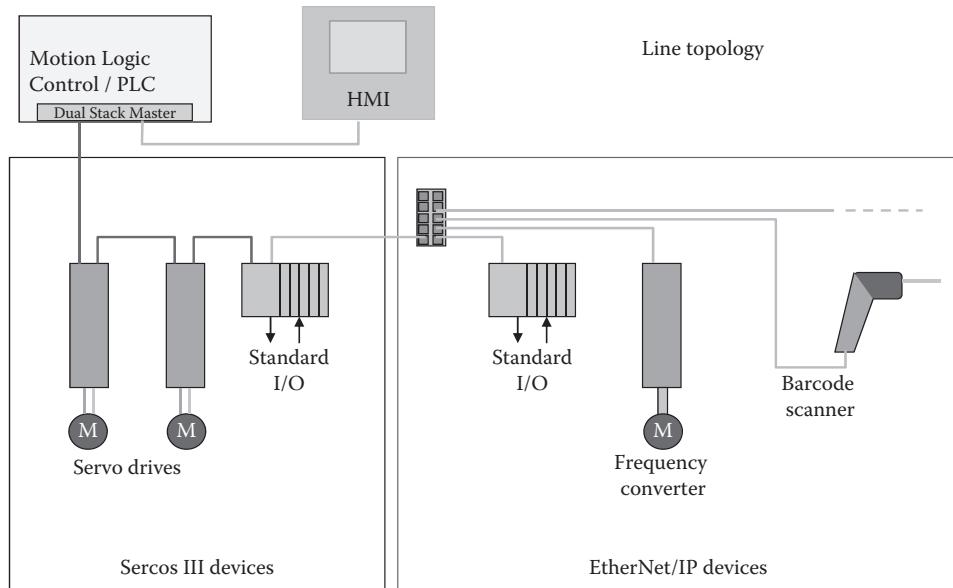

### 13.2.5.3 Oversampling and Time-Stamping

Sercos III defines two services on the protocol level that are useful for distributed automation applications. The oversampling function makes it possible to transmit more than one target/actual value per clock cycle, while time-stamping allows transmitting event-controlled information independently from the fixed clock cycle (Figure 13.10).

1. An oversampling procedure allows acquisition of equidistant values and activation of equidistant command values—faster than the configured bus or connection cycle. This increases the process control intricacy, for instance, in extremely time-critical laser applications, as it allows for more data to be collected and communicated at a faster speed. Measurement methods were integrated directly in the protocol, thereby opening up the possibility to access these mechanisms across different manufacturers and products.

**FIGURE 13.10** Oversampling and time-stamping.

**FIGURE 13.11** Blended infrastructure for Sercos III and EtherNet/IP.

2. In addition, a time-stamping procedure for event-triggered acquisition of values with corresponding time stamps, as well as time-triggered activation of command values, has been defined. This function is event controlled, promptly transmitting defined events such as certain measurement values to the controller and switching outputs independently from the clock cycle. This increases process stability, for instance, in complex solutions such as those needed in semiconductor or solar manufacturing.

#### 13.2.5.4 Blended Infrastructure for Combining Sercos III and EtherNet/IP

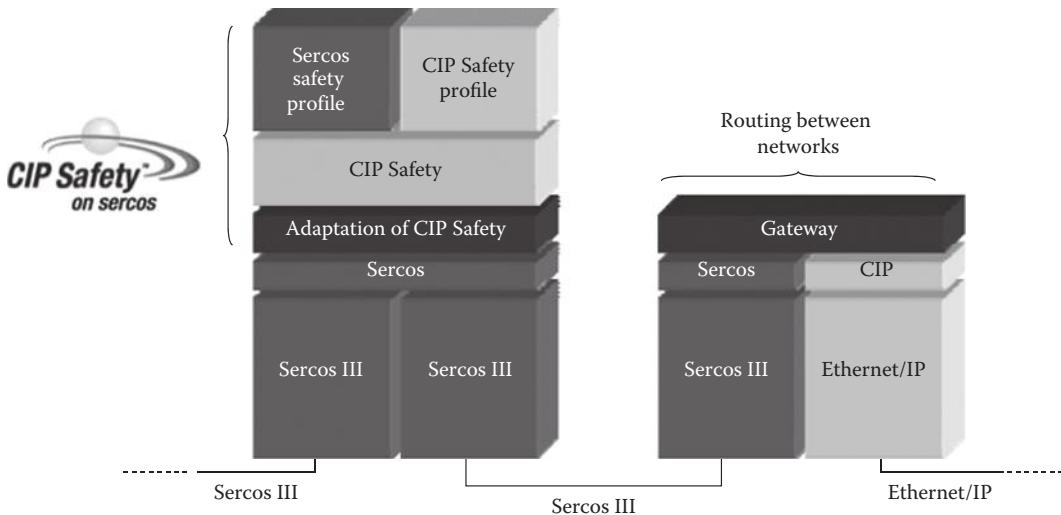

The blended infrastructure approach was announced in April 2012 by ODVA and Sercos International as one of the first practical results of the machinery initiative in which Sercos International, ODVA, and OPC Foundation collaborate (see Section 13.2.14).

Because the network infrastructure required for EtherNet/IP and Sercos III includes the physics and data link layers of Ethernet, Sercos telegrams, CIP messages, and TCP/IP messages can coexist within a network without requiring additional cables (see Figure 13.11). To keep the cyclic and clocked communication of Sercos III intact, the CIP messages and TCP/IP telegrams are transmitted in the UCC, which is an integral part of the Sercos transmission method. The blended infrastructure approach does not require any modifications to the existing Sercos III and EtherNet/IP specifications, as the respective communication mechanisms have already been integrated in the Sercos III transmission process. Only an implementation guide describing the planning and setup of such multiprotocol networks is required.

#### 13.2.5.5 CIP Safety on Sercos

CIP Safety on Sercos is the protocol used to transfer safety-critical data over the Sercos III network. It was defined in collaboration with ODVA and has been certified for compliance with IEC 61508 up to Safety Integrity Level 3 (SIL3). No additional safety bus is required because the safety information is sent in addition to the standard data on the Sercos network in RT. The combination of drives, peripherals, safety bus, and standard Ethernet in a single network simplifies handling and reduces hardware and installation costs, and it makes it easy to deploy integrated safety controllers and homogeneous safety solutions.

Reliable communication can take place between all network levels including peer-to-peer communication and cross-network communication. The master does not necessarily have to be a safety controller.

**FIGURE 13.12** CIP Safety on Sercos architecture.

It can also route data without being able to interpret it. This makes it possible for users to flexibly configure the safety network architecture for the implementation of safety programmable controllers or peer-to-peer communication between sensors and actuators. In addition, use of a standard CIP network as a backbone network enables seamless communication between safety devices in different subnetworks (see Figure 13.12).

Safety-related data are sent in a safety data container that is placed on the RT data channel (MDT and AT) similar to standard data. A multiplex protocol, the SMP, is used to transmit differently sampled safety data without a loss of bandwidth and despite short cycle times. CIP safety has been certified by TÜV Rheinland for use in applications up to SIL3 and complies with IEC standard 61508 for functional safety (Functional safety of electrical/electronic/programmable electronic safety-related systems).

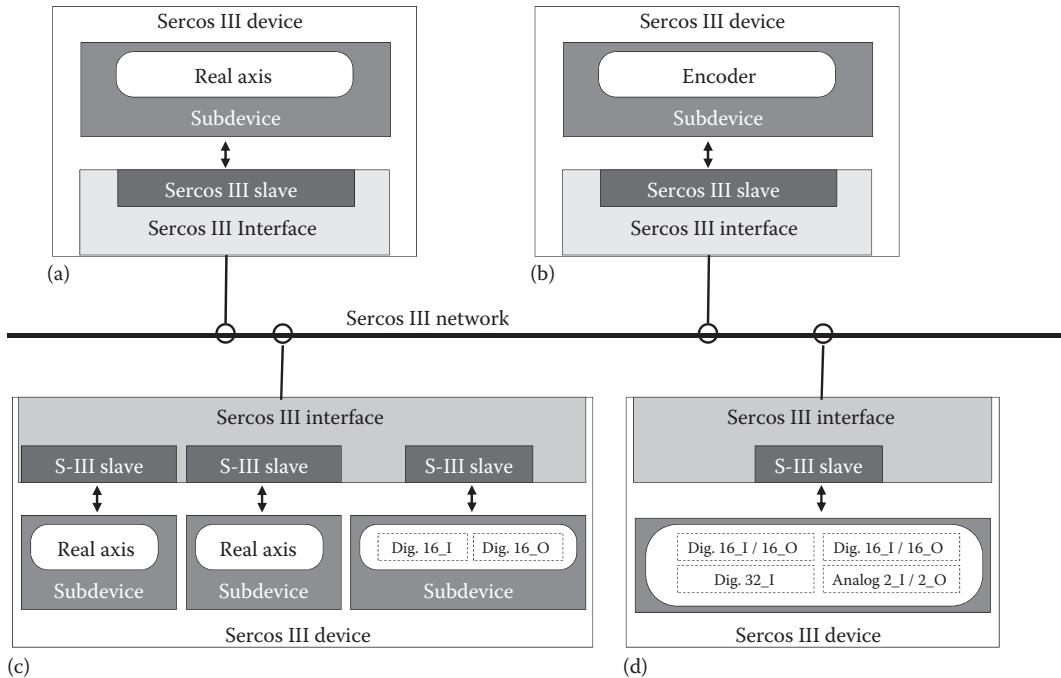

(For a detailed description of CIP Safety, refer to the ODVA contribution about CIP Safety.)

## 13.2.6 Sercos III Profiles

### 13.2.6.1 Introduction

The existing Sercos servo drive profile has evolved into a mature and established device profile during the past 15 years. Due to its broad use in different application fields, it covers an extensive and proven functional range. In the course of adapting the device profile to Sercos III, it was extended and generalized in such a way that not only pure drive, I/O, and control devices are supported, but hybrid devices, which combine different applications in one device, are also covered (see Figure 13.13). Accordingly, new device profiles for additional actuator physics and drive types (closed and open loop drives,...), as well as additional device functions, for example, I/O functions, technology modules, controls, and monitoring systems were defined.

All Sercos-related traffic across a Sercos III network consists of Idents or IDNs (parameters) with attributes (see Section 13.2.4.8). This method was first defined in Sercos I, as an essentially flat set of Idents. They were later grouped into application sets to aid in the selection of pertinent Idents required for a given industry, such as the “Pack Profile” for use with packaging machinery. During the development of the Sercos III specification, this methodology was further refined to group the Idents logically by device class. The definition of the legacy Idents has remained largely untouched; rather their grouping has been reevaluated for a more understandable architecture. This has also enabled the

**FIGURE 13.13** Profiles of Sercos III devices. (a) servo drive (single axis), (b) encoder, (c) double-axes drive with integrated I/O functions, and (d) modular I/O device.

separation of communication Idents into a logical subset, simplifying migration from Sercos I/II to Sercos III and providing a clear overview to users.

### 13.2.6.2 Generic Device Profile

The objective of the generic device profile (GDP) is to provide for a view of the subdevice that is independent of the function-specific profile (FSP) that is implemented by the subdevice. The following parts are independent of the FSP:

- Identification
- Administration
- Archiving
- GDP state machines allow a decoupling of communication and the applications state machine

### 13.2.6.3 I/O Profile

The Sercos I/O profile is a powerful and future-proof device profile for decentralized I/O periphery. The profile can be used for block I/Os as well as for modular I/Os. Furthermore, hybrid devices are supported, which combine miscellaneous functionalities in one single device (e.g., two-axis controller with I/O and master functionality).

For the configuration of corresponding devices, an XML-based device and profile description language was specified. Sercos device description markup language (SDDML) describes which profiles are supported by a certain device. Sercos profile description markup language (SPDML) is applied to specify different profiles on the basis of the parameter model of Sercos. Not only predefined standard parameters can be used, but also manufacturer-specific parameters can be defined. In this context, the Sercos communication profile, the GDP, and the FSP are differentiated. The combination of these profiles forms a so-called application-specific profile.

#### 13.2.6.4 Energy Profile

Sercos Energy is an application-layer profile that defines parameters and commands for the reduction of energy consumption in a uniform and vendor-independent manner. The control reads out defined standard parameters of each Sercos Energy component via the Sercos III network, receiving status information and detailed consumption values. Depending on the situation (e.g., scheduled or unscheduled breaks and machine components not needed in the current production process), the control can switch connected components (drives, I/O, sensors) into energy-saving conditions, up to complete shutdown, in a targeted manner, considerably reducing their energy consumption.

Using this approach, Sercos Energy is able to reduce the energy consumption in three areas. First, the permanent load at motor/machine standstill is reduced; second, the consumption depending on the process is dynamically adjusted considering the target completion times/dates (partial load operation); and third, energy is saved during processing by switching off components that are not required at a particular time or point in the process (partial machine operation).

#### 13.2.6.5 Encoder Profile

In the first and second generations of Sercos, absolute and incremental encoders were connected to the servo drives or to the control system by means of a separate fieldbus and not directly to the RT bus. Because of the universal use of Sercos III, there has been a demand to directly integrate encoders into a Sercos III network. The Sercos encoder profile ensures that the functions of an encoder—absolute or relative—are made available via clearly defined vendor-independent interfaces. The profile defines the functions supported by a device and how these functions may be used by other devices, such as control systems or servo drives.

#### 13.2.7 Device Description

The Sercos device model enables representation of all types of automation devices at the field and control level in the different phases of the life cycle both functionally and logically. For Sercos III, two languages were developed to describe devices and their functions for offline configuration and for a simple display in a generic engineering tool.

SDDML, the device description language for Sercos III devices, is an XML-based description for Sercos III devices and is based on the Sercos III device model. In each case, a device is described that can consist of several subdevices. In addition, more information can be provided for the configuration tool. It is, for example, possible to describe rules, such as which I/O components within a modular device can be combined. The device description also indicates if the range of IDN values deviates from the range defined in the profile, because the complete function is not implemented.

SPDML, the profile description language for Sercos III, offers the opportunity to describe the profile elements. These profile elements are either IDNs or areas in the RT messages of Sercos III. Furthermore, profile elements can be complete profiles. Thus, hierarchical and nested profiles can be described. The description of IDNs and areas in the existing RT messages includes the ability to set value ranges, to impose semantics to a bit sequence, to describe dependencies of profile elements, and to assign plain text in different languages to diagnostic and error codes.

#### 13.2.8 Configuration of Sercos III Networks

With the help of the device and profile description languages (SDDML and SPDML), Sercos III devices can be described uniformly and configured with the appropriate configuration tools using a configuration interface. The configuration interface (SCI) is available in two variants (see Figure 13.14). First, an XML interface is defined based on an XSD schema. Second, there is an optional resource-saving option for systems with limited resources (*embedded systems*) as a binary counterpart. The SCI interface defines the network configuration and defines the slaves that must be present and that may optionally

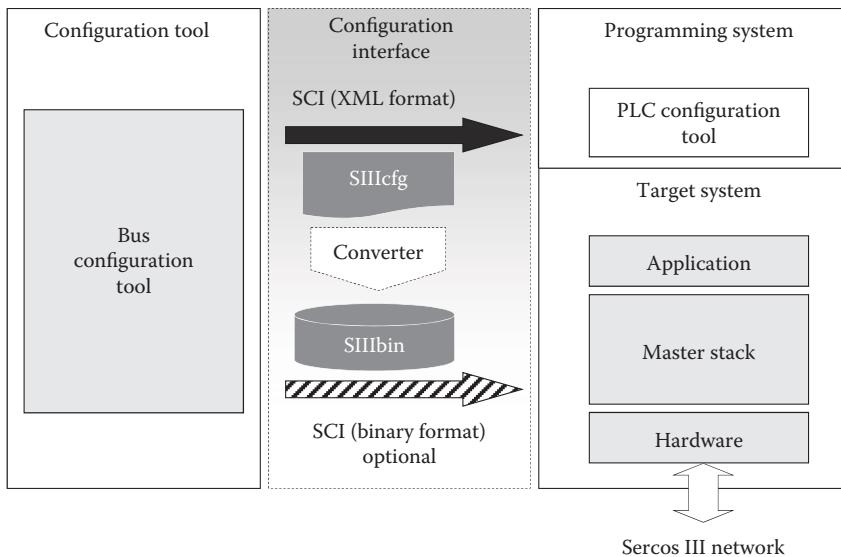

FIGURE 13.14 XML-based configuration interface for Sercos III networks.

be present. The identification of the slave devices is done via criteria described in the file. Furthermore, the configuration file describes the parameters of each device using a generic procedure. In addition, the parameterization of the master can be done.

Sercos III is applying the open and vendor-independent FDT technology in order to standardize the communication interface between field devices and engineering tools. A device manufacturer can deliver a Sercos III product with a device-specific Device Type Manager (DTM). In this case, the DTM can be directly integrated in the FDT framework application. Furthermore, a DTM can be generated from an SDDML-compliant device description using a generic converter. The device description is either already available as a file (offline) or generated from the parameter set of the device that can be accessed and read out via the bus system (online).

### 13.2.9 Implementation of Sercos III

The first and second generations of Sercos have been supported by a specific communication ASIC (Sercon410B and Sercon816). With Sercos III, a more flexible hardware solution is used (see Figure 13.15). The basis is the development of a Sercos core (Sercos III IP), with which manufacturers of components and systems are able to integrate Sercos III in an FPGA. At present, devices of Xilinx, Altera, and Lattice are supported.

IP core licenses are granted via the Sercos user organization. Different license models are available; member companies of the Sercos organization receive preferential prices.

Furthermore, the Sercos user group cooperates with chip manufacturers and system houses in order to integrate the required hardware functions into ASICs, processors, and universal multiprotocol communication controllers.

Different software packages are made available as open-source software to facilitate the device implementation (see Sections 13.2.10.1 through 13.2.10.3).

A Sercos III master can also be implemented without any special hardware (i.e., SoftMaster). Standard Ethernet controllers are used instead of the specific Sercos III hardware. Sercos-specific hardware functions are moved to the hardware-related and RT capable part of the master driver. Thus, the master can be fully implemented in software. Such a concept is interesting for PC-based control platforms that have an *onboard* Ethernet interface.

Type	FPGA				ASIC		Processor

Master (Hard)	■	■	■	■		■	■	
Slave	■	■	■	■	■	■	■	■
EasySlave				■				

FIGURE 13.15 Sercos III controllers for master and slave implementations.

### 13.2.9.1 EasySlave

The integration of I/O slaves can be easily accomplished with the EasySlave FPGA-based single-chip controller. EasySlave enables the inexpensive and flexible activation of Sercos slave devices, thus making it even easier to connect sensors and actuators. EasySlave is equipped with an RT channel with one input and one output connection and supports cycle times as low as 31.25 µs. The I/O applications are synchronized in the Sercos cycle. Features are the following:

- FPGA-internal RAM for Sercos stack, application code, and data
- RT channel with max. 32 bytes output and 32 bytes input data
- Supported cycle times down to 31.25 µs
- Synchronization of application to Sercos cycle
- Parameterization via service channel
- Support of Sercos hot-plug services
- S/IP services (Nameplate, Identify, SetIp, etc.)
- IP channel for ARP, Ping, and firmware update over TFTP
- Design targeted to Xilinx Spartan-6 FPGA series (XC6SLX16 or higher density) including a MicroBlaze Soft-core Processor

Licenses for applications are granted via Sercos International. Different license models are available; member companies of Sercos International receive preferential prices. A license-free variant of the EasySlave with limited functionality as a bitstream is also available under the product name Sercos EasySlave-IO.

## 13.2.10 Software Packages

### 13.2.10.1 Open-Source Sercos III Master Library

The Sercos user organization provides an open-source software driver library (CoSeMa = Common Sercos Master) for a Sercos III master implementation. The source files of this master library are available via the sourceforge.net Online-portal (<http://sourceforge.net/projects/cosema/>) and can be

used by interested users (control manufacturers and software tool suppliers) according to the GPL license. The library is fully tested software without any functional limitations. All features of Sercos III are supported; for example, the RT channel, the redundancy concept, and hot-plugging.

### 13.2.10.2 Open-Source S/IP Protocol Driver Library

The Sercos user organization has made available a driver library for the Sercos/IP protocol as open-source software. The driver software is available for download as C# source code via <http://sourceforge.net>, without any license fees and without any usage limitations (<http://sourceforge.net/projects/sercosips/>).

The protocol enables direct communication as well as uniform data exchange between devices, without a Sercos master or a running Sercos communication being necessary. Even in cyclic RT operation, the Sercos/IP protocol can still be used. In this case, the Sercos/IP telegrams are transferred into the UCC of Sercos, without having a negative influence on the RT behavior of the network.

With the Sercos/IP protocol, the vertical integration of devices into a production system is improved. The setup, remote maintenance, and diagnosis of Sercos devices can be carried out via Sercos/IP over an intranet or the Internet.

### 13.2.10.3 Open-Source UCC Ethernet Network Driver

The Sercos user organization also provides a sample code of an Ethernet Network Driver for handling the UCC of a Sercos III network. This driver connects the UCC (CoSeMa API) to, for example, a VxWorks TCP/IP stack (<http://sourceforge.net/projects/sercosuccend>).

### 13.2.10.4 CIP Safety Stack Software

This software package contains the protocol stack software for Sercos III and EtherNet/IP, a safety manual, and unit tests. Because all components are made available as ANSI-C code, porting to customer-specific safety platforms is possible with minimum effort. The unit tests provided considerably facilitate the recertification of the CIP Safety protocol software after porting the code to a safe target platform. IXXAT Automation GmbH\* provides various services regarding the CIP Safety technology, such as consulting, code introduction, integration workshops, implementation support of the CIP Safety software in customer-specific hardware and software, and assistance in final device certification.

### 13.2.10.5 Sercos Monitor

The Sercos user organization provides a powerful diagnostic tool for Sercos III networks that can be downloaded free of charge from the Sercos website.<sup>†</sup> The Sercos Monitor runs under Windows XP and Windows 7 operating systems and is based on the WinPcap interface (see Figure 13.16). The tool allows a comprehensive and detailed analysis of the data traffic in Sercos III networks. It allows both retroactive evaluation of stored network records in the pcap file format and analysis of the network traffic in realtime. A user-friendly interface and overview functions for the typical features of a Sercos III network, such as topology, communications phases, and service channel transmission, enable a fast and targeted launch of the analysis process. Experienced users are additionally provided with comprehensive protocol and analysis functions. Different views and filter mechanisms allow the customized evaluation of Sercos III RT telegrams and other Ethernet telegrams based on the individual requirements of the user. Users can also add additional functions to the Sercos Monitor via user-specific plug-ins, if needed.

\* See <http://www.ixxat.com/cip-safety-originator-target-software-en-html>

<sup>†</sup> See [www.sercos.de](http://www.sercos.de). Look for Downloads/Tools.

FIGURE 13.16 Diagnostic tool for Sercos III networks.

### 13.2.10.6 MultiSlave Emulator

The MultiSlave Emulator tool runs under Windows XP and Windows 7 operating systems and is based on an active Sercos PCI board from Automata GmbH & Co. KG.\* A user-friendly interface supports the emulation of complete Sercos networks and the connected Sercos slave devices. These devices can be freely configured. By reading out the available parameters from the real device and importing these into the MultiSlave Emulator, the emulation of the individual devices, as well as the complete network, can be executed with a minimum of effort.

### 13.2.11 Conformance Testing

In order to ensure that Sercos products from various manufacturers are compatible and meet IEC standards, conformance testing and certification of all Sercos products are required. Once a product passes the conformance test, a certificate can be requested, and the product can carry the Sercos trademark.

#### 13.2.11.1 Conformance Test Software

The Sercos III Slave Conformizer is a powerful and independent test system for conformance testing of Sercos III slave devices. This test system, which basically takes the form of a reference master, ensures the compatibility and interoperability of Sercos III slave configurations from different manufacturers.

\* See <http://www.cannon-automata.com/>.

Originally designed for test lab certifications, the software can also be used by companies as a testing tool for product development and quality assurance. This guarantees a high conformity of configurations and allows certification procedures to be carried out quickly and with minimal costs. The Sercos III Slave Conformizer provides a complete testing and development environment for Sercos slave devices. It includes an active PCI Sercos III interface card and test software that runs under Windows operating systems without the need for RT extensions.

With a user-friendly graphic interface based on the Eclipse Framework, individual tests are performed and documented via protocols. The tests themselves are available as readable files using the Ruby script language. Extensive test scripts are included for communication, the GDP and the FSPs for drives and I/Os. Product and manufacturer tests can also be easily integrated.

The Slave Conformizer can be purchased from Sercos International. (see [www.serco.de.](http://www.serco.de/))

A test procedure is defined for master testing. However, this is a manual test procedure (check-list) instead of an automatic test with a conformance test tool. However, there are plans to extend the MultiSlave Emulator in such a way that master devices can be tested automatically.

### 13.2.11.2 Conformance Testing Procedure

Sercos III devices are certified by the test lab at the Institute for Control Engineering of Machine Tools and Manufacturing Units (ISW) at the University of Stuttgart, in cooperation with the Steinbeis Transferzentrum für Systemtechnik (TZS) in Esslingen, Germany. Any company interested in conformance testing should contact Sercos International for scheduling and pricing.

### 13.2.11.3 Plug Fests

Sercos international holds twice-yearly Sercos III Plug Fests at the Sercos Competence Center at ISW, University of Stuttgart. The plug fests are free of charge to any manufacturer of Sercos III control systems, servo drives, I/O systems, and other peripheral devices. The staff of the testing laboratory is present with the Sercos III Slave Conformizer.

Interoperability tests are performed between each present master and slave and between masters and multiple slaves to verify implementation of Sercos III master and slave devices to ensure the best possible compliance of the different products. Various features, such as ring break detection, ring recovery, hot-plugging, UCC connectivity, and S/IP protocol support are tested and verified in different network configurations. This also helps improve the Sercos III specification, consequently limiting the scope of interpretation.

## 13.2.12 Publications

### 13.2.12.1 Sercos in IEC Standards

The Sercos technology is part of several IEC standards:

- IEC 61800-7(-1, -204, -304): Sercos Drive Profile
- IEC 61784-1, IEC 61158-2, IEC 61158-3/4/5/6-16: Sercos I/II Communication Profile
- IEC 61784-2, IEC 61158-2, IEC 61158-3/4/5/6-19: Sercos III Communication Profile
- IEC 61784-5-16 Ed 2.0: Sercos Installation Profile
- IEC 61784-3-2: CIP Safety on Sercos

Any of these standards can be obtained via the IEC web store.\*

### 13.2.12.2 Planning and Installation Guide

The Sercos III Planning and Installation Guide is intended to support engineers and electricians during the planning and installation phase of a Sercos III network in order to guarantee trouble-free operation

---

\* See <http://webstore.iec.ch/>.

of machines and systems. The cabling with copper wire and optical fiber is described, each in consideration of IP20 and IP65/67 protection class. The specification is based on the international standard IEC 61918 (Installation of communication networks in industrial premises), with an added installation profile for Sercos III, which will be standardized in IEC 61784-5.

### 13.2.12.3 Energy White Paper

The Sercos Energy White Paper describes the increasing importance of energy efficiency in production technology, the application scenarios for Sercos Energy, and the advantages of Sercos Energy. The White Paper is available for download from [http://www.Sercos.com/literature/pdf/SERCOS\\_Energy\\_Whitepaper\\_V10.pdf](http://www.Sercos.com/literature/pdf/SERCOS_Energy_Whitepaper_V10.pdf).

### 13.2.13 IO-Link Integration

The Sercos user organization provides a guide for the standardized mapping of IO-Link devices to Sercos III. IO-Link is a low-level, point-to-point communication interface technology for interconnection of binary and analog sensors and actuators. This user guide helps the automation engineer to uniformly connect and integrate sensors and actuators equipped with an IO-Link interface into a Sercos system. An IO-Link master can be implemented either as part of a modular Sercos slave I/O device or as a stand-alone Sercos III slave. The cyclic data of all inputs and outputs of IO-Link slaves are either transmitted completely within a cyclic IO container or alternatively as separate parameters. The Sercos parameter channel can be used in order to execute acyclic read/write access with regard to the addressed IO-Link slave devices.

### 13.2.14 Cooperation between Sercos, ODVA, and OPC Foundation

In March 2011, the Sercos user organization established a partnership with the ODVA and the OPC Foundation in order to foster cross-collaboration on topics of mutual interest for machinery applications for the benefit of machine builders and manufacturers (White Paper: Optimization of Machine Integration [OMI]\*). The cooperation efforts of the three organizations were set up to work on technical concepts for the following three use cases:

1. *Machine-to-machine communication:* Machine-to-machine communication is the foundation of OMI. Establishing standards will help minimize the time and cost of machine integration and reduce the custom software and special hardware needed to integrate different vendor's equipment. By sharing a unified integration model for key functions needed for machines to interoperate with one another—including command, configure, and control—along with a common data model to communicate key machine attributes, machine builders and manufacturers will find machines from multiple vendors and design cycles to be easier, faster, and cheaper to integrate.
2. *Machine-to-supervisory communication:* Communication between machines and supervisory systems is the accelerator for OMI. By leveraging SCADA and manufacturing execution systems, manufacturers can consolidate and exchange machine information across systems to collect production data, assist in asset management, and report diagnostics and alarms. This machine monitoring and management helps reduce downtime by promoting efficient utilization and multiplies the benefits of machine integration by automating actions that improve overall equipment effectiveness. OMI allows existing automation to incorporate the functionality needed to realize new efficiencies in machinery utilization, thus protecting the user's investment in technology.
3. *Communication connectivity:* Connectivity is the enabler for OMI. Machinery in the industrial ecosystem is characterized by multiple heterogeneous networks connected to multiple physical domains both inside and outside the manufacturer's enterprise. By leveraging common standards

---

\* See [http://odva.org/Portals/0/Library/Publications\\_Numbered/PUB00266R1\\_ODVA\\_Optimization\\_of\\_Machine\\_Integration\\_EN.pdf](http://odva.org/Portals/0/Library/Publications_Numbered/PUB00266R1_ODVA_Optimization_of_Machine_Integration_EN.pdf).

for physical media, network infrastructure, and secure remote access, both users and machine builders will be able to reduce the cost and complexity of machine integration while improving maintainability and safety of machines. As reliability is also essential, the OMI approach will define how communication is handled when machinery is unavailable.

The blended infrastructure approach for combining Sercos III and EtherNet/IP (13.2.5.4) is a first concrete result of this initiative (*communication connectivity* use case, as described earlier).

### 13.2.15 Performance

Sercos III shows a substantial increase in transmission speed (Figure 13.17) compared to Sercos I/II. For example, more than 70 drives can be provided cyclically with 8 bytes of data with a cycle time of 250 µs. In the following figure, some typical values are listed for different configurations of the UCC.

### 13.2.16 Sercos III Applications

Sercos III has been used since 2005 in numerous applications in mechanical engineering, for example, printing, food and packaging, machine tools, and robotics. At present, more than 200 Sercos III products from more than 70 manufacturers are offered in the market. They include complete automation solutions (package of controls, drives, and/or I/O peripherals), automation devices (control systems, drives, I/O devices, other devices such as sensors), tools (development, configuration, diagnosis), hardware and software components (controllers, drivers, stacks), and active and passive infrastructure components (switches, cables, plugs). More than a dozen service providers offer consultation and support for device manufacturers who do not wish to develop and integrate a Sercos III interface completely on their own. The range of services covers development support, training, consultation, testing, and even certification of Sercos III devices.

Additional information can be found on [www.Sercos.com](http://www.Sercos.com).

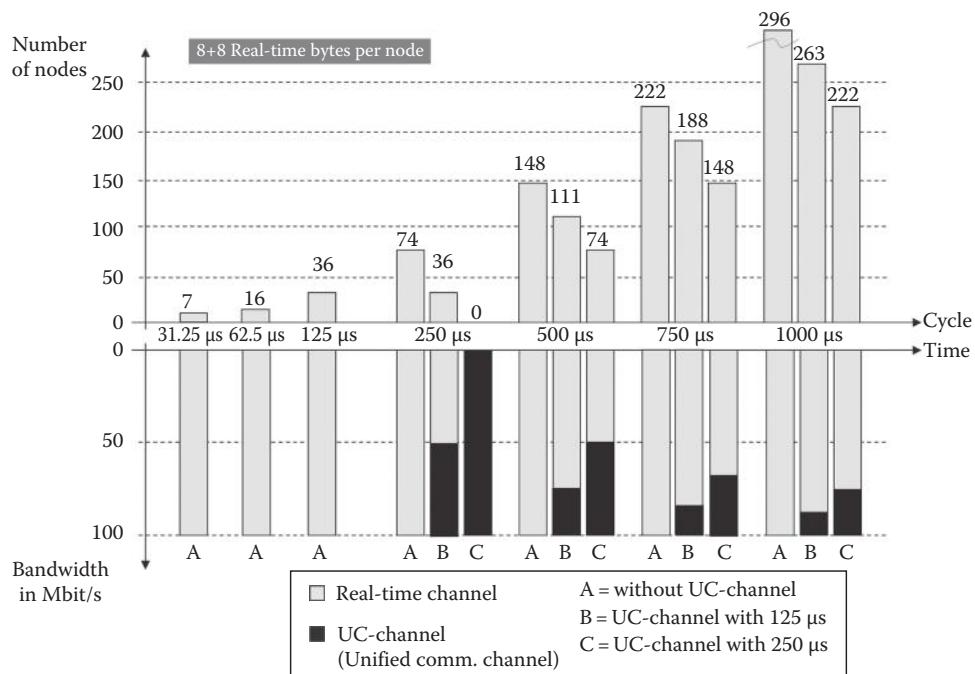

FIGURE 13.17 Sercos III performance.

### 13.2.16.1 Packaging Machines with Sercos III Communications

Rovema, a German-based packaging machine builder, supplies complete solutions for sophisticated complex packaging applications. Forming, filling, sealing, case packing, and retail packaging for today's market require a holistic approach that goes beyond the individual component level to include the specific customer process. A very powerful and highly flexible control system supports the broad product portfolio and the highly complex packaging operations. Rovema has been using its own proprietary PC-based P@ck-Control system for many years on its packaging machines. The motion control subsystem is based on a centralized control architecture. P@ck-Control takes total control of axis coordination and position control. The interface to the speed-controlled drives had traditionally been a conventional  $\pm 10$  V interface with incremental encoder feedback. Interbus-S had provided the link between the integral software PLC in the P@ck-Control system and the outside world.

The engineers at Rovema have designed the Ethernet-based Sercos III RT communications system into the new P@ck-Control generation. This new VPL260 tubular bag machine based on Sercos III was displayed for the first time at Interpack 2008. The machine also features continuous volumetric filling. The communication with the speed-controlled drives and the digital I/Os is achieved through the Ethernet-based Sercos III network. With the aid of defined profiles and the open Sercos standard, the design team succeeded in integrating the RT Ethernet network into Rovema's machines within 12 months replacing the analog  $\pm 10$  V interface (Figure 13.18).

### 13.2.16.2 Manz Scribing Systems Based on Sercos III: Maximum Thin-Film Module Efficiency

With an installation base of more than 100 machines, Manz Automation AG is a market leader in scribing systems for the thin-film technology. In this technology, very thin layers are applied to a glass surface: two conductive layers as well as the absorber layer. This promises to be a leading technology in large-scale photovoltaic modules. Manz scribing systems are available for various processes: not only mechanical but also laser-based scribing operations can be performed with maximum precision on Manz systems.

FIGURE 13.18 Rovema VPL260 tubular bag machine.

**FIGURE 13.19** Manz scribing system based on Sercos III.

Since efficiency of solar modules is key for the shortest return on investment, module manufacturers are strongly looking into process optimization. One approach for increased module efficiency is to minimize the dead area of solar modules. By using the Manz proprietary IPCS (Manz Inline Precision Control System) active tracking system, it is possible to achieve a dead area of <200 µm. This unique feature was introduced to the market in 2009 and has been successfully sold to numerous customers. This is a milestone compared with other systems on the market, where the dead area is approx. 150–300 µm above this figure.

In 2010, the Sercos II motion bus was replaced by the Sercos III automation bus to achieve higher RT bandwidth and optimum integration of machine control, IPCS, and other field devices. Together with its outstanding RT performance, Sercos III allows direct TCP/IP access with engineering and diagnostic tools from the desktop into servo drives, IPCS, and other field devices to achieve optimum service capabilities and minimum downtimes.

Because of the available bandwidth, Sercos III provides the opportunity to integrate all fieldbus-based devices on a single bus and is another contribution to clear system structure and reliability. Sercos III is ready for the fieldbus-independent CIP Safety protocol relevant for safe control of servo drive systems and laser sources. It will reduce total cost of ownership and increase system reliability (Figure 13.19).

## 13.3 Features and Operation of Sercos II

---

### 13.3.1 Introduction

Sercos I and II are the first two generations of Sercos and transmit data over a noise-immune, fiber-optic cable. Sercos I is now obsolete, so this section refers only to Sercos II. The only difference between the two versions is that Sercos I used an ASIC operating at 2 and 4 Mbps, while Sercos II uses an ASIC (Sercon816) that operates at 2/4/8/16 Mbps.

Work began on Sercos I in 1987, first products were introduced in 1990, and a draft international standard was created in 1990 and approved by the IEC in 1995.

ASIC development occurred in parallel with the standardization process. In 1993, SGS Thomson (now STMicroelectronics) developed the Sercon410B ASIC, operating at 2/4 Mbps. This made implementation of Sercos simpler and less expensive.

In 1999, STMicroelectronics developed the Sercon816 ASIC, operating at 2/4/8/16 Mbps, quadrupling available interface speeds. In 2000, Sercos II products from Sercos association members begin shipping with the Sercon816, and product shipments continue strongly today.

### 13.3.2 How Sercos II Communicates

#### 13.3.2.1 Topology\*

Components in a Sercos II-based motion control system are connected via fiber-optic rings using a master/slave configuration. A typical system may include several rings, with up to 254 devices per ring. A Sercos master controls each ring, assigning time slots to ensure deterministic and collision-free access for all slaves.

##### 13.3.2.1.1 Communications Structure

In order to ensure strict synchronization of multiple axes and a predictable update time at each axis, Sercos utilizes a master/slave communication structure, where the machine/motion control acts as a master, communicating with slave devices such as drives. The slaves are only permitted to respond to queries from the control.

#### 13.3.2.2 Fiber Optics

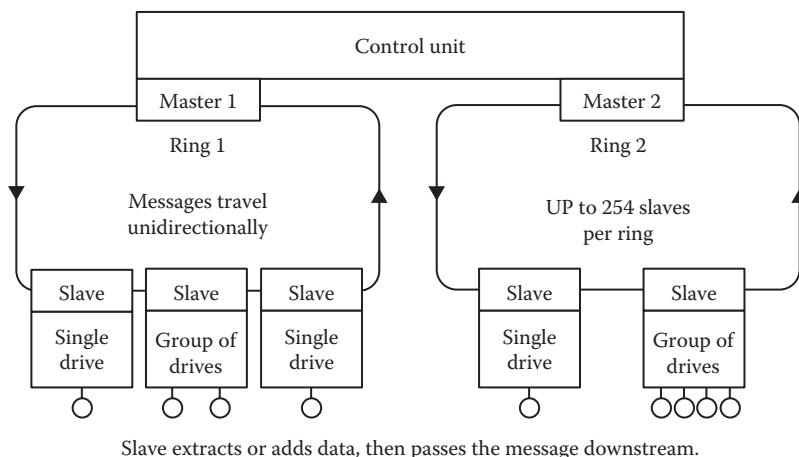

With Sercos II, one fiber-optic ring is used to exchange full 32-bit data between controllers, drives, I/O, and sensors. This includes commands, status, parameters, and diagnostics. Fiber optics provides inherent noise immunity and eliminates the immense requirements for conduit, wiring, and terminations normally required with the analog interface. The ring architecture reduces the number of components required on a motion control. Adding an additional motion axis often requires nothing more than opening the ring and placing the new slave device in the ring.

A Sercos ring is composed of a number of fiber-optic segments as illustrated in Figure 13.20. Each device in a system receives signals via a fiber-optic receiver with an F-SMA connector and transmits the signals to the next device via a fiber-optic transmitter, again with a standard F-SMA connector. Both plastic and glass fiber are specified, with wavelength specified at 650 nm.

Maximum cable lengths are as follows:

- Plastic fiber (POF)—1 mm diameter
  - Node to node—40 m
  - Maximum ring length (254 nodes)—10,000+ m

Master controls the ring and assigns time slots to ensure deterministic and collision-free access for all drives.

**FIGURE 13.20** Sercos generation I and II topology.

\* Illustrations and text adapted by permission from the technical paper *Open Drive Interfaces for Advanced Machining Concepts* by Scott Hibbard of Bosch Rexroth, January 1995.

**TABLE 13.2** Performance of Sercos Rings: Generations I and II

Cycle Time (ms)	Data Record per Drive (MDT + AT)	Transmission Rate (Mbit/s)	Number of Drives	Data Rate (Noncyclic Data)	Remaining Cycle Time (μs)
2	32 bytes	2	8	8 kbit/s (2 bytes)	390
1	32 bytes	4	8	16 kbit/s (2 bytes)	125
1	36 bytes	8	15	32 kbit/s (4 bytes)	208

- Glass fiber (HCS)—200 μm diameter
  - Node to node—200 m
  - Maximum ring length (254 nodes)—50,000+ m

The maximum number of drops per fiber-optic ring is 254. However, the number of drives that can be serviced per ring depends on three application requirements:

1. The communication cycle time
2. The volume of operational data
3. The communications speed required

Table 13.2 illustrates performance for generations I and II, showing examples of the number of drives per ring at various transmission rates and cycle times.

The number of rings that can be synchronized together is limited only by the controller, which will have a limit to the number of axes it can process. Sercos-compliant controllers can have a much higher axis limit than their predecessors, since Sercos supports distributed processing, which relieves the controller of many time-intensive tasks, which are now handled by the drives or other slave devices.

#### 13.3.2.2.1 Fiber-Optic Transmitters/Receivers

Fiber-optic transmitters and receivers from Agilent Technologies and Honeywell have been tested and approved by the Sercos Technical Working Group (TWG). The Sercos N.A. and Sercos International websites ([www.Sercos.com](http://www.Sercos.com) and [www.Sercos.de](http://www.Sercos.de)) provide links to downloadable data sheets for these products. Signal levels are defined in the IEC standard.

#### 13.3.2.3 Sercos ASICs

The Sercon816 ASIC is an integrated circuit for Sercos II RT communication systems. A Sercos II communications system consists of one master and several slaves, connected by a fiber-optic ring that starts and ends at the master. While its use is not mandatory, the ASIC contains all the hardware-related functions of Sercos and considerably reduces the hardware costs for a design. Unlike other bus interface devices, the Sercon816 ASIC features the capability to perform all sequencing and synchronization tasks, relieving the host microprocessor of these time-intensive functions. The ASIC is the direct link between the fiber-optic receiver and transmitter and the microprocessor that executes the control algorithms in a Sercos device. The same ASIC is used both for Sercos II masters and slaves.

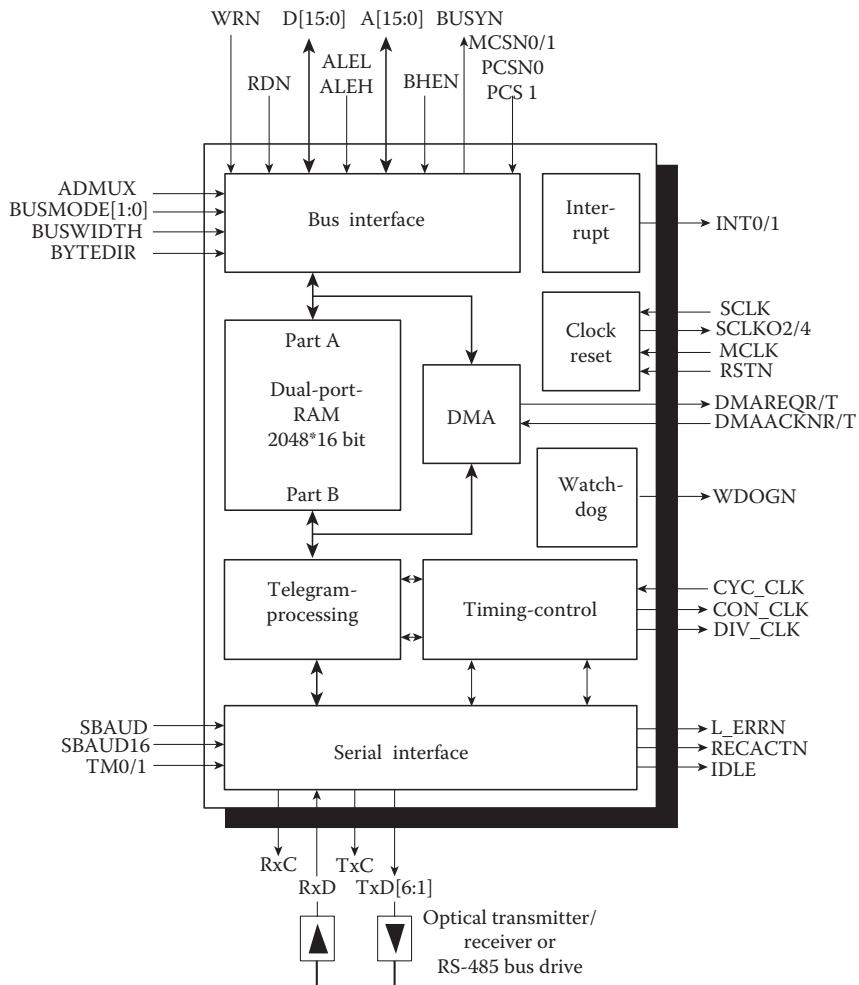

The Sercon816 is manufactured by STMicroelectronics in the 0.5 μm/5 V HCMOS technology. It operates at 2/4/8/16 Mbps and is downward compatible with the now obsolete Sercon410B (2/4 Mbps) ASIC (Figure 13.21).

Features of this device are as follows\*:

- Single-chip controller for Sercos, available in 100-pin flat-pack QFP100 and TQFP100 packages.
- Physically compatible with the Sercon410B.

---

\* Feature list and Figure 13.21, SERCON816 ASIC Block Diagram, from SERCON816 Sercos Controller reference manual, courtesy of Sercos International e.V., Suessen, Germany, 2001.

**FIGURE 13.21** Sercon816 ASIC block diagram.

- Faster and lower cost than Sercon410B.
- Interface to the microprocessor with a data bus width of 8 or 16 bits and with control lines per Intel or Motorola standards.
- Serial transmission rate of 2/4/8/16 Mbps with an internal clock. The chosen bit rate can be selected by pins or software. The ASIC can be run in Sercon410B compatible mode by tying pin SBAUD16 to a logical 1.
- Data communication is available via fiber-optic rings or RS-485 rings and RS-485 buses. RS-485 is seldom used.
- Dual port RAM with 2048 16-bit words for control and communication data.
- Data and clock regeneration, the repeater for ring topologies, and serial transmitter and receiver are integrated. The signals are monitored, and test signals are generated.
- Full duplex operation.
- Modulation of power of optical transmitter diode.
- Telegram processing for automatic transmission and monitoring of synchronous and data telegrams. The transmission of service channel information over several communication cycles is executed automatically.

- Flexible RAM configuration, communication data stored in RAM (single or double buffer), or transfer via DMA.
- Timing control signals.
- Automatic service channel transmission.
- Watchdog to monitor software and external synchronization signals.
- Reset value for repeater mode of the serial interface is configurable through input pins.

### 13.3.2.4 Timing

Timing is critical in serial networks because motion controls cannot accurately reconstruct the state of the machine unless everything is precisely synchronized—measurements, transmissions, and replies. Many of the messages that controls and slave devices send each other are for timing and synchronization.

In CNC position loop software, the position error is determined in a software routine that takes time to execute. The system works because the position error updates are designed to occur at predictable points in time. The same logic is applied in the Sercos bus. Methods are specified to keep the jitter on the serial link down to a low level, and then an internal timing sequence is used to ensure that all drives in a loop act upon their command signal at the exact same moment, and all acquire their feedback information at the exact same moment. The result is transparent to the user.

### 13.3.2.5 Interface Placement

Sercos supports position, velocity, and torque mode control, which maintains technology independence between drives and motion controls. This independence was one of the Sercos design goals, to ensure that the interface restricted neither the design of controls or drives, but allowed both to proceed independently. For this reason, the power stage interface controlling commutation/phase current was ruled out. A power stage interface is highly hardware dependent, requiring the vendor to design motion controls around specific motors, limiting the use of the control to that type of motor. It also involves transmitting high-speed commutation signals over long distances with microsecond update rates. Thus, the demands for speed on the Sercos bus are less than those for competitive interfaces that offer power stage control (Figure 13.22).

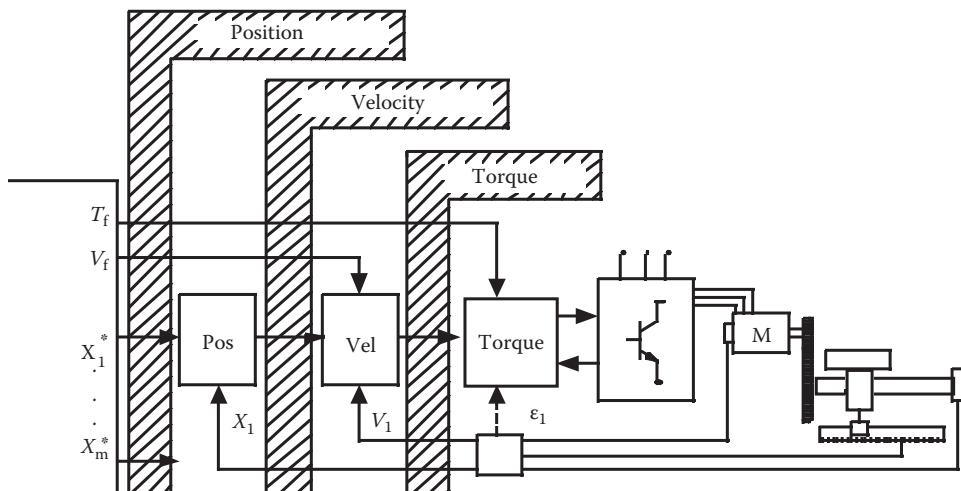

FIGURE 13.22 Interface placement.

### 13.3.2.6 Sercos IDNs

All communication between master and slaves is performed via a set of Sercos telegrams, each of which includes data records that each has an identification or *Ident* (IDN) number. All parametric data, such as scaling and loop gains, and RT loop closure information are set up this way. This allows Sercos to standardize the most common interface data.

The IEC standard allocates a block of 32,767 IDN numbers for standard commands. Over 700 of these are presently used to define a comprehensive set of motion control and I/O commands. All Sercos products must incorporate a subset of these, but do not necessarily need to include all IDNs.

The format used for a Sercos I/II IDN is shown in Figure 13.23.

#### 13.3.2.6.1 IDNs for Real-Time Data

The standard defines a number of IDNs for RT data. For example, in each communication cycle, the master transmits an MDT that contains a series of IDNs (idents) specifying RT operating data and drive commands for the addressed slaves. The master sends an acknowledge telegram in which each slave places 1–16 IDNs, reporting data such as speed, torque, and position measurements to the master, effectively closing the control loop.

For example, IDN 00047 transfers the specified position command value as a 32-bit value to the drive. IDN 00051 communicates the actual position feedback value 1 (motor feedback) back to the control, as illustrated in Figure 13.24.

#### 13.3.2.6.2 IDNs for Parameters

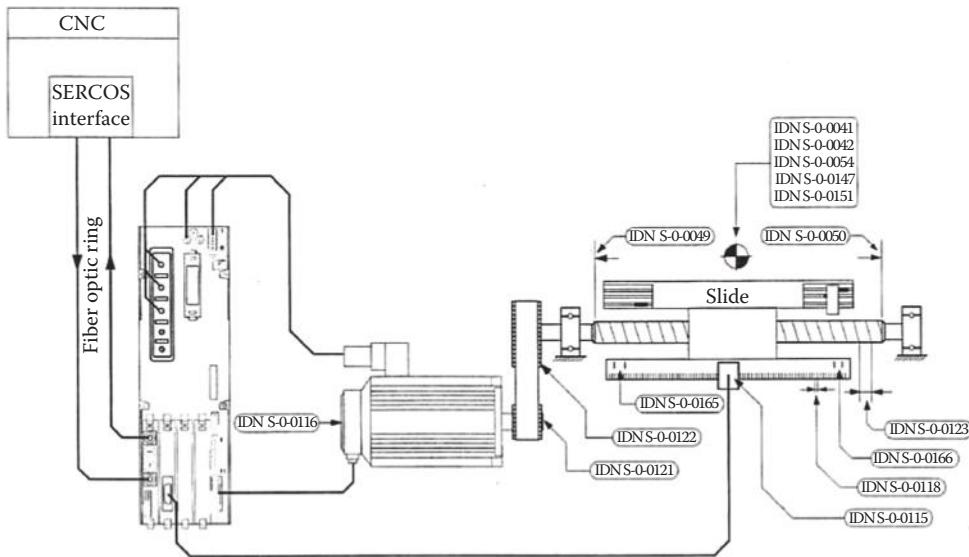

Figure 13.25 illustrates a Sercos drive system used to control a machine tool axis. It shows some of the control-specific and machine-specific parameter IDNs that would be used for control for such an axis and lists the function of each IDN.

IDN Name (abbreviation)	Function/description	Length in bytes	Minimum input value	Maximum input value	Scaling/resolution Units

FIGURE 13.23 Standard IDN format

S-00047	Position command value	During the position control drive operation mode, the position command values are transferred from the control unit to the drive according to the time pattern of the control cycle. 4 (bytes) $\geq -2^{31}$ Scaling type: IDN 00076 Max. $\leq +2^{31} - 1$ Scaling factor: IDN 00077 Scaling exponent: IDN 00078 Rotational position resolution: IDN 00079			
S-00051	Position feedback value 1 (motor feedback)	The position feedback value 1 is transferred from the drive to the control unit so that it is possible for the control unit to perform block stepping and to display position information if necessary. 4 (bytes) $\geq -2^{31}$ Scaling type: IDN 00076 Max. $\leq +2^{31} - 1$ Scaling factor: IDN 00077 Scaling exponent: IDN 00078 Rotational position resolution: IDN 00079

### 13.3.2.6.3 Manufacturer-Defined IDNs

In order to avoid restricting drive/control development, the IEC standard defines 32,767 vendor-defined IDNs that can be used by individual vendors to incorporate special features in their products. The standard provides that these vendor-defined IDNs enable *only* additional functionality not already handled by standard functions, thus ensuring interoperability.

One of the values of the vendor-defined IDNs has proven to be their use in incorporating new features into Sercos. A number of vendors have utilized the vendor-defined IDNs to introduce and field-prove some new control/drive feature, such as block mode in which the controller sends the drive a final destination, a velocity, a ramp, and possibly a jerk command, and then the drive operates independently until the destination is reached. Many of these features, including block mode, have been brought to the Sercos TWGs, where they have been incorporated into the standard IDN set for use in a standardized manner by all manufacturers.

### 13.3.2.7 I/O Functions

A set of I/O functions was defined and accepted as a part of Sercos II, but as Sercos was originally developed as a drive interface, these were not originally included in the formal IEC standard. A document describing these functions and parameters is available from the Sercos user organizations.

On the other hand, Sercos III incorporates a detailed and powerful set of I/O functions, as defined in the IEC standards.

### 13.3.2.8 System of Units and Variable Format

Wherever possible, tables of acceptable units such as revolutions, inches, and millimeters are defined for standardized telegrams. The format of the byte values is also defined. One of the more valuable results of the standards effort was the application of a predictable system of units for up-to-then unstandardized values, such as loop gains and feedback values. This is another step toward predictable operation of any servo system a machine builder may choose.

### 13.3.2.9 Sercos Cycle Times

The Sercos cycle time is specified in a flexible format of 62.5, 125, 250, 500 µs, and then multiples of 1 ms. (Sercos III cycle times begin at 31.25 µs.) The amount and type of data contained in a cycle are also variable.

This flexibility permits a designer to vary cycle time, content, and the number of slaves to achieve a particular project's requirements. More data can be sent faster to a smaller number of slaves, such as drives. Slowing the rate down permits a higher density of drives per ring. For example, with Sercos II, four to eight axes are common on a ring in machine tool applications where intense communication is required to control a high-speed tool path. Up to 40 axes may be controlled on a ring in packaging applications, and up to 100 axes may be found in web-fed printing applications, where electronic line shafting is utilized to synchronize a number of print cylinders and auxiliary axes. When necessary, multiple rings can be employed in an application.

### 13.3.2.10 Cyclic Operation

Sercos devices communicate and stay in sync by sending each other a series of telegrams. A telegram is a rigidly defined bit stream carrying data and timing information. Telegrams are

Master Synchronization Telegram (MST)—establishes the timing for the system

AT—response by the slaves to the MST

MDT—provides data records for all slaves in the loop

*Note:* In Sercos III, the MDT and MST functions are combined into a single telegram. (See Section 13.2 for details of operation.)

#### 13.3.2.10.1 Telegram Format

All Sercos telegrams consist of five major fields, as illustrated earlier. Teleograms are transmitted in the non-return-to-zero-inverted format. The transmitted signal remains at a 0 or 1 as long as the bit is a 0 or 1. In order to ensure edge synchronization and to prevent the delimiter pattern from reoccurring, the master forces a signal change every six bits by utilizing a *bit stuffing* technique of inserting a zero after five consecutive ones (Figure 13.26).

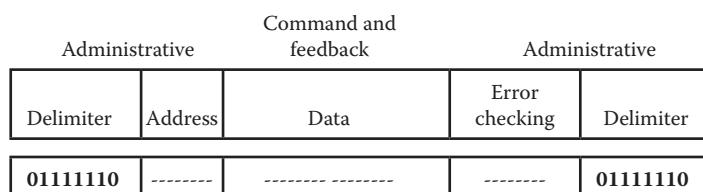

FIGURE 13.26 Standard telegram format.

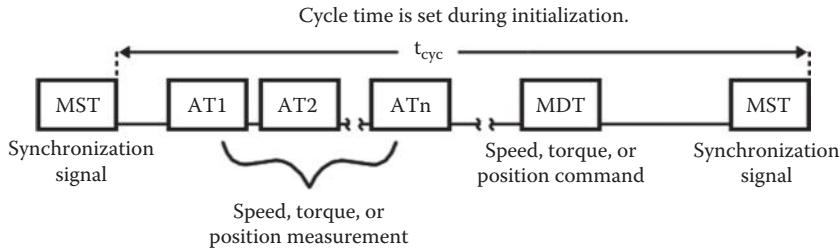

FIGURE 13.27 Timing diagram for cyclic operation.

### 13.3.2.10.2 Telegram Sequence

A Sercos II cycle involves three different types of telegrams, as illustrated in Figure 13.27.

1. It begins with the transmission of an MST from the master (CNC or motion control). The MST is used as a time mark for all slaves (e.g., drives) to determine when to talk on the bus, when to acquire feedback signals, and so forth.
2. At a predetermined time after the end of the MST, the first slave in the system places its data on the bus in an AT. Each slave follows in turn, all synchronized off the MST. During a Sercos initialization phase, the slaves are instructed when they should transmit their message with respect to the MST.
3. After the last slave has placed its data on the bus, the master sends out an MDT. The MDT is one long message with space set aside for each slave in the ring. The slaves have been previously instructed where their data are located within the MDT. As the MDT is received by a slave, it fast-forwards to the start location for its information and retrieves the data.

After the MDT is sent, another MST is transmitted by the master control, signaling the beginning of another cycle, as illustrated earlier.

### 13.3.2.10.3 Master Synchronization Telegram

The Sercos master begins a communication cycle by transmitting an MST, as detailed in Figure 13.28. The MST sets the timing and synchronization for the network. Each slave device (drive or I/O) synchronizes its clock from the MST and then uses this timing to calculate when to acquire feedback signals and other processing.

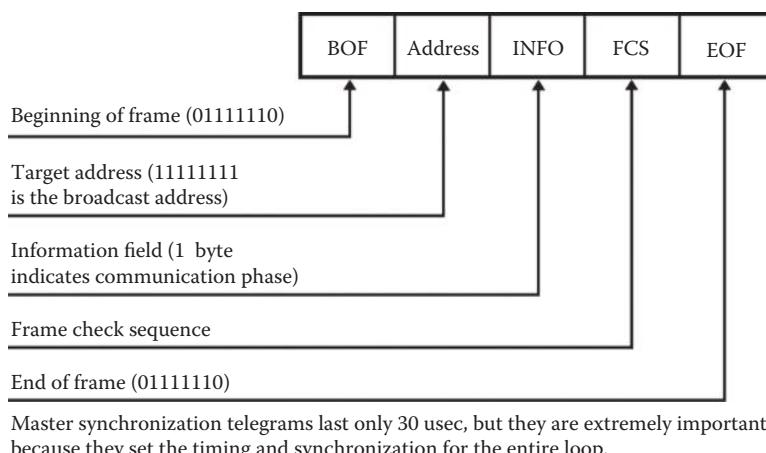

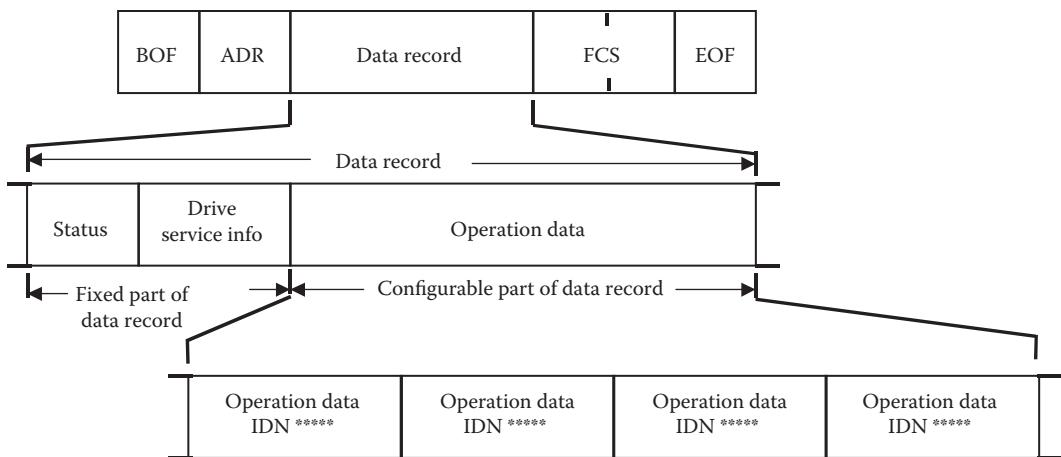

FIGURE 13.28 Master synchronization telegram structure.

**FIGURE 13.29** Acknowledge telegram structure.

The MST data field also contains information. Upon startup, the Sercos loops go through an extensive initialization procedure, where drives are assigned an operating mode (speed, torque, or position) and the exact configuration of their cyclic data. They are also told to synchronize and phase-lock their internal loop-closure frequency, eliminating the risk of harmonics. Cyclic communication doesn't begin until this initialization is complete. The MST data field indicates whether the loop is in one of the initialization phases or in the communication cycle.

#### 13.3.2.10.4 Acknowledge Telegram

Slaves respond to the MSTs via an AT sent by and returned to the master. At a predetermined time after the MST, the first slave in the system places its data in its predetermined slot. Each slave follows in succession, all synchronized off the MST.

An AT is composed of five main fields (Figure 13.29):

1. Beginning of frame
2. Drive address (ADR)
3. Data record
4. Frame check sequence
5. End of frame

The data record is composed of both fixed and variable data in three fields:

1. Status—The 8-bit status field indicates whether the slave (e.g., drive) is ready and verifies that it is in the correct operating mode.
2. Drive service info—This 2-byte service channel field contains non-time-critical data such as torque limits, travel limits, time constants, and gains.
3. Operation data—This is the most important field, containing from 1 to 16 IDNs reporting data such as speed, torque, and position measurements to the master, effectively closing the control loop. For example, if a drive is operating in velocity mode, meaning it receives velocity information from the motion control, it may be configured with current actual velocity in the AT. Because all slaves take their measurements at the same time, the control can construct an instantaneous snapshot of all axes of motion (Figure 13.30).

#### 13.3.2.10.5 Master Data Telegram

The MDT is transmitted by the master after the AT. It consists of one long message, with space allocated for each slave on the ring, as shown in Figure 13.31. All slaves have previously been instructed where

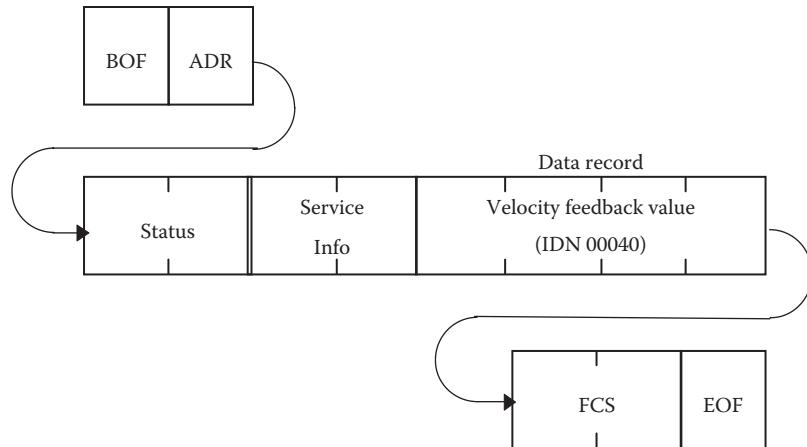

FIGURE 13.30 Acknowledge telegram example.

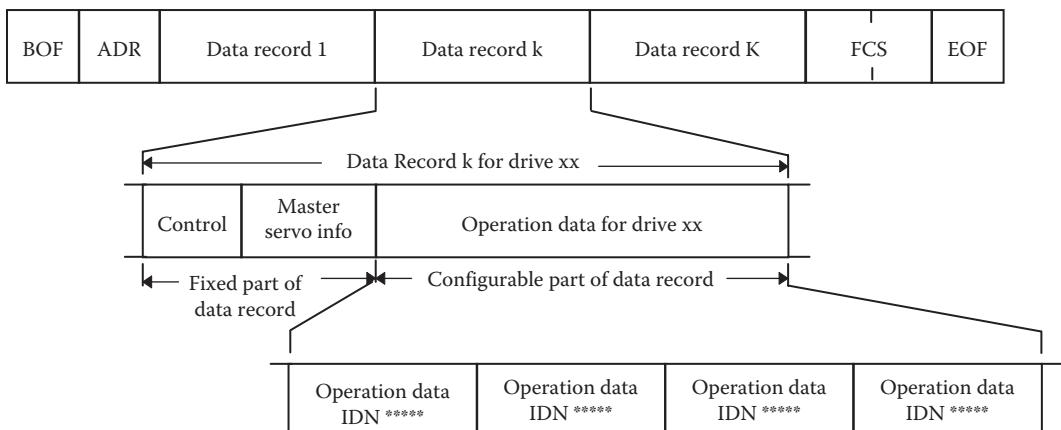

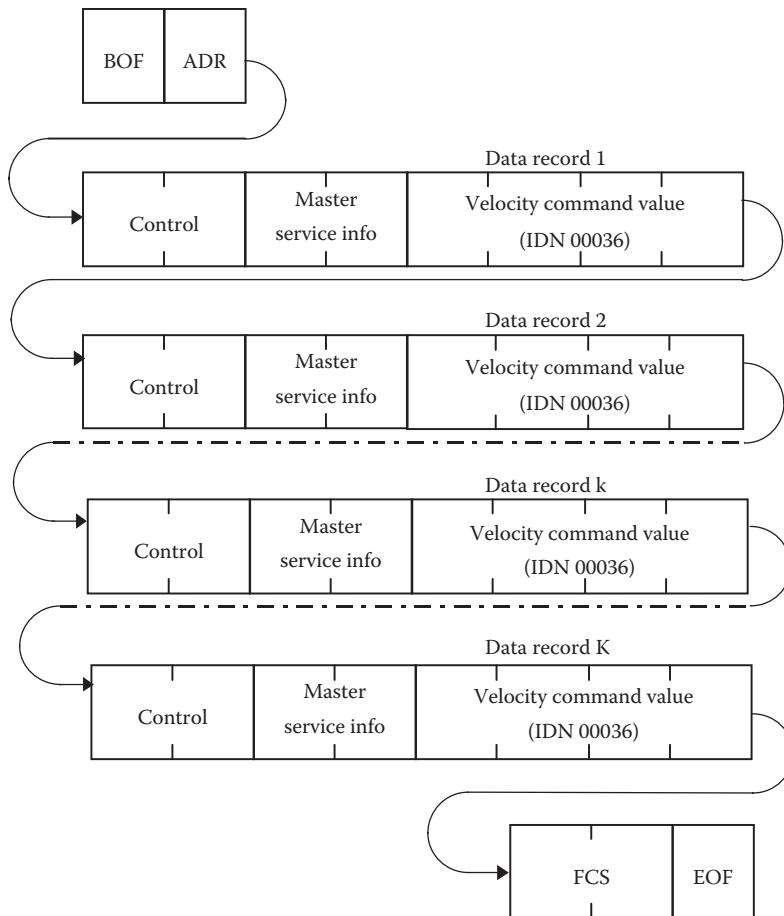

FIGURE 13.31 Structure of the master data telegram.

their data are located within the MDT. As the MDT is received by a slave, it fast-forwards to the starting location for its information and retrieves it.

The MDT is structured much the same as the AT, except that the data field includes a record for each slave on the ring. Like the AT, each data record in the MDT consists of a fixed and variable data portion in three fields:

1. Control field—This 8-bit field enables or disables the slave and configures the service channel.
2. Master servo info—Implements setup parameters and special functions, such as homing, probing, and coordinate offsets.
3. Operation data for slave xx—This field contains a series of IDNs (idents) specifying RT operating data and drive commands for the addressed slave. The chosen idents depend on the application. Using the previous example, in velocity mode, this data record would contain the velocity commands for the drives.

**FIGURE 13.32** Example of a master data telegram.

#### 13.3.2.10.6 Service Channel

The service channel allows high-level, non-time-critical data transfers without disturbing the synchronous transfer of data. For example, items such as diagnostics and loop gains do not need to be transmitted repeatedly, so it is not necessary to impact loop performance by setting aside bandwidth for them. Long messages are broken into 2-byte chunks, sent over the service channel in the AT, and reassembled on the other end. Via the service channel, operators can retrieve diagnostic and status information, reprogram or display setup parameters, and change operating data on the fly.

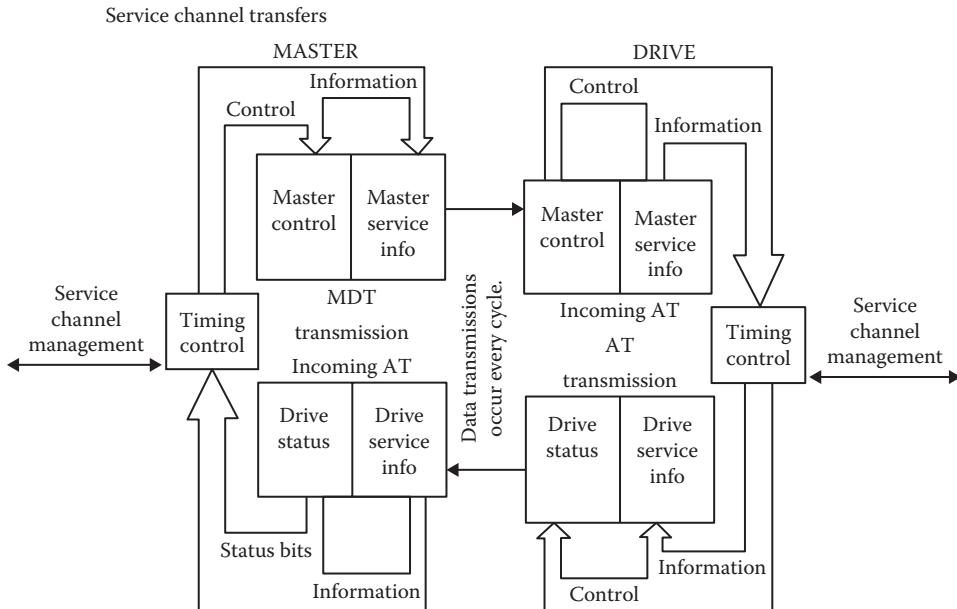

Some manufacturer's drives include a software oscilloscope function that captures data on drive performance, sends the data over the service channel 2 bytes at a time, and formats the information into an oscilloscope-type display on the operating terminal.

#### 13.3.2.10.7 Example of Cyclic Operation: Sercos II

The best way to imagine how a system works is to take a real-world example such as a system with 14 drives and a 500- $\mu$ s cycle rate using Sercos II. Under these conditions, the following information can be transferred every cycle:

From control to each drive

- 32-bit command value (e.g., velocity or position)
- 16-bit limit value (e.g., torque)

Service channel transmissions occur using corresponding data fields in the MDT and AT telegrams. The asynchronous service channel allows masters and slaves to exchange non-time-critical data.

FIGURE 13.33 Service channel operation.

From each drive to control

- 32-bit feedback value (e.g., velocity or position)
- 16-bit feedback value (e.g., torque)

This means that every 500 µs, one Sercos ring can transport a very high-resolution velocity command signal to 14 drives, plus a torque limit command to each of those drives that can be enabled at will. In addition, each cycle is returning two feedback values from each drive. This reduces the customary feedback wiring to the control to nothing.

In addition to all these RT data being exchanged, the service channel provides the equivalent of a 128-kbaud serial port to *each and every drive on the ring*. This can be used to set and archive performance variables, to read diagnostics, etc.

Note that this example does not state that Sercos performance is limited to 500 µs or 14 drives. Neither is the case. Flexibility exists in the update rate (down to 62.5 ms—31.25 ms for Sercos III), the number of drives per ring (up to 511), the amount of data exchanged, and even the number of rings. Performance for Sercos III is even better, as shown in Figure 13.17.

### 13.3.3 Error Correction/Diagnostics

If a Sercos loop detects an error, it continues to operate for one cycle using previously valid data. However, if a second consecutive error is detected, the slaves are shut down in a predefined, orderly fashion, and a diagnostic message is issued.

Sercos offers extensive diagnostic reporting and produces detailed reports on fault conditions. For example, IDNs 00200 through 00205 report drive and motor temperature warning and shutdown conditions, IDN 00309 indicates spindle synchronization error, IDN 00323 specifies target position outside travel range, and there are many more.

This allows vendors to incorporate detailed context-sensitive troubleshooting procedures in their motion controls. An operator can go to his control panel and acquire instant diagnosis of every axis motor and drive at every section of the machine. Failures can be immediately pinpointed by the control system and quickly and easily be repaired as opposed to hit-and-miss troubleshooting.

A number of Sercos vendors include built-in soft oscilloscope functions in their products to simplify troubleshooting. Data can be uploaded from the slaves using the service channel, allowing operators to display and analyze torque, velocity, and position. For predictive maintenance purposes, a snapshot of operating status can be saved and then compared to another snapshot taken at a later time to determine operation/failure trends.

### 13.3.4 System Safety

Digital intelligent drives with Sercos offer outstanding protection against uncontrolled drive movements and excessive velocities. Using position values, command values, actual values, and drive parameters, a Sercos drive monitors itself and provides error warnings or error shutdowns, including forced orderly shutdown in the event of a malfunction or failure of the drive processor.

Excessive velocities, overtravel, or axis runaway due to faulty or incorrectly transmitted position commands can be eliminated by logical monitoring by the drive of the values it receives from the control. Safety redundancy can be achieved by the control as it monitors the actual value data fed back from the drive via Sercos. This internal monitoring can ensure safe shutdown in the event of a communications failure.

### 13.3.5 Sercos II Conformance Testing

*Conformance testing of products carrying the Sercos logo is required!* Any manufacturer can purchase the IEC standards and design controls and drives according to the standard. However, the Sercos logo is the property of Sercos International e.V. and may be used only on Sercos products that have passed a conformance test. This is important to ensure customers of the compatibility and interoperability of products from various manufacturers.

Conformance testing of Sercos products is done at the Institute for Control Engineering of Machine Tools and Manufacturing Units (ISW) at the University of Stuttgart. The intent of the conformance test is to ensure the compatibility and interoperability of devices from different vendors in multiple-vendor environments.

Manufacturers seeking conformance certification for their products submit their Sercos products to ISW for testing. Once a product has passed the conformance test, the manufacturer can apply to Sercos International for a conformance certificate and can apply the Sercos logo to that product.

#### 13.3.5.1 Conformance Test Environment

The conformance test environment for Sercos II devices consists of Sercos II Conformizer test software running on a standard PC with an enhanced Sercos II card, an optical analyzer, and a digital oscilloscope. There are three facets to the testing:

1. Logical test—Per the script files in the Sercos II Conformizer package
2. Physical test—Measures optical signals
3. Time measurement—Handled by special test hardware

The Sercos II Conformizer is an easy-to-use package that includes a high-level scripting language with control flow statements and over 80 functions, variables, and input/output programming features. It includes a command shell, parameter browser, script editor, function browser, script browser, protocol window, and error code browser. The test results can be directly processed in RTF or HTML format. The Conformizer software runs under Windows NT, 2000, and XP.

The Sercos II Conformizer test software is available for purchase by any Sercos vendor who wishes to pretest his products in his own facilities prior to submitting them for the conformance test. This provides a 90% assurance of passing the formal test.

The Conformizer is sold as a complete test and development environment for Sercos master and slave devices and includes a passive PCI-Sercos card. It operates under the VenturCom RTX system, running Windows NT/2000/XP. A runtime license for VenturCom RTX 5.5 is included with the package.

### 13.3.6 Sercos II in Machine Tool Applications

Sercos was originally developed to meet the needs of the machine tool industry, thus it incorporates a rich set of parameters for machine tool functions, such as probing, backlash compensation, feed forward, lead screw error compensation, adaptive positioning, move to positive stop, and torque monitoring. The interface provides all parameters necessary for control of machine tool axes, including spindle axis control.

#### 13.3.6.1 Application Note: Contouring Control System\*

andron GmbH from Wasserburg, Germany, has been using Sercos as a digital drive interface on its control units since 1992. The andronic 2060 is currently regarded as one of the fastest contouring control systems for use in complex multiaxis contouring interpolation applications.

In contrast to the general rule that speed decreases as the number of axes increases, block change times on this controller remain below 250 µs even with 16 interpolating axes. At a transmission speed of 16 Mbps, the system delivers a guaranteed cycle time of 250 µs regardless of the number of axes present in the ring. This means that all axes that are simultaneously involved in an interpolation receive new position data every 250 µs. In combination with high-performance position controllers in the servo amplifier (position control cycle <250 µs), the system can deliver high path velocities (even at high resolution of, e.g., 1/10 µm) as well as high precision. The stability and predictability of Sercos is indispensable, as any timing error or even a transmission repetition can have fatal consequences at the workpiece.

Tool grinding machines (for complete machining of drills and cutters) can have up to 11 axes. In practice, this normally means simultaneous interpolation of five axes. With two Sercos rings, the cycle time is 500 or 250 µs at machining speeds of <1 m/min, a resolution of <1/10 µm, and a precision of 1 µm.

Similar performance can be achieved during camshaft grinding and grinding of knives and scissors.

For HSC milling applications using Cartesian machines and parallel kinematics machines (Figure 13.34), high path speeds in combination with high contour accuracy and finish quality are required. Processing speeds of 30 m/min at 1/10 µm resolutions and accelerations of up to 8 g ares common.

During gearwheel honing operations, the machines must meet stringent requirements for synchronization of several drives in the start phase and during workpiece machining. This means axis synchronization in the position controller with a cycle time of 500 µs and a position control cycle rate of 250 µs using eight machining axes, five of which are interpolating.

## 13.4 Future Technical Advancements

---

Updates to the Sercos specifications' are defined by multicompany Technical Working Groups in both North America and Europe, which ensure that the latest enhancements proposed by member companies are incorporated into the specifications.

### 14.1 Introduction

FOUNDATION Fieldbus is an all-digital, serial, two-way communication system for industrial applications; its specification has been developed by the not-for-profit Fieldbus Foundation association established in 1994 [1]. Please note that in the following, Fieldbus Foundation will refer to the name of the association while FOUNDATION Fieldbus (FF) will be used for the communication system.

Since the first fieldbus communication systems [2–4] have appeared on the market, the need to achieve just only one fieldbus standard was felt immediately. More than 20 years ago, the International Electrotechnical Commission (IEC) and Instrument Society of America (ISA) embarked on a joint standardization effort identified by two codes: 61158 on the IEC side and SP50 on the ISA one. One of the main aims of the joint standardization committee was the definition of a unique communication system able to merge the main features of the fieldbuses available on the market at that time (e.g., WorldFIP [5] and Profibus [6]). This aim was partially realized by the definition of the IEC/ISA specifications (among which the reader may refer to [7–12]); these specifications do not define a unique standard, but they put under the same umbrella different fieldbus systems, called subtypes in the IEC 61158 specifications.

Among the different fieldbus systems integrated into the common IEC 61158 specifications, there are the two communication specifications produced by the Fieldbus Foundation; they are called H1FOUNDATION Fieldbus (included in the IEC 61158 as type 1, for the physical and data link layer definitions and type 9 for the application layer definition) [8–13] and HSE FOUNDATION Fieldbus (included in the IEC 61158 as type 5 for the application layer definition) [11,12].

H1 FF was the first communication system defined by the Fieldbus Foundation; since its definition, H1 FF has shown two fundamental and novel (at that time, at least) features: an emphasis on the standardization of the description of the fieldbus devices and the adoption of both the distributed and centralized link access mechanisms [4].

During the time, FF has been enriched by new and useful features. The first of them is related to the transmission medium; besides the original IEC/ISA physical medium [7], Fieldbus Foundation decided to adopt also the high-speed Ethernet (HSE) and to integrate FF into a wireless environment. Another important feature is the improvement of interoperability using other standards different from the original one.

This chapter will point out the main (original and novel) technical features of the FF communication system, allowing the reader to clearly understand its key points. In particular, Section 14.1 will describe the main features of the H1 and HSE FFs. Section 14.2 will point out the current wireless extensions; finally, Section 14.3 will describe how implementation of interoperability in FF changed during these last years, pointing out the most recent solutions adopted by Fieldbus Foundation.

## 14.2 Technical Description of FOUNDATION Fieldbus

As said in the Introduction, FF specifications include two different configurations: H1 and HSE.

H1 FF communication system is mainly devoted to distributed continuous process control; running at 31.25 Kbit/s, it interconnects digital *field* equipment such as sensors, actuators, and I/Os, allowing to integrate existing 4–20 mA devices. H1 FF communication stack is minimal, in order to guarantee maximum speed in the data handling. Below the Fieldbus application layer, H1 FF directly presents the data link layer (DLL) managing access to the communication channel. A physical layer deals with the problem of interfacing with the physical medium. A network and system management layer is also present. Figure 14.1 compares the H1 FF architecture against the ISO OSI reference model.

HSE FF is mainly foreseen for discrete manufacturing applications; it provides integration of controllers (e.g., distributed control systems [DCSs] and programmable logic controllers [PLCs]), H1 subsystems, foreign protocols (e.g., Modbus and Profibus DP [decentralized peripherals]), conventional input/output (I/O) (e.g., digital I/O, 4–20 mA), data servers, and workstations. HSE FF defines an application layer and associated management functions, designed to operate over a standard Transport Control Protocol (TCP)/Unit Datagram Protocol (UDP)/Internet Protocol (IP) stack over twisted-pair or fiber-optic switched Ethernet. Figure 14.2 compares the HSE FF architecture against the ISO OSI reference model.

Looking at Figures 14.1 and 14.2, it becomes evident that the Fieldbus Foundation has specified only one user application layer, for both the H1 and HSE configurations. The H1 and HSE FF user application layer is mainly based on function blocks (FBs), providing a consistent definition of inputs and outputs that allow seamless distribution and integration of functionality from various vendors.

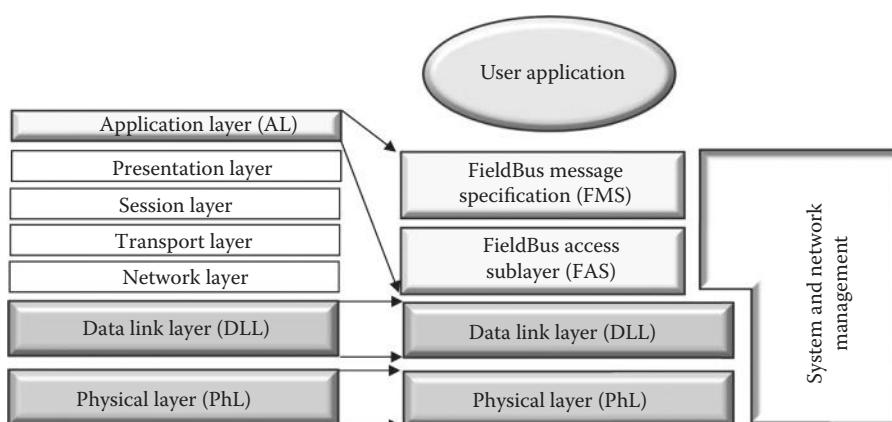

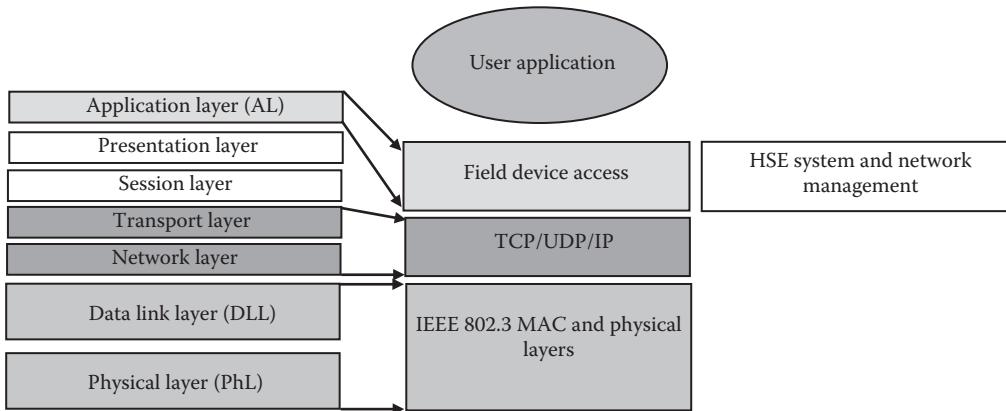

FIGURE 14.1 H1 FF vs. ISO OSI architecture.

**FIGURE 14.2** HSE FF vs. ISO OSI architecture.

### 14.2.1 H1 FOUNDATION Fieldbus

H1 FF is made up by different layers (as shown in Figure 14.1), whose functionalities will be described in the following.

#### 14.2.1.1 H1 FOUNDATION Fieldbus Physical Layer

H1FF physical layer is the 31.25 KBd version of IEC(type 1)/ISA Fieldbus [7,8,14]. Signals ( $\pm 10$  mA on  $50 \Omega$  load) are encoded using the synchronous Manchester Biphasic-L technique and can be conveyed on low-cost twisted-pair cables. The signal is called “synchronous serial” because the clock information is embedded in the serial data stream. Data are combined with the clock signal while creating the fieldbus signal. The receiver of the fieldbus signal interprets a positive transition in the middle of a bit time as a logical “0” and a negative transition as a logical “1.” Special codes are defined for the preamble, start delimiter, and end delimiter. Special N+ and N– characters are used in the start delimiter and end delimiter. Note that the N+ and N– signals do not have a transition in the middle of a bit time.

The transmitting device delivers  $\pm 10$  mA at 31.25 Kbit/s into a  $50 \Omega$  equivalent load to create a 1.0 V peak-to-peak voltage modulated on top of the direct current (DC) supply voltage. The DC supply voltage can range from 9 to 32 V.

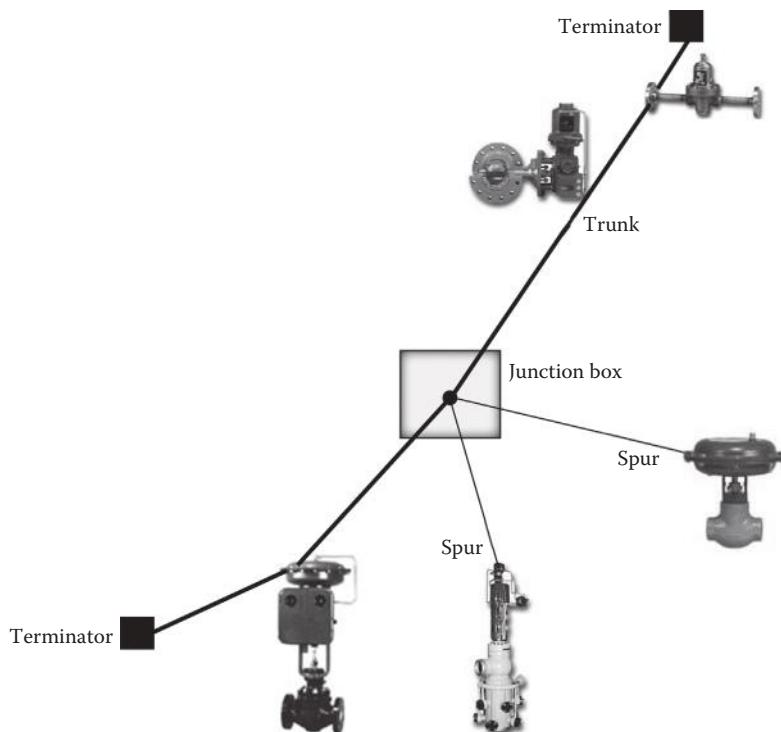

H1 FF supports intrinsically safe (I.S.) feature for bus-powered devices. To accomplish this, an I.S. barrier is placed between the power supply in the safe area and the I.S. device in the hazardous area. In the case of I.S. applications, the allowed power supply voltage depends on the barrier rating.

H1 FF wiring is based on trunk cables featuring terminators installed at each end; up to five trunks can be connected in a Fieldbus link by means of repeaters. Spurs may be located anywhere along each trunk, and connected to the trunk by junction box, as shown in Figure 14.3; a single device can be connected by each spur. Existence of spurs allows that a 31.25 Kbit/s devices can operate on wiring previously used for 4–20 mA devices [15,16]. The length of each spur varies from 1 m up to 120 m depending on the number of devices connected to the Fieldbus link.

The maximum number of devices on a Fieldbus link is 32; the actual number depends on factors such as the power consumption of each device, the type of cable, the use of repeaters, etc. In particular, the maximum number of devices is usually 6 for I.S. applications and power delivered through the bus [17], 12 for non-I.S. applications but power still delivered through the bus, and 32 for non-I.S. applications without any power delivered through the bus.

#### 14.2.1.2 H1 FOUNDATION Fieldbus Data Link Layer

H1 FF DLL controls the access to the bus for the transmission of messages; it is based on the idea to merge the two different access paradigms: circulated token and scheduled access [4]. Thus, H1 FF makes available an

**FIGURE 14.3** Trunk, junction box, and spurs in H1 FF.

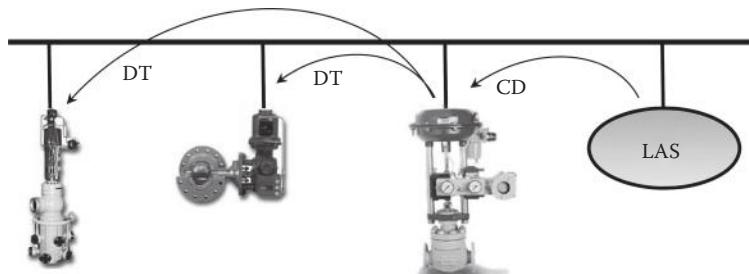

overall schedule able to guarantee the needed data at the needed time, but also allowing gaps within which a circulated token mechanism can take place while complying with a defined maximum rotation time.

Such a philosophy clearly needs an arbitrator that univocally imposes the transmission of a defined data at a defined time by a defined entity, when so required, but also guarantees a defined minimum amount of free time to each entity. This arbitrator is called link active scheduler (LAS) within IEC(type 1)/ISA DLL and H1 FF DLL [9,10,18,19].

#### 14.2.1.2.1 Scheduled Communication

The way the LAS manages the scheduled access is based on the following mechanism. The LAS has a list of transmitting times for all data buffers in all devices that need to be cyclically transmitted. When it is time for a device to send contents of a buffer, the LAS issues a compel data (CD) message to the device.

Upon the receipt of the CD, the device broadcasts or *publishes* the data item (DT) in the buffer to all devices on the fieldbus. Any device configured to receive the data is called a “subscriber.” Figure 14.4 shows this access mechanism.

**FIGURE 14.4** Scheduled access mechanism.

Scheduled data transfers are typically used for the regular, cyclic transfer of control loop data between devices on the fieldbus.

#### 14.2.1.2.2 Unscheduled Communication

The federal autonomy of each device is given by a bandwidth distribution mechanism based on the use of a circulating token. In unused portions of the bandwidth (i.e., not occupied by the transmission of CDs), the LAS sends a Pass Token (PT) to each device included in a particular list called “live list” (described in the following). Each token is associated with a maximum utilization interval, during which the receiving device can use the available bandwidth to transmit what it needs. On the expiration of the time interval or when the device completes its transmissions, the token is returned to the LAS by using another frame called return token (RT). A target token rotation time (TTRT) defines the interval time desired for each token rotation. The value to be assigned to this parameter is linked to the maximum admissible delay in the transmission of the unscheduled information flow. Figure 14.5 shows the token circulation managed by the LAS.

#### 14.2.1.2.3 Live List Maintenance

The list of all devices that are properly responding to the PT is called the *live list*. New devices may be added to the fieldbus at any time. The LAS periodically sends probe node (PN) messages to all the addresses not yet present in the live list. If a new device appears at an address and receives the PN, it immediately returns a probe response (PR) message. When a device returns a PR, the LAS adds the device to the live list and confirms its addition by sending the device a node activation message.

The LAS is required to probe at least one address after it has completed a cycle of sending PTs to all the devices in the live list.

The device will remain in the live list as long as it responds properly to the PTs sent from the LAS. The LAS will remove a device from the live list if the device does not reply to the relevant PT for three successive tries.

#### 14.2.1.2.4 Data Link Time Synchronization

A DLL time synchronization mechanism is provided so that any device can request the LAS for a scheduled action to be executed at a defined *time* that represents the same absolute instant for all the devices. The LAS periodically broadcasts a time distribution (TD) message on the fieldbus so that all devices have exactly the same data link time. This is important because scheduled communications on the fieldbus and scheduled function block (FB) executions in the user application layer are based on timing derived from these messages.

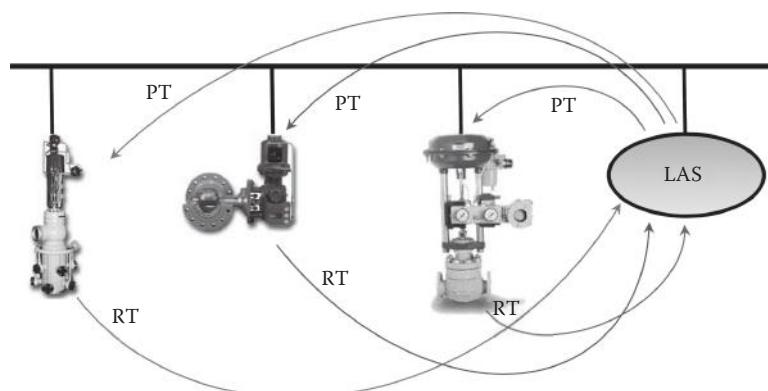

FIGURE 14.5 Token passing mechanism.

### 14.2.1.3 H1 FOUNDATION Fieldbus Application Layer

The H1 FF application layer includes two sublayers: Fieldbus access sublayer (FAS) and Fieldbus message specification (FMS) [20,21].

#### 14.2.1.3.1 Fieldbus Access Sublayer

FAS uses both the scheduled and unscheduled features of the DLL to provide services for the FMS [20].

The type of each FAS services is described by a virtual communication relationship (VCR). VCR defines the main features of the information exchange between two applications; among them, maybe the number of receivers (one or many) for each transmitter, memory organization (queue or buffer) used to store the messages to be sent/received, and the DLL mechanism used to send the message (PT or CD). The types of VCR defined by Fieldbus Foundation are as follows:

- *Client/server VCR type.* The client/server VCR type is used for queued, unscheduled, user-initiated, one-to-one communications between devices on the fieldbus. “Queued” means that messages are sent and received in the order submitted for transmission, according to their priority, without overwriting previous messages. When a device receives a PT from the LAS, it may send a request message to another device on the fieldbus. The requester is called the client, and the device that receives the request is called the server. The server sends the response when it receives a PT from the LAS. The client/server VCR type is used for operator-initiated requests such as setpoint changes, access to and change of a tuning parameter, alarm acknowledgment, and device upload and download.
- *Report distribution VCR type.* The report distribution VCR type is used for queued, unscheduled, user-initiated, one-to-many communications. When a device, holding an event or a trend report to send, receives a PT from the LAS, it sends its message to a group address defined by its VCR. Devices that are configured to listen to that VCR will receive the report. The report distribution VCR type is normally used by fieldbus devices to send alarm notifications to the operator consoles.
- *Publisher/subscriber VCR type.* The publisher/subscriber VCR type is used for buffered, one-to-many communications. “Buffered” means that only the latest version of the data is maintained within the network. New data completely overwrite previous data. When a device receives CD, the device will publish (broadcast) its message to all devices on the fieldbus. Devices that wish to receive the published message are called subscribers. An attribute of the VCR indicates which method is used. The publisher/subscriber VCR type is normally used by the field devices for cyclic, scheduled publishing of user application FB inputs and outputs.

#### 14.2.1.3.2 Fieldbus Message Specification

FMS services allow user applications to exchange messages across the fieldbus using a standard set of message formats. FMS describes the communication services, message formats, and protocol behavior needed to build messages for the user application [21].

Data transmitted over the fieldbus are described by particular objects maintained by an object dictionary (OD) and called object descriptions. Each object description is identified by its index in OD; index 0, called the OD header, provides a description of the dictionary itself.

A virtual field device (VFD) is used to remotely view local device data described in the OD; the VFD are accessed using VCRs. A typical device will have at least two VFDs: the network and system management VFD and the user application VFD. The network and system management VFD provides access to the network management information base (NMIB) and to the system management information base (SMIB). NMIB data include VCRs, dynamic variables, statistics, and LAS schedules (if the device may assume an LAS role); SMIB data include device tag and address information, and schedules for FB execution (see Section 14.1.3.4). The user application VFD is used to make the device functions visible to the fieldbus communication system.

FMS communication services provide a standard way for user applications to communicate over the fieldbus. Specific FMS communication services are defined for each object type. The list of the communication services available can be found in [21,22]. Detailed description of each service is given in [21].

#### 14.2.1.4 H1 FOUNDATION Fieldbus System Management

Inside H1 FF specification, system management handles important system features ([23]) such as the following:

- *FB scheduling.* FBs on which a user application layer is built (as it will be explained in Section 14.1.3) must often be executed in a particular device at precisely defined intervals and in the proper sequence for correct control system operation. System management of the relevant device synchronizes the execution of the FBs to a common time clock shared by all devices. The execution of the FBs are scheduled inside a so-called macrocycle, which contains the precise sequence of FB execution for each device; a macrocycle is repeated once all the scheduled executions there contained are completed. According to the type of the device, we can have an LAS macrocycle and a device macrocycle. LAS macrocycle allows the system management to synchronize the execution of the FBs across the entire fieldbus link; on the basis of the device macrocycle, instead, the system management can synchronize the execution of FBs inside each device. Further information about FB scheduling will be given inside Section 14.1.3.4.
- *Application clock distribution.* This function allows publication of the time of day to all devices, including automatic switchover to a redundant time publisher. System management has a time publisher, which periodically sends an application clock synchronization message to all fieldbus devices. The data link scheduling time is sampled and sent with the application clock message so that the receiving devices can adjust their local application time. During the intervals between synchronization messages, application clock time is independently maintained within each device relying on its own internal clock.
- *Device address assignment.* Fieldbus devices do not use jumpers or switches to configure addresses; instead, device addresses are set using system management services.
- *Find tag service.* For the convenience of host systems and portable maintenance devices, system management supports a service for finding devices or variables by a tag search. The find tag query message is broadcasted to all fieldbus devices. Upon the receipt of the message, each device searches its VFDs for the requested tag and returns complete path information (if the tag is found), including the network address, VFD number, VCR index, and OD index. Once the path is known, the host or maintenance device can access the data by its tag.

All of the configuration information needed by system management (e.g., the FB schedule) is maintained by object descriptions in the network and system management VFD; this VFD provides access to the SMIB and to the NMIB, as said before.

#### 14.2.1.5 H1 FOUNDATION Fieldbus Network Management

H1 FF network management mainly provides for the configuration management (e.g., initialization and setting of communication parameters), performance management (e.g., capturing data for the description of the performance of device communication), and fault management (e.g., supporting fault detection, fault location, and fault correction) [24]. The following specific tasks are performed by H1 FF network management:

- Loading the list of communication links
- Configuring the communication stack
- Loading the LAS
- Monitoring the performance of device communication
- Detecting communication errors

An H1 FF network has at least one network manager (NMgr), who coordinates the network management tasks of the whole system. Each field device has a network management agent (NMA) who manages the

communication stack within the device. An NMA carries out commands issued by the NMgr and can report events and status changes to the NMgr. The NMgr and NMA communicate through the use of the FMS and VCR.

### 14.2.2 HSE FOUNDATION Fieldbus

HSE FF enhances the H1 applications of FF by providing a high-speed backbone, redundancy, and bridging capabilities for multiple protocols. The main feature of the HSE FF is the use of Internet architecture for high-speed discrete control and, more generally, for interconnecting several H1 segments in order to achieve a plant-wide fieldbus network.

A generic HSE FF field device features the communication stack shown in Figure 14.2. The HSE field device is the HSE counterpart to the H1 field device; instead of an H1 communication stack, it has an HSE communications stack.

There are four typical HSE devices (but several of them are typically combined into a single real device): linking device (LD), Ethernet device (ED), host device (HD), and gateway device (GD). An LD connects one or more H1 networks to an HSE backbone; an ED connects some conventional I/O. A GD interfaces other network protocols (e.g., Modbus, DeviceNet, and Profibus). An HD is a non-HSE device capable of communicating with HSE devices; examples include configurators, operator workstations, and open productivity and connectivity (OPC) servers.

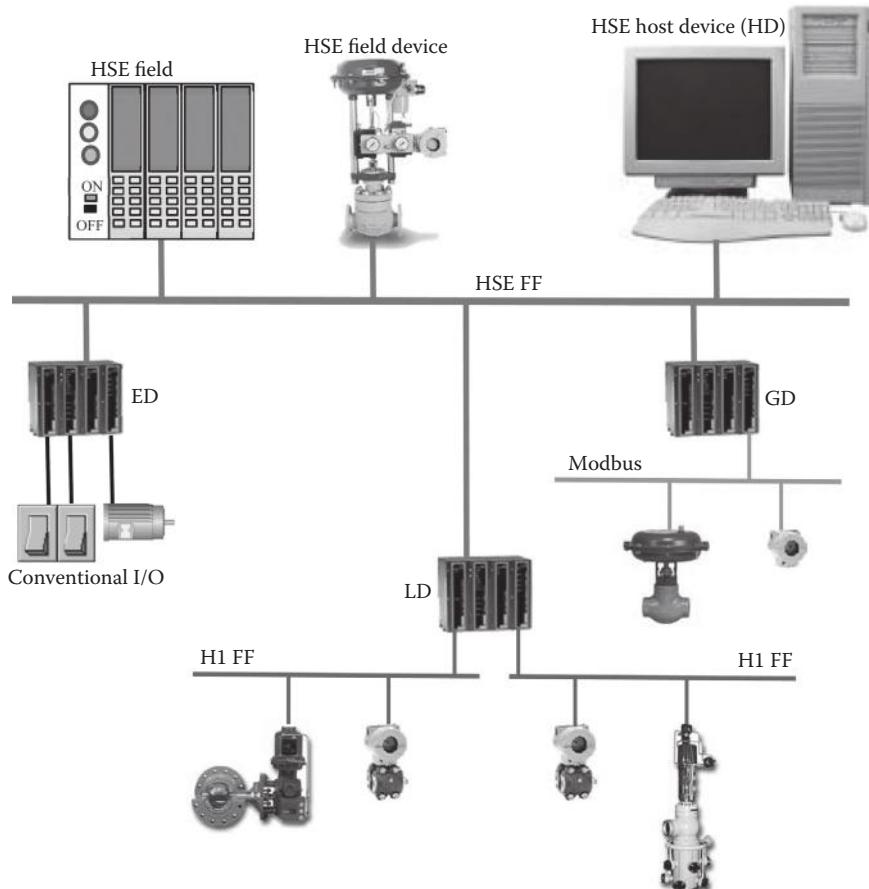

FIGURE 14.6 HSE FF interconnections.

The communication system shown in Figure 14.6 features a realistic example of HSE backbone to which several HSE field devices, an HSE HD, an LD, a GD, and an ED, are connected. The LD allows interconnection with two H1 FF networks; the GD allows interconnection with a Modbus network. Finally, the ED allows the exchange of information with conventional I/Os (e.g., 4–20 mA, digital I/O).

The capabilities of the interconnections allowed by HD, GD, LD, and ED are as follows:

- HSE HD/H1 segment. The HSE HD interacts with an H1 device through an LD. In this situation, the HSE HD is able to configure, diagnose, and publish and subscribe data to or from the H1 device.
- HSE HD/HSE segment. The HSE HD interacts with an HSE field device and is able to configure, diagnose, and publish and subscribe data to or from the HSE field device.
- H1/H1 segment. In this situation, the interaction is between two H1 devices on two distinct H1 bus segments. The segments are connected by LDs. In Figure 14.6, the same LD connects two H1 networks; but interconnections may occur by means of different LDs connected to the HSE backbone. Communications between devices on two H1 segments are functionally equivalent to communications between two H1 devices on the same bus segment. But it is clear that real-time communication between devices belonging to different H1 segments cannot be guaranteed due to the lack of a unique scheduler of the communication (i.e., LAS) among different H1 segments.
- HSE HD/Foreign Protocol. This connection defines the relationship between a foreign device and the FF application environment. The connection is made by GD. The foreign device is seen as a publisher to an HSE resident subscriber; the HSE HD can handle the data stream from the I/O gateway in the same manner as it treats the data streams from devices on H1/HSE segments.

One of the main advantages of using HSE FF is the adoption of commercial, off-the-shelf (COTS) Ethernet equipment; this simplifies the realization of HSE backbone and reduces the relevant installation and maintenance costs. Figure 14.7 shows an example of network interconnections using a commercial Ethernet switch; it allows connections with LD, HD, ED, GD, and with HSE field devices, as clearly depicted by the same figure.

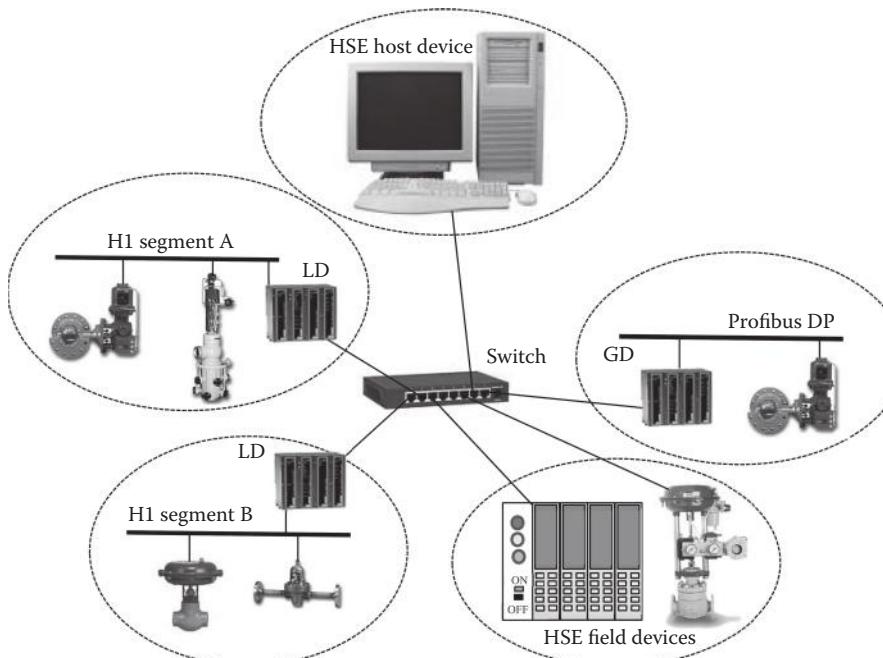

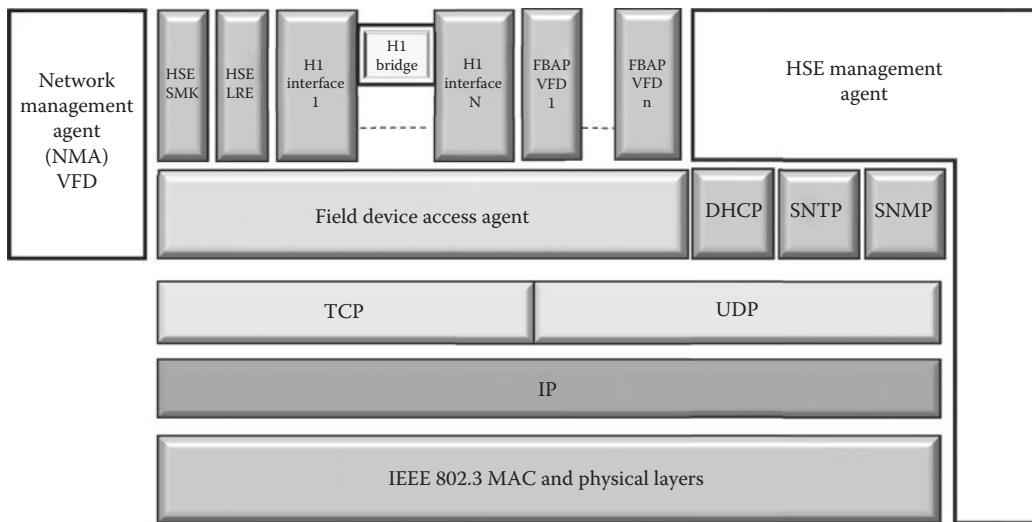

FIGURE 14.7 Interconnection based on COTS Ethernet equipment.

**FIGURE 14.8** HSE FF architecture.

#### 14.2.2.1 HSE FOUNDATION Fieldbus Architecture

As said before, Figure 14.2 shows the HSE FF architecture for a generic HSE field device. Figure 14.8 gives a more detailed description of its internal organization.

As shown, the standard IEEE 802.3 physical and media access control (MAC) layers have been adopted at the bottom of the HSE architecture [25,26]. HSE also makes use of the well-established TCP, UDP, and IP [27]. Standard HSE stack components are Distributed Host Configuration Protocol (DHCP), Simple Network Time Protocol (SNTP), and Simple Network Management Protocol (SNMP), which rely on TCP and UDP over IP and over the IEEE 802.3 MAC and physical layers.

Messages sent on Ethernet are bounded by a series of data fields called frames. The combination of a message and frame is called an Ethernet packet. Typically, a packet encoded according to the TCP/IP protocols will be inserted in the message field of the Ethernet packet. HSE FF uses a similar data structure where messages are bounded by addressing and other DTs. What corresponds to a packet in Ethernet is called a protocol data unit (PDU) in HSE FF.

Let us consider a communication between two H1 devices over an interposed HSE backbone, as illustrated in Figures 14.6 and 14.7; the easiest method for LD might be, upon receiving a communication from an H1 device, to simply insert the entire H1 PDU into the message part of the TCP/IP packet. Then LD on the destination H1 segment, upon receiving the Ethernet packet, would merely strip away the Ethernet frame and send the H1 PDU on to the receiving H1 bus segment. This technique is called tunneling and is commonly used in mixed protocol networks.

The solution developed by HSE FF is somewhat more complex, but more efficient than tunneling. HSE FF PDU is inserted into the data field of a TCP/IP message field. However, the Fieldbus address is encoded as a unique TCP/IP address, so the Fieldbus PDU address is used to fill the address field of the TCP/IP packet. The entire TCP/IP packet is then inserted into the message field of the Ethernet packet. Because of the HSE encoding scheme, networks having multiple LDs can locate and transfer messages to the correct destination much more quickly, with far less extraneous bus traffic, as opposed to tunneling. Perhaps even more important, every H1 device (and every HSE device for that matter) has a unique TCP/IP address and can be directly accessed over standard IT and Internet networks.

##### 14.2.2.1.1 Field Device Access Agent

A new technology has been developed and tested to provide a complete high-speed communication and control solution; it is the field device access agent (FDA Agent) [28]. The FDA Agent allows control

systems to operate over the HSE and/or through LDs, and it enables remote applications to access field devices of any type across UDP/TCP using a common interface.

In particular, the FDA Agent has the following objectives:

- Conveying H1 system management (SM) services over UDP and H1 FMS services over UDP/TCP. This allows communication between HSE and H1 devices.
- Republishing H1 data from LDs that do not support H1 bridging. This allows LDs to be constructed from multiple standalone H1 interfaces instead of using an H1 bridge (see the next subsection).
- Sending and receiving local area network (LAN) redundancy messages to support the redundancy of HSE interfaces in devices.

#### ***14.2.2.1.2 H1 Interfaces and Bridge***

Each H1 network attached to an HSE LD requires an H1 interface; an H1 bridge is used to convey H1 network messages directly between other H1 interfaces within the same HSE LD. Figure 14.8 depicts access of several H1 interfaces (numbered from 1 to N) to the FDA Agent; as it can be seen, an H1 bridge may be present in the architecture, performing data forwarding and republishing between H1 interfaces.

#### ***14.2.2.1.3 Function Block Application Process Virtual Field Device***

The FDA Agent supports the function block application process (FBAP) VFD. The FBAP VFD provides a common means for defining inputs, outputs, algorithms, control variables, and behavior of the automation system. There may be multiple FBAP VFDs (e.g., n FBAP VFDs as shown in Figure 14.8) in a device in order to satisfy the particular needs of an application.

#### ***14.2.2.1.4 HSE System Management Kernel***

Referring again to Figure 14.8, the HSE system architecture includes an HSE system management kernel (SMK).

The HSE SMK maintains information and a level of coordination that provides an integrated network environment for the execution and interoperation of the FBAP VFD.

HSE SMK provides for routine configuration of certain basic system information prior to device operation. For example at start-up, HSE SMK takes a device through a set of predefined phases for this purpose; during this procedure, a system configuration device recognizes the presence of the device on the network and prepares a basic configuration information, which is sent to the device. Once this happens, the HSE SMK brings the device to an operational state without affecting the operation of other devices on the network. It also enables the HSE FDA Agent for use by other functions in the device.

The HSE SMK also operates to keep a local time and keeps the difference between the local time and a system time provided by a time server within a certain specified value. The local time is used to time stamp events so that event messages from devices may be correlated across the system.

#### ***14.2.2.1.5 HSE Local Area Network Redundancy Entity***

HSE FF is used at the host level of the control system; the host-level network ties the whole system together linking the various subsystems to the host. Thus, the visibility of hundreds and perhaps thousands of loops depends on the host-level network as does any intra-area control loops. A complete failure could result in heavy losses. High availability for the host-level network is therefore paramount. HSE FF adopts media and device redundancy to reach this aim.

Special integrity-checking diagnostics and redundancy management part of the HSE protocol in each device enables the use of two completely independent networks, redundant communication ports, and also redundant device pairs.

All parts of the network have redundancy, including the hubs (i.e. two independent networks ensuring that communication can continue even if one network fails). This means that the network can

sustain multiple faults but still continue to function. All redundant ED pairs and the workstations are connected to both Ethernet buses.

A device may have redundant communication ports, and in this case, the two ports are named "A" and "B." In case of fault, the switchover is totally bumpless and transparent. Every communication port has a unique IP address; the IP address does not change when the communication ports switch.

True device redundancy is implemented using two identical devices, one primary and one secondary; when a primary device fails, the secondary takes over the role of the primary. Primary and secondary devices need to have identical configuration in order to allow for a quick switchover in case of failure. The HSE protocol specifies how these devices communicate with others and how the communication is switched over. However, HSE does not specify how the functionality is switched or how device configuration and data are synchronized. The control application sees either the primary or the secondary ED depending on which one is active, whereas the system diagnostics sees both. Thus, the diagnostics insures that even the inactive devices are fully functional and ready to take over at any moment.

A wide diagnostic coverage is an integral part of the HSE protocol going far beyond mere hardware duplication. Every HSE device and HSE LD contains an HSE local area network redundancy entity (HSE LRE), shown in Figure 14.8. The HSE LRE independently keeps track of the status of the networks and all the devices on it; it periodically sends and receives redundancy diagnostic messages, which represent its view of the network with each other. Each HSE device or LD uses the diagnostic messages to maintain a network status table (NST), which is used for fault detection and transmission port selection. In this way, every device has a complete picture of the network and knows the health of the primary and secondary, as well as communication port A and B, of every other device on the network in order to intelligently select which network, device, and port to communicate with.

Because the redundancy management is distributed to each device, no centralized *redundancy manager* is required [29].

#### **14.2.2.1.6 HSE Management Agent**

The following aspects of management are supported in the HSE management agent [30]:

- Acquisition of an IP address for the device, using the DHCP
- Time synchronization with a time server, using the SNTP
- Managing the TCP, UDP, and IP layers, using SNMP

#### **14.2.2.1.7 HSE Network Management Agent VFD**

The HSE system architecture includes an NMA VFD for each HSE device and each HSE LD. The NMA VFD provides means for configuring, controlling, and monitoring HSE device and HSE LD operation from the network [31]. The following capabilities are provided by the NMA VFD:

- Configuring the H1 bridge, which performs data forwarding and republishing between H1 interfaces (see Figure 14.8).
- Loading the HSE session list, or single entries in this list, called endpoints. An HSE session endpoint represents a logical communication channel between two or more HSE devices.
- Loading the HSE VCR list, or single entries in this list. An HSE VCR is a communication relationship used for accessing VFDs across HSE.
- Performance monitoring for session endpoints, HSE VCRs, and the H1 bridge.
- Fault detection monitoring.

### **14.2.3 H1 and HSE FOUNDATION Fieldbus User Application Layer**

As shown in Figures 14.1 and 14.2, Fieldbus Foundation has defined a common standard user application layer on both the H1 and HSE FF. User application layer is based on "blocks," which are representations

of different types of application functions. The types of blocks used in a user application are resource, function, and transducer. Devices are configured by using resource blocks and transducer blocks; the control strategy is built by using FBs [32–36].

#### 14.2.3.1 Resource Block

The resource block describes the features of the fieldbus device such as the device's name, manufacturer, and serial number. There is only one resource block in a device.

#### 14.2.3.2 Function Block

FBs provide the control system behavior. There can be many FBs in a single user application, both standard and user-defined. The Fieldbus Foundation has defined sets of standard FBs. Ten standard FBs for basic control are defined by the “FBAP” Part 2 specification [33]; they are summarized in Table 14.1. Other, more complex, standard FBs are defined by the Parts 3 and 4 specifications [34,35].

The flexible function block (FFB) is defined by the [36] Part 5; it is a user-defined block. FFB allows a manufacturer or user to define block parameters and algorithms to suit an application that interoperates with standard FBs and host systems.

FBs can be built into fieldbus devices as required in order to achieve the desired (distributed) control. For example, Figure 14.9 shows a complete control loop made up by an analog input, analog output, and a PID control.

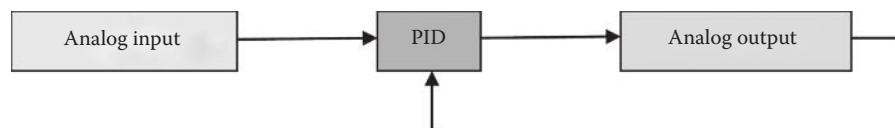

In order to realize this control loop in an H1 FF, a simple temperature transmitter may contain an AI FB; a control valve might contain a PID FB as well as the expected AO FB. Thus, as shown in Figure 14.10, the complete control loop shown in Figure 14.9 can be built using only a simple temperature transmitter (FF Device 1) and a control valve (FF Device 2), made up by the earlier-mentioned FBs.

#### 14.2.3.3 Transducer Block

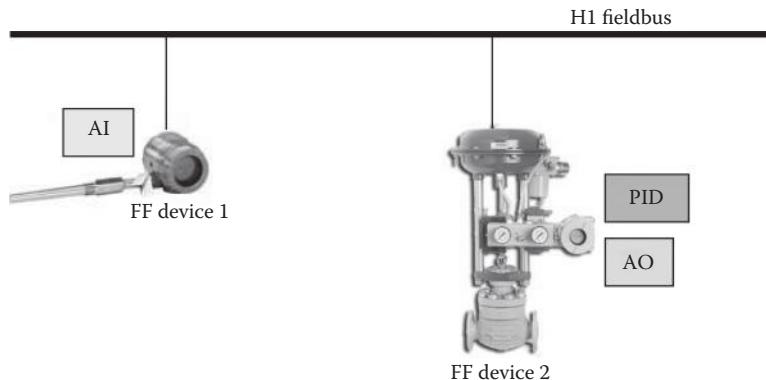

Like the resource block, the transducer blocks are used to configure devices. Transducer blocks decouple FBs from the local input/output functionalities required in order to read sensors or to command actuator's output. They contain information such as calibration date and sensor type [37].

**TABLE 14.1** Basic Function Blocks

Function Block Name	Symbol Name
Analog input	AI
Analog output	AO
Bias/gain	BG
Control selector	CS
Discrete input	DI
Discrete output	DO
Manual loader	ML
Proportional/derivative	PD
Proportional/integral/derivative	PID
Ratio	RA

**FIGURE 14.9** Example of a PID complete control loop.

**FIGURE 14.10** Realization of a PID complete control loop using FBs in FF devices.

#### 14.2.3.4 Function Block Linking and Scheduling

A control or measurement application consists of FBs connected to each other; as seen, Figure 14.10 shows an example of mapping of a complete control loop on two devices, made up by the AI, AO, and PID basic FBs. These blocks must be connected in order to realize the distributed control loop; for this reason, FF features the link objects, defining the links between FB inputs and outputs internal to the device and across the fieldbus network.

An FB must obtain input parameters prior to the execution of its algorithm; its output parameters must be made available after the execution of the algorithm. Therefore, algorithm execution and the relevant communication must be synchronized even when the FBs are distributed among devices. For this reason, FF allows scheduling of FBs execution in each device. A macrocycle is defined in each device, containing the instants at which each FB must be executed, starting from an absolute start time; the content of each macrocycle may be repeated in each device forever, until a modification in the schedule occurs. The same scheduling may be also realized with communication, involving the LAS if present, in order to realize the exchanges of input/outputs between distributed FBs exactly when they are needed.

As an example, assuming to consider the FBs presented in Figure 14.10 (AI, PID, and AO) and their mapping to real devices shown in the same figure, the following scheduling may be realized in an H1 FF network:

- AI FB in Device 1 is executed at offset 0 (from an absolute start time).
- Communication of AI occurs at offset 20.
- PID FB in Device 2 is executed at offset 30.
- AO in Device 2 is executed at offset 50.
- All the sequence must be repeated in time after a certain offset.

Figure 14.11 shows the macrocycles present in each device of the H1 network, including LAS, which takes into account the previous scheduling. As it can be seen, according to these macrocycles, the previous sequence is repeated in time.

According to the macrocycles, system management in Device 1 will cause the AI FB to be executed at offset 0. At offset 20, the LAS will issue a CD to the AI FB buffer in the transmitter, and data in the buffer will be published on the fieldbus. At offset 30, system management in the valve (Device 2) will cause the execution of PID FB followed by the execution of the AO FB at offset 50. The pattern exactly repeats itself ensuring the integrity of the control loop dynamics. Note that during the FB executions, the LAS is sending the PT message to all devices so that they can transmit their unscheduled messages such as alarm notifications, or operator setpoint changes. For this example, the only time that the fieldbus cannot be used for unscheduled messages is when the AI FB starts to be published on the fieldbus.

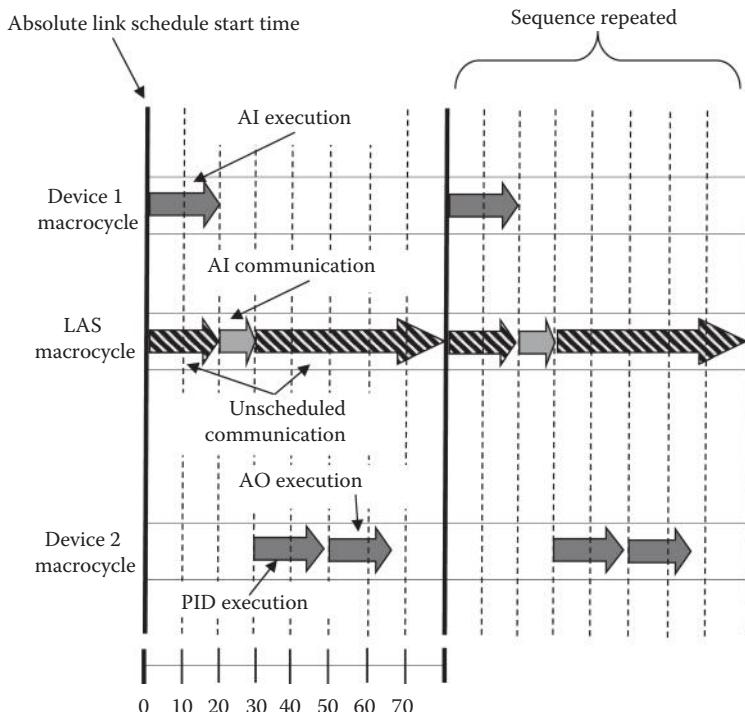

FIGURE 14.11 FB scheduling using macrocycles.

### 14.3 Wireless Solutions for FOUNDATION Fieldbus

Currently, a large amount of the total cost of a manufacturing plant over its lifetime is spent on installation, set-up, and reconfiguration. If a plant is subjected to changes in its process flow or in its equipment, then the downtime and lifetime costs rise considerably [38].

Some of the main obstacles to fast reconfiguration are the inflexible wired communication infrastructure; this problem can be largely eased by the use of wireless technologies. With wireless technologies, not only the installation costs are much lower, but also the true self-reconfiguration of a system without any rewiring becomes possible as ever did before [38,39]. Together with other technologies like service-oriented architectures, web services, and the use of agent-based technology, wireless at the physical level plays an important role toward flexible and self-reconfiguring systems.

Several wireless solutions to be used in industrial environment are nowadays available.

One of these is the ISA100.11a, “Wireless Systems for Industrial Automation: Process Control and Related Applications”; it is an open wireless standard developed by the ISA SP-100 committee, starting from 2005 [40].

HART Communication Foundation (HCF) [41] is an organization made up by the producers and end users of wireless devices; HCF developed an open standard, the HART 7.0, which extends the HART protocol with wireless features known as *WirelessHART*. In March 2010, the IEC has approved the *WirelessHART* specification as a full international standard (IEC 62591 Ed. 1.0) [42].

In June 2008, ISA100 leaders established a new working group, ISA100.15—Wireless Backhaul Networks Working Group, to develop standards and technical reports to address dedicated or shared wireless backhauls to support technologies running multiple applications. Very recently, ISA published the work as technical report ISA-TR100.15.01, “Backhaul Architecture Model: Secured Connectivity over Untrusted or Trusted Networks,” within the ISA100 family of standards [43].

Fieldbus Foundation made a lot of effort to integrate FF specifications with these novel wireless solutions. In order to reach this aim, two project teams have been defined inside Fieldbus Foundation: the Wireless

Sensor Integration Team (for the integration with ISA 100.11a and *WirelessHART*) and the Wireless HSE Backhaul Team (to assist the ISA100.15 working group in developing a wireless backhaul standard).

In the following, the main features of the FF integrations with wireless standards will be pointed out.

### 14.3.1 *WirelessHART* Integration

About integration between FF and *WirelessHART*, Fieldbus Foundation has recently defined a specification addressing fieldbus transducer blocks for wired and *WirelessHART* devices [44]. This technical specification defines a fieldbus transducer block used to represent HART devices within FF; *WirelessHART* devices may be represented in this block. In addition, the specification describes the expected method for HART configuration tools and asset-managing hosts to access HART devices using the native HART command protocol transported through the Foundation HSE network. The specification also defines structures to identify and maintain HART device status in wired multidrop networks as well as in *WirelessHART* mesh networks.

### 14.3.2 ISA 100.11a Integration

The ISA 100.11a project has made a considerable effort in the integration of the ISA 100.11a wireless sensor network into the FF infrastructure. Similar to *WirelessHART* devices, ISA 100.11a devices are represented as transducer blocks inside FF.

### 14.3.3 Wireless HSE Backhaul Team

In late 2008, the Fieldbus Foundation and ISA entered into a cross-licensing agreement allowing the two organizations to collaborate on wireless networks. This agreement will assist the ISA100.15 working group in developing a wireless backhaul standard. Backhaul networks integrated remote locations and applications with central control facilities.

### 14.3.4 FOUNDATION for Remote Operations Management

In December 2011, the Fieldbus Foundation announced the release of an extension to its technology, called FOUNDATION for Remote Operations Management (ROM) [45]. Integration of FF with existing wireless standard is fully realized into this very novel suite of technologies and additions to the FF specification that provide for both a wireless and wired infrastructure for remote assets and applications. FOUNDATION for ROM provides for direct access to information and diagnostics in wireless and remote I/O devices. Conversely, FOUNDATION for ROM can take the data from those devices and place into the FF environment for data management and quality.

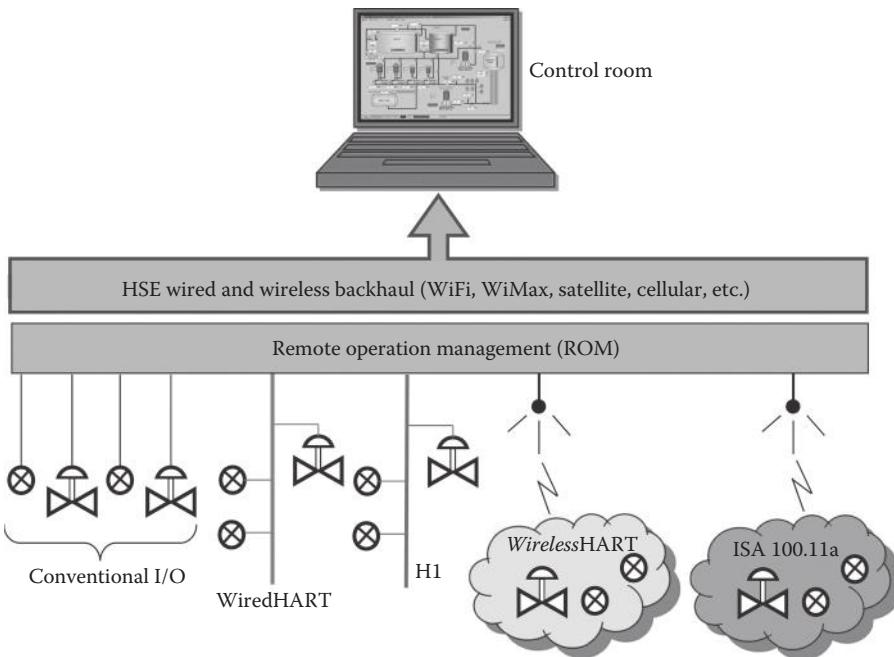

FOUNDATION for ROM provides an open path for the integration of multiple wireless and wired networks, from conventional remote I/O to ISA 100.11a and *WirelessHART*, and enables direct access to device information and diagnostics. It extends the range and capabilities of Foundation Fieldbus to encompass many more devices throughout the plant, regardless of their communications technology.

Figure 14.12 shows the FOUNDATION for ROM architectures; both wireless and wired technologies are integrated inside ROM. Communication with control room occurs through HSE wired and wireless backhaul.

## 14.4 Open Systems Implementation

---

One of the main features of FF (in both H1 and HSE configurations) is the availability to build open communication systems. It is clear that this represents a key issue in a communication system as building up a perfect communication stack between two devices is completely useless if those two devices are not able to understand the meaning of each other data, or each other behavior.

**FIGURE 14.12** FOUNDATION for ROM architecture.

Implementation of open systems in FF has been achieved from the beginning through the adoption of a standard way to represent and manage information exchanged by devices: the device description language (DDL).

Very recently, a strong effort has been put by Fieldbus Foundation to integrate FF with the field device tool/device type manager (FDT/DTM) technology. Furthermore, starting from, 2003 Fieldbus Foundation contributes to the FDI, the field device integration initiative, as part of an industry effort to integrate DDL and FDT/DTM.

In the following subsections, a detailed description of both DDL and FDT/DTM will be given; finally, the FDI initiative will be pointed out.

#### 14.4.1 Electronic Device Description Language

The electronic device description language (EDDL) is a language for describing the behavior of the field devices and is defined by the international standard IEC 61804 [46,47].

The IEC 61804 specifies EDDL as a generic language for describing the properties of automation system components, such as device parameters and their dependencies, device functions (e.g., simulation mode and calibration), graphical representations (e.g., menus), interactions with control devices, graphical representations, and persistent data store. EDDL technology was designed to avoid the need for special, proprietary, and operating system-specific host application files. It allows a host system to configure as well as to monitor devices online.

An electronic data description (EDD) is the computer readable file written in EDDL that describes the data in a field device; it is the file that the host application reads in order to learn how to retrieve information from the field device. EDD is a clear and unambiguous structured text description that precisely describes field device data to host systems. EDD is independent from the operating system, DCS platforms, and communication and interface paths. There is no executable code with EDD, which may have an effect on the stability of the operating system; EDD is interpreted and therefore encapsulated.

An EDD contains the following information about the parameters of a device: attributes (e.g., coding, name, engineering unit, and write protection), the arrangement of the parameters in a menu structure; names of menus and submenus, information about the relation of parameters to others, information about help texts and help procedures, information about necessary operating interactions (e.g., calibration), also called methods, and information about visualization tools (e.g., charts and graphs). EDD can describe also communication features: communication orders, sorting of parameters, bit positioning and bit length of parameters, sorting of communication orders, read and write timeouts, and error handling, including user messages.

The IEC 61804 includes the DDL used as an underlying technology by FF to achieve interoperability [48]. A device description (DD) file, written in the DDL, provides an extended description of each object in the VFD; it provides information needed for a control system or a host to understand the meaning of the data in the VFD, including the human interface for functions such as calibration and diagnostics. Thus, the DD can be thought of as a *driver* for the device; any control system or host can operate with the device if it has the device's DD.

In FF, DD file is used together with a capability file (CF) to fully describe the functions and the capabilities of a device; it tells the host what resources the device has in terms of FBs and VCRs, etc. This allows the host to configure the device even if not connected to it. The host can ensure that only functions supported by the device are allocated to it and that other resources are not exceeded.

On account of what is said, a device is always supplied with DD and CFs. New devices are added to the fieldbus by simply connecting the device to the fieldbus wire and providing the control system or host with the DD for the new device.

#### **14.4.1.1 Device Description Services**

On the host side, library functions called Device Description Services (DDS) are used to read the device descriptions, but they cannot read operational values [49]. The operational values are read from the fieldbus device over the fieldbus using FMS communication services.

#### **14.4.1.2 Device Description Hierarchy**

The Fieldbus Foundation has defined a hierarchy of DDs to make it easier to build devices and perform system configuration. The first level in the hierarchy is referred to as universal parameters, which consist of common attributes such as tag, revision, mode, etc.; all blocks must include the universal parameters. The next level in the hierarchy is FB parameters; at this level, parameters are defined for the standard FBs and resource blocks. The third level is called transducer block parameters; at this level, parameters are defined for the standard transducer blocks. In some cases, the transducer block specification may add parameters to the standard resource block. These first three layers are the standard Fieldbus Foundation DDs. The fourth level of the hierarchy is called manufacturer-specific parameters; at this level, each manufacturer is free to add additional parameters to the FB parameters and transducer block parameters.

#### **14.4.1.3 Device Description Interoperability Test**

Before Fieldbus Foundation registers a DD file, the file undergoes a series of tests using FF's Interoperability Test Kit [50]. The first test loads the DD binary into a test system to validate correct identification information. Next the file undergoes multiple test cases to ensure the DD matches the device and follows protocol rules for maintaining interoperability between host and device. Finally, FF logs the DD file information, including name, date, size, and the 32-bit cyclic redundancy checksum value.

### **14.4.2 Field Device Tool**

Field device tool (FDT) technology has been promoted by the not-for-profit organization FDT Group [51]. FDT has been accepted as IEC 62453 standard [52,53]. The FDT standard currently supports several industry network standards, including FF.

According to the IEC 62453 standard, the DTM is the driver supplied by the manufacturer of the device that supports the configuration, operation, diagnostics, maintenance, and calibration of the device. A single DTM may support an entire family or class of devices offered by that manufacturer.

There are two types of DTMs. The most common DTM supports end devices such as pressure and temperature transmitters, I/O blocks, and valve positioners. The second type, called COM (communications) DTM, is provided by the manufacturers of the network infrastructure components such as GDs, SIL barriers, and network power supplies.

The COM DTM has brought a complete revolution to network management; a COM DTM now can monitor the health of the network and its infrastructure such as barriers, network power supplies, and terminators. Gone are the days of having to haul out network analyzers to see if the problem could be related to the network infrastructure. The pulled terminator, the forklift-damaged cable, the colliding packets, the network reaching bandwidth limits, and the failing redundant supply can be proactively detected and reported through the diagnostics of the COM DTM.

The DTM is installed in a host application, which is called the frame. An FDT frame is a higher level software application, such as a DCS, a PLC programming tool, or a maintenance management system, which is compliant with the FDT standard and needs access to the intelligent devices on the fieldbuses or networks associated with the application. The frame gains access to the device intelligence and functionality by installing the appropriate DTMs into the topology tree of the application.

#### 14.4.3 EDDL versus FDT: Field Device Integration

EDDL and FDT are different technologies both aimed at providing easy plug-and-play access to information in smart field devices. For the past few years, many people have seen EDDL and FDT as competing technologies; but the two technologies must be viewed as complementary.

In a growing number of cases, plants are using a combination of EDDL and FDT. There are at least two cases for this. First, the basic integration is done with EDDL, but additional advanced diagnosis functionality is provided by the device vendor at FDT/DTM, which runs in an FDT frame application. In the second case, several device vendors do not provide DTMs for their simple to medium-complex devices; in this instance, those EDDs are run in an EDD interpreter DTM.

Because both EDDL and FDT have their adherents, and both are clearly here for the long run, the industry has started an initiative to integrate the two technologies, mainly because many end users weren't comfortable with these two technologies in tandem.

This effort to integrate EDDL and FDT led to the creation of the Field Device Integration (FDI) initiative, consisting of a combination of representatives from the EDT Group and EDDL Cooperation Team; the simple idea behind FDI was to combine the best features of EDDL and the FDT standards.

In September 2011, a new joint company, FDI Cooperation LLC (a limited liability company under US law), was formed. The new company is headed by a board of managers that includes representatives from the Fieldbus Foundation, FDT Group, HART Communications Foundation, OPC Foundation, and PROFIBUS & PROFINET International.

FDI Cooperation LLC is committed to developing a single technology for the management of information from intelligent devices throughout all areas of the plant. Among its missions, there is the standardization of FDI under the IEC; currently, the FDI standard is under the definition as IEC 62769 [54].

One piece of glue that represents a factor in integrating EDDL and FDT is the IEC 62541, OPC UA (OPC Unified Architecture) [55,56], used to put some standards around the process of getting data from devices.

Basically, the FDI architecture is a client/server structure based on OPC UA. The field device integration is realized by an FDI device package provided by the device supplier. The FDI device package is intended to give information about one or more device type(s) to a system. Typically, an FDI device package describes a single device type; modular devices, such as remote I/O, may be represented as multiple device types.

An FDI device package contains up to four different elements, depending upon the complexities and requirements of the device. It is made up by a mandatory package catalogue and a mandatory EDD for each device type within the FDI package; the FDI device package may also include one or more user interface plug-in (UIP) and attachment. The mandatory EDD acts as the information model of the device and describes the device data and type. Optional UIP is a user-defined software component that defines special device functions/application information and user interfaces to run on the client. Attachments are also optional and include things like product manuals, images, and electronic certifications. EDD is based on EDDL, IEC 61804-3; the optional UIP offers the advantages of freely programmable user interfaces familiar from FDT, based on Windows Presentation Foundation (WPF).

Another important FDI feature is nested communication, that is, the open integration of gateways, and the integration of communication drivers via communication servers. In FDI, all operations and services that are necessary for communication are described and provided in a standardized format as part of an FDI communication package via EDDL code. FDI communication package has a structure similar to the FDI device package and contains the mandatory component EDD. In IEC 62769, two particular profiles have been defined for the description of both FF H1 and HSE communication functionalities inside the EDD component of an FDI communication package [57,58].

## 14.5 Conclusions

---

The chapter has given an overview on the main features of the FF. Since its definition, a lot of new technologies have been introduced in the Information and communications technology (ICT), ranging from transmission media to information modeling techniques; updates of the original FF specifications were mandatory in order to integrate these new technologies, when they led to real advantages for the communication system. For this reason, the chapter tried to give an exhaustive overview about all the integrations already done and about all the work that is carried on at this moment to integrate more features.

### 15.1 Introduction to Field Communication

---

The growing degree of automation in machines and systems also increases the amount of cabling required for parallel wiring due to the large number of input/output (I/O) points. This brings with it increased configuration, installation, start-up, and maintenance effort. The cable requirements are often high because, for example, special cables are required for the transmission of analog values. Parallel field wiring thus entails serious cost and time factors. In comparison, the serial networking of components in the field using fieldbus systems is much more cost-effective. The fieldbus replaces the bundle of parallel cables with a single bus cable and connects all levels, from the field to the control level. Regardless of the type of automation device used, for example, programmable logic controllers (PLCs) from various manufacturers or PC-based control systems, the fieldbus transmission medium networks all components. They can be distributed anywhere in the field and are all connected locally. This provides a powerful communication network for today's rationalization concepts. There are numerous advantages to a fieldbus system in comparison with parallel wiring: the reduced amount of cabling saves time during planning and installation, while the cabling, terminal blocks, and the control cabinet dimensions are also reduced. Self-diagnostics minimize downtimes and maintenance times. Open fieldbus systems standardize data transmission and device connection regardless of the manufacturer. The user is therefore independent of any manufacturer-specific standards. The system can be easily extended or modified, offering flexibility as well as investment protection (Figure 15.1).

Fieldbus systems, which are suitable for networking sensors and actuators with control systems, have represented state-of-the-art technology for some time. The main fieldbus systems are combined under the umbrella of IEC 61158 [1]. This also includes INTERBUS as Type 8 of IEC 61158 and CPF6 of IEC 61784, with an installed base of 17 million nodes and more than 1000 device manufacturers.

The requirements of these systems can be grouped according to the following four basic types of arithmetic operations for field communication.

**FIGURE 15.1** Serial instead of parallel wiring.

## 15.2 INTERBUS Overview

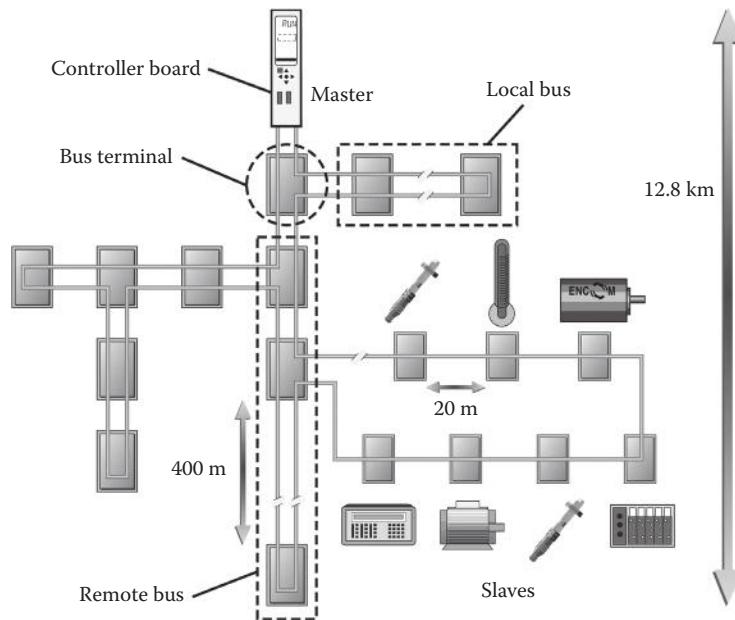

INTERBUS has been designed as a fast sensor/actuator bus for transmitting process data in industrial environments. Due to its transmission procedure and ring topology, INTERBUS offers features such as fast, cyclic, and time-equidistant process data transmission, diagnostics to minimize downtime, easy operation and installation, as well as meeting the optimum requirements for fiber optic technology.

In terms of topology, INTERBUS is a ring system, that is, all devices are actively integrated in a closed transmission path (see Figure 15.2). Each device amplifies the incoming signal and forwards it, enabling higher transmission speeds over longer distances.

Unlike other ring systems, the data forward and return lines in the INTERBUS system are led to all devices via a single cable. This means that the general physical appearance of the system is an *open tree* structure. A main line exits the bus master and can be used to form seamless subnetworks up to 16 levels deep. This means that the bus system can be quickly adapted to changing applications.

The INTERBUS master/slave system enables the connection of up to 512 devices, across 16 network levels. The ring is automatically closed by the last device. The point-to-point connection eliminates the need for termination resistors. The system can be adapted flexibly to meet the user's requirements by adding or removing devices. Countless topologies can be created. Branch terminals create branches, which enable the connection and disconnection of devices. The coupling elements between the bus segments enable the connection and disconnection of a subsystem and thus make it possible to work on the subsystem without problems, for example, in the event of an error or when extending the system.

Unlike in other systems where data are assigned by entering a bus address using dual in-line package (DIP) or rotary switches on each individual device, in the INTERBUS system, data are automatically assigned to devices using their physical location in the system. This plug and play function is a great advantage with regard to the installation effort and service-friendliness of the system. The problems and errors, which may occur when manually setting device addresses during installation and servicing, are often underestimated. The ability to assign "easy to understand" software names to the physical addresses enables devices to be added or removed without readdressing.

**FIGURE 15.2** Topology flexibility.

In order to meet the individual requirements of a system, various basic elements must be used (see Figure 15.2):

1. **Controller Board.** The controller board is the master that controls bus operation. It transfers output data to the corresponding modules, receives input data, and monitors data transfer. In addition, diagnostic messages are displayed, and error messages are transmitted to the host system.
2. **Remote Bus.** The controller board is connected to the remote bus devices via the remote bus. A branch from this connection is referred to as a remote bus branch. Data can be physically transmitted via copper cables (RS-485 standard), fiber optics, optical data links, slip rings, or other media (e.g., wireless). Special bus terminal modules and certain I/O modules or devices such as robots, drives, or operating devices can be used as remote bus devices. Each has a local voltage supply and an electrically isolated outgoing segment. In addition to the data transmission lines, the installation remote bus can also carry the voltage supply for the connected I/O modules and sensors.
3. **Bus Terminal Module.** The bus terminal modules, or devices with embedded bus terminal module functions, are connected to the remote bus. The distributed local buses branch out of the bus terminal module with I/O modules, which establish the connection between INTERBUS and the sensors and actuators. The bus terminal module divides the system into individual segments, thus enabling you to switch individual branches on/off during operation. The bus terminal module amplifies the data signal (repeater function) and electrically isolates the bus segments.
4. **Local Bus.** The local bus branches from the remote bus via a bus coupler and connects the local bus devices. Branches are not allowed at this level. The communications power is supplied by the bus terminal module, while the switching voltage for the outputs is applied separately at the output modules. Local bus devices are typically I/O modules.

## 15.3 INTERBUS Protocol

INTERBUS recognizes two cycle types: the identification cycle for system configuration and error management and a data transfer cycle for the transmission of user data. Both cycle types are based on a summation frame structure (see Figure 15.3).

The layer 2 summation frame consists of a special 16 bit loopback word (preamble), the user data of all devices, and a terminating 32 bit frame check sequence (FCS). As data can be simultaneously sent and received by the ring structure of the INTERBUS system (full duplex mode), this results in very high protocol efficiency.

The logical method of the operation of an INTERBUS slave can be configured between its incoming and outgoing interface by the register set shown in Figure 15.4. Each INTERBUS slave is part of a large, distributed shift register ring, whose start and end point is the INTERBUS master.

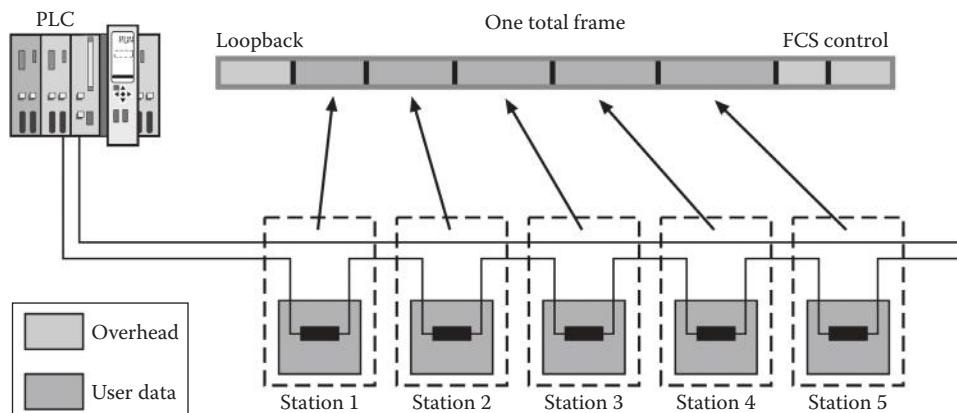

FIGURE 15.3 The layer 2 summation frame structure of INTERBUS.

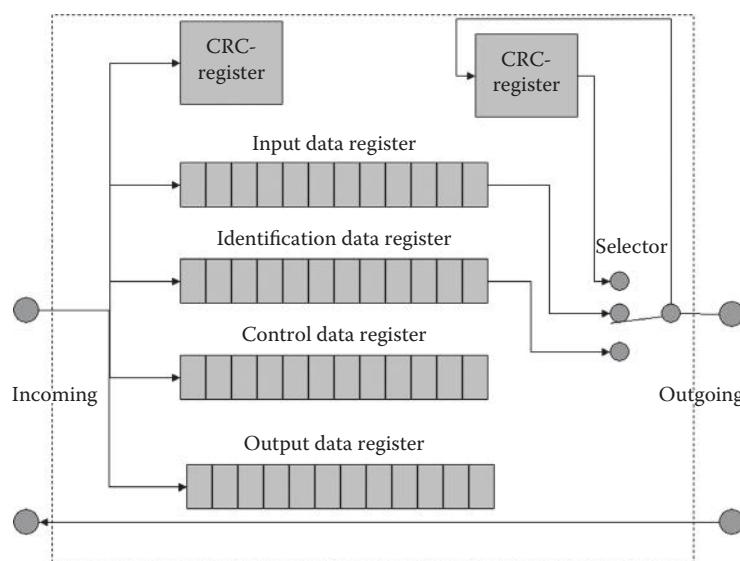

FIGURE 15.4 Basic model of an INTERBUS slave node.

In the input data register, input data, that is, data that are to be transmitted to the master, are loaded during data transfer. The output data registers and the cyclic redundancy check register (cyclic redundancy check) are switched to the input data register in parallel. The Comite Consultatif International Telephonique et Telegraphique (CCITT) polynomial  $g(x) = x^{16} + x^{12} + x^5 + 1$  is used for the CRC. After finishing a valid data transfer cycle, output data from the output data register are written to a memory and then accepted by the local application. The CRC registers are used during the FCS to check whether the data have been transmitted correctly. The length of the I/O data registers depends on the number of I/Os of the individual node.

The master needs to know which devices are connected to the bus so that it can assign the right I/O data to the right device.

Once the bus system has been switched on, the master starts a series of identification cycles, which enable it to detect how many and which devices are connected. Each slave has an identification data register, which has a 16 bit ID code. The master can use this ID code to assign a slave node to a defined device class (e.g., digital I/O node and analog I/O node) and detect the length of the I/O data registers in a data cycle. The control data registers are switched in parallel to the identification data registers, whereby the individual devices can be managed by the master. Commands are transmitted, for example, for local resets or outgoing interface shutdown. The identification cycle is also used to find the cause of a transmission error and to check the integrity of the shift register ring.

The individual registers are switched in the different phases of the INTERBUS protocol via the selector in the ring.

On layer 1, INTERBUS uses two telegram formats with start and stop bits similar to universal asynchronous receiver transmitter (UART):

1. The 5 bit status telegram
2. The 13 bit data telegram

The status telegram is used to generate defined activity on the medium during pauses in data transmission. The slave nodes use the status telegram to reset their internal watchdogs, which are used to control a failsafe state. The data telegram is used to transmit a byte of the layer 2 payload. The remaining bits of both telegrams are used to distinguish between data and ID cycles, as well as the phase data transfer and FCS within a cycle. This information is used by the selector shown in Figure 15.4 to switch the relevant register in the ring. INTERBUS uses a physical transmission speed of 500 kbps or 2 Mbps.

The cycle time, that is, the time required for I/O data to be exchanged once with all the connected modules, depends on the amount of user data in an INTERBUS system. Depending on the configuration, INTERBUS can achieve cycle times of just a few milliseconds. The cycle time increases linearly with the number of I/O points, as it depends on the amount of information to be transmitted. For more detailed information, refer to the performance evaluation.

The architecture of the INTERBUS protocol is based on the open systems interconnection (OSI) reference model according to ISO 7498. The protocol architecture of INTERBUS provides the cyclic process data and an acyclic parameter data channel, using the services of the peripheral message specification (PMS) as well as a peripheral network management (PNM) channel (see Figure 15.5). As is typical for fieldbus systems, for reasons of efficiency, ISO layers 3–6 are not explicitly used but are combined in the lower layer interface (LLI) in layer 7. The process data channel enables direct access to the cyclically transmitted process data. It is characterized by its ability to transmit process-relevant data quickly and efficiently. From the application point of view, it acts as a memory interface. The parameter channel enables data to be accessed via a service interface. The data transmitted in the parameter channel have a low dynamic response, and this data transmission occurs relatively infrequently (e.g., updating text in a display).

Network management is used for manufacturer-independent configuration, maintenance, and startup of the INTERBUS system.

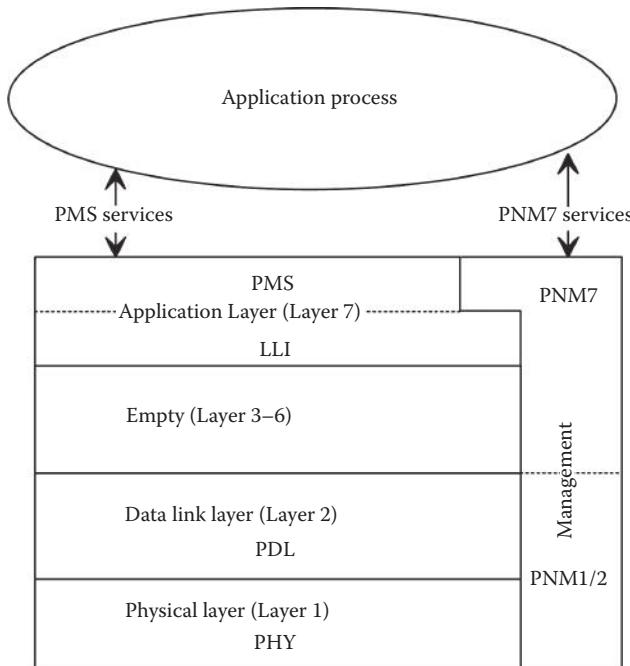

FIGURE 15.5 Protocol architecture of an INTERBUS node.

Network management is used, for example, to start/stop INTERBUS cycles, to execute a system reset, and fault management. Furthermore, logical connections between devices can be established and aborted via the parameter channel in the form of context management, for example.

To transmit parameter data and time-critical process data simultaneously, the data format of the summation frame must be extended by a specific time slot. In several consecutive bus cycles, a different part of the data is inserted in the time slot provided for the addressed devices. The peripherals communication protocol (PCP) performs this task. It inserts a part of the telegram in each summation frame and recombines it at its destination (see Figure 15.6). The parameter channels are activated, if necessary, and they do not affect the transfer of I/O data. The longer transmission time for parameter data that are segmented into several bus cycles is sufficient for the low time requirements that are placed on the transmission of parameter information.

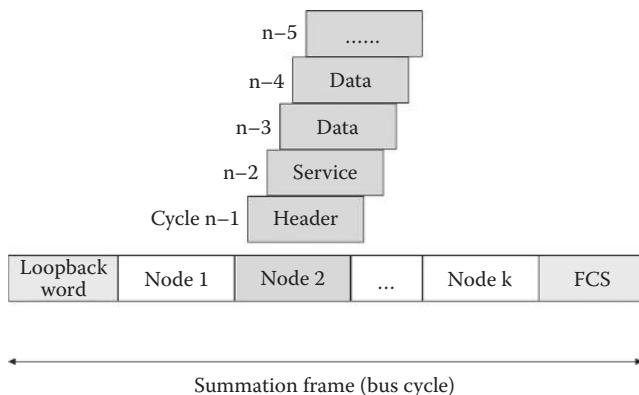

FIGURE 15.6 Transmission of parameter data with a segmentation and recombination mechanism.

INTERBUS uses a master/slave procedure for data transmission. The parameter channel follows the client/server paradigm. It is possible to transmit parameter data between two slaves (peer-to-peer communication). This means that both slaves can adopt both the client and server function. With this function, layer 2 data are not exchanged directly between the two slaves but are implemented by the physical master/slave structure, that is, the data are first transmitted from the client to the master and then forwarded to the server from the master. The server response data are also transmitted via the master. However, this diversion is invisible for slave applications.

The task of a server is described using the model of a virtual field device (VFD).

The VFD model unambiguously represents that part of a real application process, which is visible and accessible through the communication. A real device contains process objects. Process objects include the entire data of an application process (e.g., measured values, programs, or events). The process objects are entered in the object dictionary (OD) as communication objects. The OD is a standardized public list, in which communication objects are entered with their properties. To ensure that data are exchanged smoothly in the network, additional items must be standardized, in addition to the OD, which can be accessed by each device. This includes device features such as the manufacturer name or defined device functions that are manufacturer-independent. These settings are used to achieve a closed and manufacturer-independent representation of a real device from the point of view of the communication system. This kind of modeling is known as a VFD.

## 15.4 Diagnostics

---

The system diagnostics play an important role in practical applications. In increasingly complex systems, errors must be located quickly using system diagnostics and clearly indicated to the user. In addition to detecting errors, good error diagnostics include reliable error localization. For message-oriented fieldbus systems with a bus structure, only one telegram is ever transmitted to a device at any one time. An error, which affects the system via a specific device or a device nearby, can even destroy telegrams, which are not themselves directed at the faulty device but may be directed at remote devices. It is therefore virtually impossible to determine the exact error location.

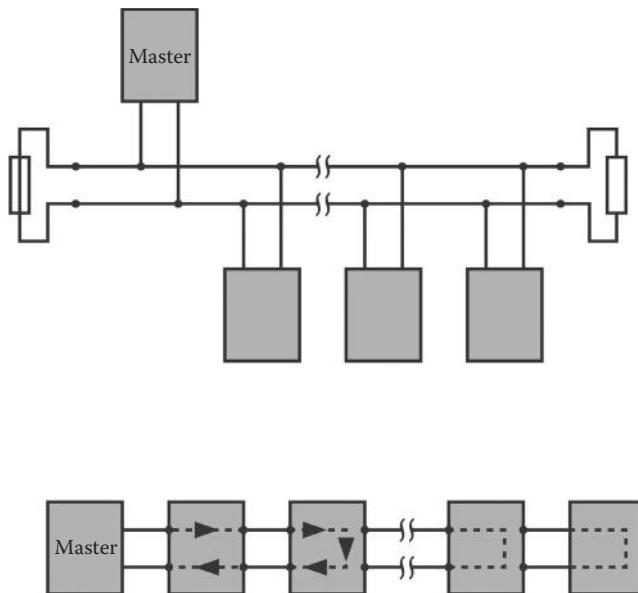

INTERBUS uses the CRC procedure in each device to monitor the transmission paths between two devices and, in the event of CRC errors, can therefore determine in which segment the error occurred.

An important criterion for maintaining data communication is the response of the master in the event of the following errors:

- Cable break
- Failure of a device
- Short circuit on the line
- Diagnostics of temporary interference—electromagnetic interference (EMI)

In all fieldbus systems, in the event of a line interrupt, the devices after the interrupt are no longer reached. The error localization capability depends on the transmission system used. In linear systems, telegrams are still sent to all devices. However, these telegrams are lost because the devices are no longer able to respond. After a certain period, the master detects the data loss. However, it cannot precisely determine the error location because the physical position of the devices is not known. The system diagrams must be consulted so that the service or maintenance personnel can determine the probable error location (see Figure 15.7).

Unlike linear systems, the individual devices in the INTERBUS system are networked so that each one behaves as a separate bus segment. Following a fatal error, the outgoing interfaces of all devices are fed back internally via a bypass switch. In the event of a line interrupt between the devices, the master activates each separate device in turn. To do this, the master opens the outgoing interface, starting from the first device up until the error location, thus clearly identifying the inaccessible device. The controller board can then clearly assign the error location as well as the

**FIGURE 15.7** The behavior of bus systems and ring systems in the event of a cable break.

station or station name and display it in plain text. This is a huge advantage, particularly in large bus structures with numerous devices, where bus systems are typically used.

If a device fails, the fieldbus behaves in the same way as for a line interrupt. However, the functional capability of the remaining stations differs in linear and ring systems. In a linear system, bus operation cannot be maintained because the condition of physical bus termination using a termination resistor is no longer met. This can lead to reflections within the bus configuration. The resulting interference level means that correct operation is not possible. In an INTERBUS ring system, the termination resistor is opened and closed together with a bypass switch, which ensures that the condition of the closed ring is always met. In the event of a line interrupt or device failure, the master can either place the devices in a safe state or start up the remaining bus configuration autonomously.

Short circuits on the line are a major challenge in a bus system. In the event of a direct or indirect (e.g., via ground) short circuit on the line, the transmission path is blocked for the entire section. In linear systems, the transmission line is used equally for all devices, which means that the master cannot reach segment parts either. This considerably reduces further error localization. In the INTERBUS system, the user is aided by the physical separation of the system into different bus segments. As described for the line interrupt, the devices are activated by the master in turn, and the ring is closed prior to the short circuit, which means that subsystems can be started up again. The error location is reported in clear text on the controller board. Linear systems also support a division into different segments. Repeaters, which are placed at specific points, can then perform diagnostic functions. However, a repeater cannot monitor the entire system; it can only cover a defined number of devices per segment. Furthermore, the use of repeaters incurs additional costs, which should not be underestimated, and increased configuration effort.

In summary, the INTERBUS diagnostic features are essentially based on the physical segmentation of the network into numerous point-to-point connections. This feature makes INTERBUS particularly suitable for use with fiber optics, which are used increasingly for data transmission in applications with large drives, welding robots, etc. In linear systems, the use of fiber optics—like bus segmentation—requires expensive repeaters, which simulate a ring structure. Fiber optic path check in the INTERBUS system is another feature, which is not offered by other buses. In this system, a test pattern for the fiber optic cable is transmitted between the interfaces to determine the quality of the connection. If the cable

deteriorates due to dirt, loose connections, bending, etc., the transmission power is increased automatically. If a critical value is reached, the system generates a warning message so that the service personnel can intervene before the deterioration leads to expensive downtimes.

Studies by the German association of electrical and electronic manufacturers, ZVEI, and the German Engineering Federation, VDMA, indicate that many bus errors are caused by direct or hidden installation faults. For this reason alone, bus diagnostics simplify start-up and ensure the smooth operation of the system, even in the event of extensions, servicing, and maintenance work. Every bus system should automatically carry out comprehensive diagnostics of all connected bus devices without the need to install and configure additional tools. Additional software tools for system diagnostics often cost several thousand Euro.

In the INTERBUS system, all diagnosed states can be displayed directly on the controller board. If the master has a diagnostic display, various display colors can be used so that serious errors are clearly visible even from a distance. In addition, each master has a diagnostic interface, which can be used to transfer all functions to visualization systems or other software tools.

## 15.5 Functional Safety

In recent years, safety technology has become increasingly important in machine and system production. This is because complex automation solutions require flexible and cost-effective safety concepts, which offer the same advantages that users have come to appreciate in nonsafe areas. This means that considerable savings can be made, for example, in terms of both cost and time, by changing from parallel to serial wiring.

From the user's point of view, however, various requirements must be taken into consideration. Firstly, safe and nonsafe signals must be separated in order to simplify the programming, operation, and acceptance of safety applications. Secondly, all components used should be operated on a fieldbus, as a standardized installation concept, and standard operation make planning operation, start-up, and maintenance easier. These requirements have led to the safety extension of INTERBUS (Figure 15.8).

As the INTERBUS master, the controller board uses an integrated safe control system.

The INTERBUS controller board with integrated safe controller is the basic unit in the system. It processes all safety-related inputs and confirms them to the standard control system by setting an output or resets the output. This method of operation is similar to existing contact-based safety technology. The enabling of output data is programmed with preapproved blocks such as emergency stop, two-hand control, or electro-sensitive protective equipment in *SafetyProg* Windows software, which is compatible

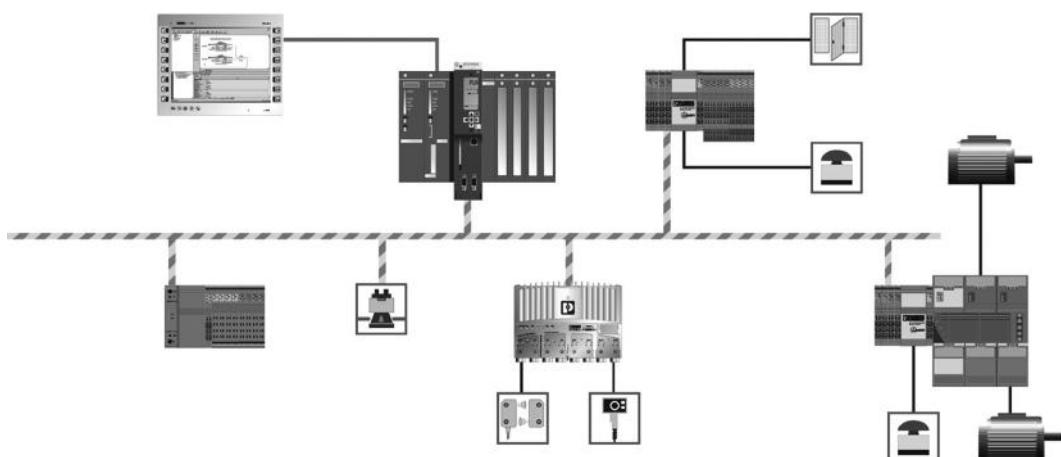

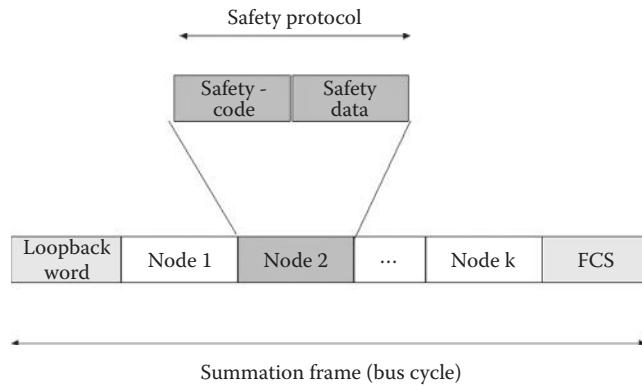

FIGURE 15.8 The safety extension of INTERBUS.

**FIGURE 15.9** Safety protocol on top of the INTERBUS summation frame.

with IEC 61131. The amount of programming required is reduced considerably through the use of blocks and the enable principle.

The safe input and output components form the interface to the connected I/Os. They control, for example, contactors or valves and read the input status of the connected safety sensors, including intelligent sensors. The user uses the parameterization function of INTERBUS to select the settings for the I/O components such as clock selection, sensor type, and signal type. The INTERBUS safety system meets safety functions up to Category 4 according to EN 954 [2] and SIL 3 according to IEC 61508 [3]. Depending on the application, the user can choose to use either a *one-cable solution with integrated safety technology* or a *two-cable solution*, where one bus cable is used for standard signals and the other for safety signals.

A safety protocol is used between the safe controller and the connected I/O safety devices. This protocol provides the desired security of data transmission and can only be interpreted by the connected safety devices. The safety data are integrated transparently into the INTERBUS summation frame (see Figure 15.9). This feature ensures the simultaneous operation of standard and safety devices in the bus system.

## 15.6 Interoperability, Certification

The basic aim of open systems is to enable the exchange of information between application functions implemented on devices made by different manufacturers. This includes fixed application functions, a uniform user interface for communication, and a uniform transmission medium. For the user, this profile definition is a useful supplement to standardized communication and provides a generally valid model for data content and device behavior. These function definitions standardize some essential device parameters. As a result, devices from different manufacturers exhibit the same behavior on the communication medium and can be exchanged without altering the application software when these standard parameters are used.

INTERBUS takes a rigorous approach to the area of interoperability using the XML-based device description Fieldbus Description Configuration Markup Language (FDCML) [4]. FDCML enables the different views of a field device to be described due to the generic device model used. Some examples include identification, connectivity, device functions, diagnostic information, and mechanical description of a device.

FDCML features the following characteristics:

- Can be used for devices of various complexity
- System-independent

- Can be extended by typifying generic FDCML elements
- Supports online changeover to a variety of national languages
- Can be used for devices that support more than one communication system

The FDCML device model is made up of the following basic elements:

- Device identity object
- Device manager object
- Device function object
- Application process object

This electronic device description is used in the configuration software for configuration, start-up, and other engineering aspects. Different applications can use FDCML to evaluate various aspects of a component.

To simplify interoperability and interchangeability, the members of the INTERBUS Club compile a set of standard device profiles in several user groups for common devices such as drives (DRIVECOM Profile 22), human machine interfaces (MMI-COM D1), welding controllers (WELD-COM C0), and I/O devices (Sensor/Actuator Profile 12). These profiles can also be described neutrally with regard to the manufacturer and bus system in FDCML.

The INTERBUS Club and various partner institutes have offered certification for several years to ensure maximum safety when selecting components. Independent test laboratories carry out comprehensive tests on devices as part of this process. The device only receives the *INTERBUS Certified* quality mark, which is increasingly important among users, if the test object passes all the INTERBUS conformance tests. The conformance test comprises tests and examinations, which are carried out by test laboratories using various tools.

The conformance test is divided into the following sections:

- Basic function test (mandatory)
  - General section (valid for all interface types)
  - Fiber optics (for devices with fiber optic interfaces)
  - Burst noise immunity test (mandatory)
- PCP protocol software conformance test (for devices with PCP communication) (dependent)

## 15.7 Connectivity

---

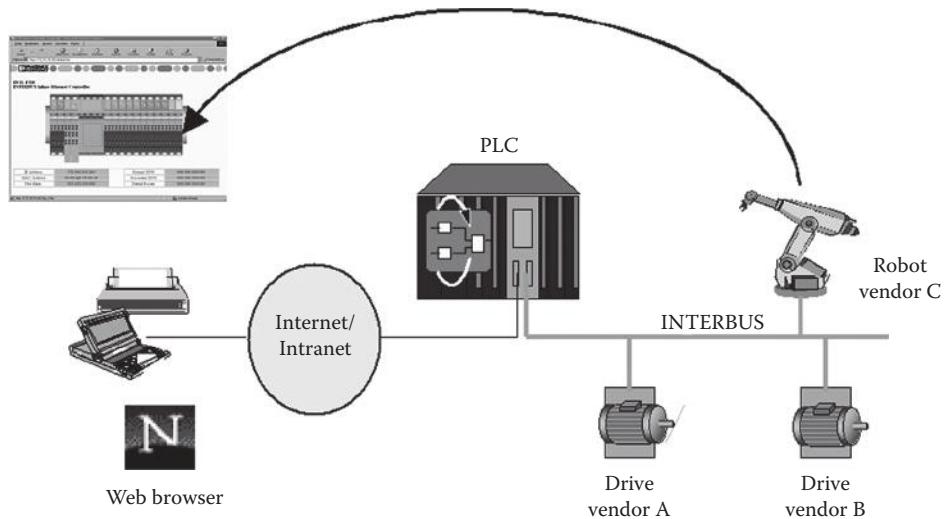

As shown in Table 15.1, connectivity is one of the four basic arithmetic operations of field communication. Connectivity is the integration of fieldbus technology in company networks.

However, there are still no standard concepts for *connectivity* solutions. This makes it more difficult to integrate the field level in the company-wide distributed information system and is only possible through increased programming and parameterization.

The Internet protocol (IP) can be used here as an integration tool. IP is increasingly used in automation technology in conjunction with Ethernet and is then frequently referred to as *industrial Ethernet*. In many cases, IP is therefore already well-suited to the field (Figure 15.10).

**TABLE 15.1** Four Basic Types of Arithmetic Operations for Field Communication

Signal Acquisition	Quick and Easy Acquisition of Signals from I/O Devices
Functional safety	Transmission of safety-related information (e.g., emergency stop)
Drive synchronization	Quick and precise synchronization of drive functions for distributed closed-loop controllers
Connectivity	Creation of seamless communication between business processes and production

**FIGURE 15.10** Connectivity creates new options such as web-based management.

This section deals with transparent IP communication at field level, taking into consideration the real-time requirements. This means that the advantages of fieldbus technology are maintained, and at the same time, the user is provided with a new quality of connectivity. For example, well-known office applications such as browsers can be used to load device descriptions, e-mails can be used to send maintenance messages, or FTP can be used to upload and download files.

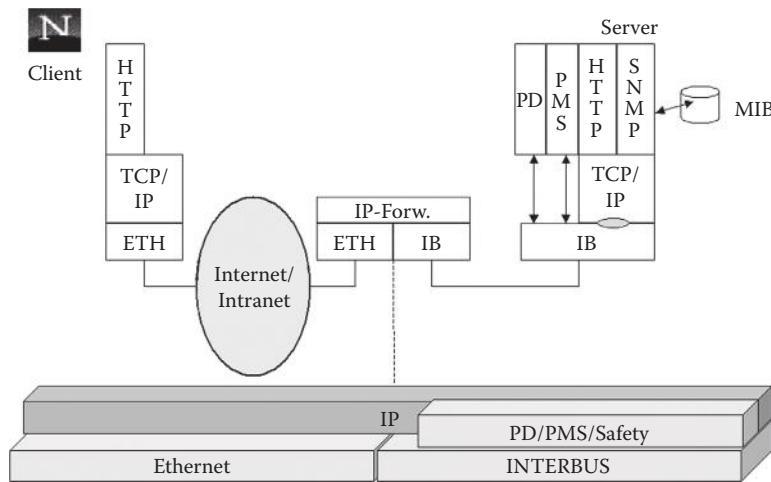

Ethernet's role in the future of automation is an important current issue. On the one hand, its specification suggests it could solve all of the communication problems in automation applications and supersede fieldbuses. On the other hand, fieldbuses, with their special characteristics, have arisen because the real world does not consist simply of bits and bytes.

However, Ethernet and INTERBUS can only be fully integrated if transparent communication beyond the boundaries of the system is possible without complex conventional gateway processes. This is achieved by using TCP/IP (Transmission Control Protocol) as the standard communication protocol on both systems. While TCP/IP is now standard on Ethernet, this is by no means the case in the factory environment. Virtually all fieldbus organizations and promoters map their fieldbus protocol to Ethernet TCP/IP in order to protect their existing investments. INTERBUS took a different direction early on and integrated TCP/IP into the hybrid INTERBUS protocol. TCP/IP standard tools and Internet technologies based on TCP/IP can therefore be readily transferred to the factory environment without additional expense.

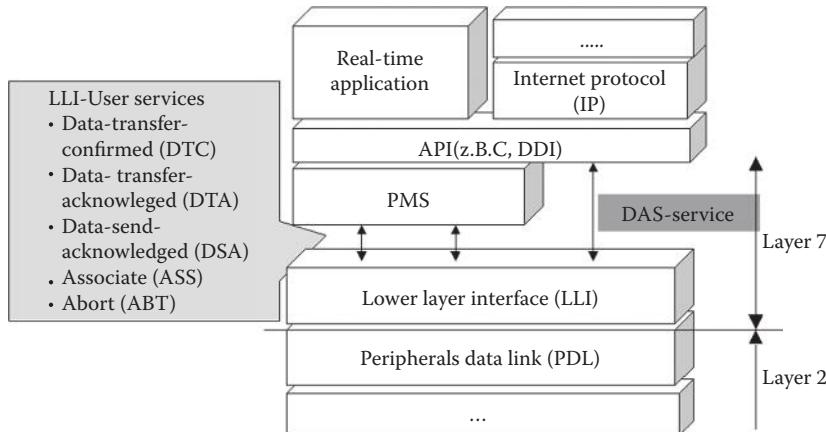

For example, on INTERBUS, the FTP service can be used to download control programs and other data to a process controller. The use of FTP to upload and download files such as robot programs is just one advantage, since TCP/IP opens up automation to the world of the Internet. Internet browsers will also be the standard user interface of the factory of the future, when all devices have their own integrated web page. Special configuration tools, now supplied for devices by virtually every manufacturer, will no longer be needed, as in the future these devices will be configured through ActiveX controls or Java applets, which are loaded through the network and therefore do not have to be present on the control computer beforehand.

## 15.8 IP over INTERBUS

Figure 15.11 shows the system architecture for IP tunneling. The known Ethernet TCP/IP structure can be seen on the left, and the extended protocol structure of an INTERBUS device can be seen on the right. An IP router, with the same mechanisms as in the office environment, is used for coupling.

**FIGURE 15.11** Basic architecture for IP tunneling.

**FIGURE 15.12** Protocol architecture of an IP-enabled INTERBUS node.

This function is best performed in the PLC. IP tunneling is performed by introducing a new Data-Send-Acknowledged (DAS) service in the INTERBUS parameter channel (Figure 15.12).

This DAS service enables LLI user protocol data unit (PDU) to be transmitted for unconfirmed, connectionless LLI user services and is used for transparent IP data transmission. These data are transmitted in the same way as the parameter channel peripheral management services (PMS) at the same time as the time-critical process data exchange process data (PD).

## 15.9 Performance Evaluation

This section considers the performance of the concept in relation to the relevant fieldbus parameters, such as the number of I/O modules and the amount of cyclic I/O data. The achievable data throughput for IP tunneling is a key performance indicator. Due to the determinism of the INTERBUS system, the throughput can be easily calculated.

The following applies to the INTERBUS MAC cycle time  $T_{IB}$  [ms]:

$$T_{IB} = 13 \cdot (6 + N) \cdot \frac{1}{\text{Baud rate}} \cdot 1000 + T_{SW}$$

where

$$N = \sum_{i=1}^{i=k} PL_i$$

The IP throughput ( $IP\_Th$ ) of a device is calculated as follows:

$$IP\_Th = \frac{M - 1}{T_{IB}} \cdot 8$$

$N$	Total payload size: sum of all user data [bytes] of all devices $k$ , where $N \leq 512$ bytes and $k \leq 512$
<i>Baud rate</i>	Physical transmission speed of INTERBUS [bps] {0.5; 2} Mbps
$T_{SW}$	Software runtime [ms] of the master (0.7 ms, typical, depending on implementation)
$PL_i$	L2 payload of the $i$ th device [bytes], where $1 \leq i \leq k$ , where $k \leq 512$
$M$	Reserved MAC payload [bytes] for the IP channel of a device ( $M = 8$ , typical)
$IP\_Th$	Throughput [kbps] for IP data telegrams

In Figure 15.13, the curve for the INTERBUS cycle time at MAC level and the IP throughput for a baud rate of 2 Mbps is illustrated as the function of payload size  $N$ .

For a medium-sized configuration of  $N = 125$  bytes, an IP throughput of 36 kbps at an INTERBUS cycle time of approximately 1.6 ms is achieved. This roughly corresponds to the quality of an analog modem for Internet access. For smaller configurations, even Integrated Services Digital Network (ISDN) quality can be achieved. The calculated values could be confirmed in a practical application. In this configuration, it should be noted that, in addition to the dedicated process data devices, several IP-compatible devices can be operated at the same time with this throughput.

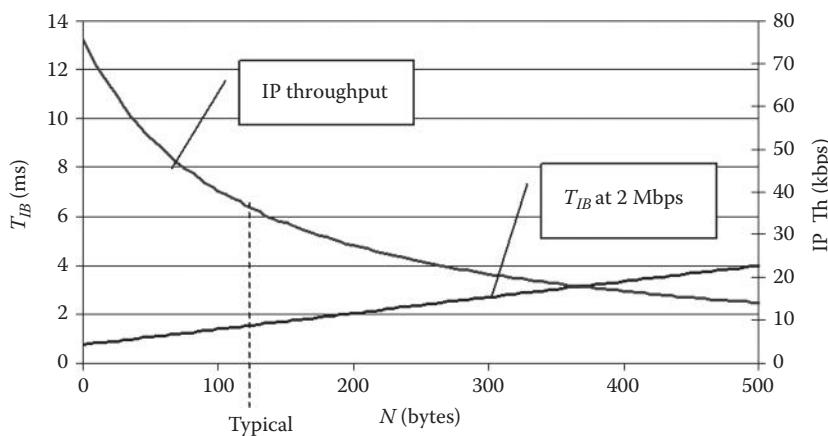

FIGURE 15.13 Performance data.

## 15.10 Conclusions

---

The open INTERBUS fieldbus system for modern automation seamlessly connects all the I/O and field devices commonly used in control systems. The serial bus cable can be used to network sensors and actuators, to control machine and system parts, to network production cells, and to connect higher-level systems such as control rooms.

After a comprehensive introduction to INTERBUS, IP tunneling for fieldbuses was described for improved connectivity at field level. An essential requirement is that time-critical process data transport is not affected.

The integration of the IP in INTERBUS creates a seamless communication platform to enable the use of new IP-based applications, which can make it considerably easier to engineer distributed automation solutions. Analysis has shown that the IP throughput can be as high as ISDN quality.

### 16.1 Introduction

---

Ethernet is a very important communication platform (a physical layer and partly a data link layer) for automation systems. While the fieldbuses are still important in automation with large sales and a huge installed base, there is no doubt that the development of communication technology for automation purposes is now mainly on Ethernet. In addition, wireless communication is being used in some scenarios (mainly wireless sensor networks).

There is a long list of automation protocols developed for various purposes running on top of Ethernet. A key strength of Ethernet is its ability to run many protocols simultaneously on the same network. Ethernet enables flexibility, scalability, and performance in a way not seen before in automation. However, modern networking is a complex domain, which requires investment in competence and product development to be able to succeed. The complexity of automation networks is increasing as new functionality is added to the system. This added complexity is not a negative thing as it both replaces a lot of manual work related to engineering and management and increases the robustness of the systems by the addition of features such as redundancy and accurate synchronization.

A state-of-the-art industrial Ethernet system is therefore not just a communication protocol but includes a carefully designed communication architecture and a set of communication technologies to be used within this architecture. This represents a significant change from fieldbus systems and even early Ethernet-based industrial systems, which utilized Ethernet in a fairly simple way. This chapter will cover some of the most important features of modern switched Ethernet networks.

Before continuing, we need to discuss some basic features of Ethernet and Ethernet-based networks.

1. In the Open Systems Interconnection (OSI—ISO/IEC 7498-1) model, Ethernet covers Layer 1 (the physical layer) and part of Layer 2 (the data link layer) and is defined by IEC 802.3.
2. The term “industrial Ethernet” is often used to describe the combination of Ethernet-based communication protocols targeting industrial automation systems (PROFINET, EtherCAT, IEC 61850, etc.) and a wide variety of fundamental technologies (e.g., switching, routing, and networking protocols).
3. A number of technologies using an enhanced Ethernet data link layer have been developed for the most demanding real-time applications. These solutions (e.g., EtherCAT) support very short communication cycles and deterministic communication requirements. Such technologies typically need some additional hardware support. They are beyond the scope of this chapter.
4. Modern Ethernet networks run at speeds of 100 Mbps and upward. Gigabit Ethernet is now entering into the industrial domain. The development of the Ethernet technology is now going beyond 100 Gbps.
5. Modern Ethernet networks use full duplex communication with no collisions. However, there may be queuing in switches, routers, and end nodes, leading to unpredictable communication delays.

## 16.2 Requirements and Challenges

---

### 16.2.1 Topology

Modern automation systems cover a very wide range of applications, and thus, their physical layout and structure range from simple, small systems with a controller and a few devices to large, very complex systems consisting of very many controllers and devices and IOs in the tens of thousands or even higher. In addition, a single system may consist of various parts responsible for completely different applications such as process control, power distribution, distributed motion, and surveillance. There are also often tough requirements on flexibility and scalability and the coexistence of various protocols on the same physical network [1].

In addition to high numbers of controllers and various types of devices, a system may contain up to hundreds or even thousands of Ethernet switches and tens of routers in addition to a wide range of other nodes. The system may also cover a large geographical area (e.g., in the IEC 61850 standard, it is required that *the communication network within the substation should be capable of covering distances up to 2 km*).

The physical topology of a system can be constructed in many ways, but simple ring topologies and more complex ring-of-rings topologies are common in large installations, for example, within process automation. The line and star topologies are also common, especially in factory automation-related systems. More meshed types of networks are also used, but such networks are typically more complex to handle from a network redundancy perspective (see discussion later in this chapter). This could change with the arrival of new solutions utilizing the potential of meshed networks (e.g., Shortest Path Bridging [SPB] [2]).

### 16.2.2 Availability

Availability is an important requirement in most automation systems. It is basically a measure of the proportion of time a system is in the operational state. In many automation systems, 24/7 operation is expected and every hour of downtime may have an excessive cost. As an example, there are process automation systems where each hour of downtime may cost millions of dollars in lost production.

The availability of a system depends on a wide range of factors including the quality of the components used, the amount of induced stress, the robustness of the communication, the extent of status and health monitoring of the equipment, the frequency of service, and the system complexity.

The availability of the communication network has a huge impact on the overall availability of the system. The communication system is the backbone of any automation system, and it is crucial that it is working so that the applications running are not negatively affected. The amount of time a system can tolerate that the communication is not working varies from virtually zero to seconds. This time is often expressed as the recovery time. The requirements on recovery time found in the industry can somewhat be simplified and divided into three categories.

In the process automation area (chemical industry, petrochemical, pulp, and paper), the system recovery time requirements are typically from hundreds of milliseconds up to a few seconds. Factory automation applications typically involve movement of machinery such as conveyor belts and may have system recovery time requirements of around 50 ms. The toughest recovery requirements are found in motion control applications involving robots or synchronized motor drives, in systems like drive-by-wire, electrical power distribution systems, and other application areas where maximum recovery times are down to a few milliseconds. The above numbers are just indications but this implies that there are industrial requirements on network recovery times ranging from more or less zero to seconds.

### 16.2.3 Performance

Communication performance is a term comprised of several factors such as data update rates or cycle times, time synchronization accuracy, jitter, latency, and data throughput.

Automation systems vary widely in their requirements on cycle times (or data update rates), but cycle times ranging from approximately 10  $\mu$ s up to seconds can be found. Process automation systems typically go down to the milliseconds in cycle times, whereas some power-related applications and discrete automation may have cycle times going down to 10  $\mu$ s. Some systems use event-based communication instead of cyclic communication, in such systems the fastest update rates may be in the milliseconds range.

Jitter and latency are two important factors. Data needs to get there in time, that is, there is a bound on the tolerable latency. Similarly, the jitter in the communication cannot be higher than a certain limit; otherwise, the process will become unstable or with degraded quality.

In this context, it is relevant to discuss whether a switched network can handle all these requirements or not. A switched network is very efficient and flexible in handling a wide range of protocols and functionality. There are normally many protocols competing about the resources and there are delays in switches related to address lookup. In a store-and-forward switch, a maximum sized Ethernet packet (1500 bytes payload) will be delayed at least 123  $\mu$ s (one forwarding delay) on 100 Mbps Ethernet (12.3  $\mu$ s on 1 Gbps Ethernet). For so-called cut-through switches, this time is reduced significantly but this comes together with numerous drawbacks). In addition comes time related to address lookup (a few microseconds) and time spent in waiting for already ongoing transmissions to finish (may range up to several forwarding delays in the worst case). There are Quality of Service (QoS) measures to use to improve this (prioritization, stream reservation functionality, etc.), but there is a limit to what can be achieved with a standard network. For such applications, a set of technologies addressing real-time performance on Ethernet has been developed. EtherCAT is one of these and offers deterministic cycle times down to the 10  $\mu$ s range with delays through a node of approximately 1  $\mu$ s (independent of the packet size) [3].

### 16.2.4 Time Synchronization

Time synchronization is an important requirement in many automation systems and is used in a wide range of scenarios. An automation system typically needs time synchronization for correct time stamping of input data, for control of distributed devices and correct logging of alarms and events.

The components of a distributed automation system thus need to have the same notion of time. Sometimes it is sufficient to use relative time (the nodes share the same time but it is not necessary for

the process to relate it to the actual time in the physical world) but often it is needed to use absolute time (e.g., to be able to relate specific events to the actual time). It should be noted that in some rare cases only frequency synchronization is required but this will not be handled here.

In the process automation domain the, typical time synchronization accuracy required for sequence of event timestamping is 1 ms. In power system automation, there is a need for synchronized sampling of voltages and currents and timestamped values for protection functions. The accuracy requirement may be as challenging as 1  $\mu$ s in these applications. Within discrete automation and motion control, the requirements on time synchronization are ranging from the microseconds level to the hundreds of microseconds, depending on the application.

### 16.2.5 Security

Security is becoming more and more important in automation systems, and the customers are expecting that the systems are secure against all reasonable threats. This is a huge challenge but the automation industry has been targeting this for years and many solutions are used already. Due to space limitations, the topic of security will not be discussed in this text.

## 16.3 Network Architectures

---

The topology of a network refers to the physical layout of the devices. Ethernet-based process automation networks have in recent years favored the ring topology due to its simplicity and the abundance of network redundancy protocols for rings. Star networks are typical for more controller-centric architectures but not very efficient from a networking perspective. Networks may have any layout, so meshed or partially meshed networks are also common; however, it is normally more difficult to achieve determinism and low recovery times in such systems. Recent developments within Ethernet technologies used in other domains may change this and lead to new and flexible topologies (e.g., using technologies related to SPB [2]).

There is no single network topology that is the best in all situations. This depends on the requirements for availability, the physical layout of the system, and other requirements such as cost and real-time performance.

## 16.4 Switches

---

### 16.4.1 What Is a Switch?

Switches are crucial infrastructure components of modern Ethernet-based communication networks. The main function of a switch is to decide for each incoming packet on which port to send the packet out on. The switch may decide to send the packet out on either one, many, all, or no other ports. In this part, we shall see how this is done.

The switch functionality is defined by IEEE 802.1D [4], which describes an architecture and a set of functions distributed throughout this architecture [5]. Ethernet switches are multiport devices designed for efficient communication and utilize various filtering mechanisms to optimize the bandwidth utilization. In addition to the handling of user data communication, they also provide a set of network management-related functionality. Thus, switches are in a completely different league from their predecessors, the hubs, which were basically just signal repeaters, that is, a packet coming in on one port was immediately mirrored out on all other ports.

While a hub acts at the physical layer (Layer 1 in the OSI model), a switch works at the data link layer (Layer 2 in the OSI model). Switches take decisions based on the data link layer destination address of packets, that is, the media access control (MAC) address. Correspondingly, routers work at the transport layer (Layer 3 in the OSI model) and deal with IP addresses.

An actual switch is normally implemented with a combination of switching silicon and a central processing unit (CPU) (sometimes called the management CPU) although some switches have small, inbuilt CPUs and some CPUs have integrated switching capabilities. The communication between the CPU and the switch silicon can occur via various interfaces, including using one of the switch ports.

### 16.4.2 Switch Architecture

Ethernet switches as defined by IEEE 802.1D in principle consist of three parts as shown in Figure 16.1:

1. Two or more MAC entities
2. A MAC relay entity
3. A number of higher layer entities (HLEs)

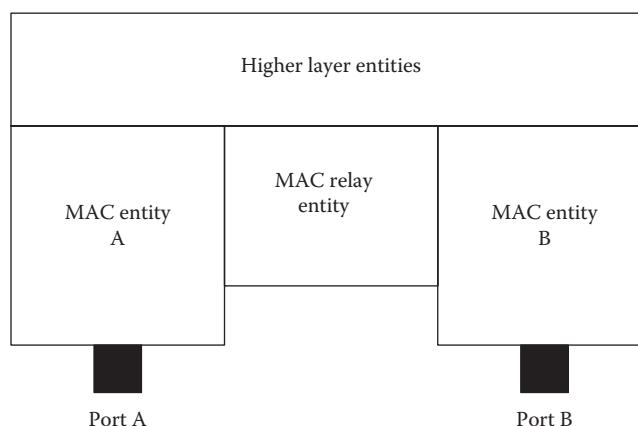

These parts interact by exchanging both Ethernet frames and control information.

#### 16.4.2.1 MAC Entity

The MAC entity (sometimes called the MAC port entity) contains the media access part of the switch, including the connectors. A switch with eight physical ports thus has eight MAC entities. The switch MAC entity receives and transmits Ethernet frames (ingress and egress frames, respectively) and validates the Ethernet checksum (it may also calculate the checksum of egress frames). Ingress frames are either sent to the MAC relay entity or to an HLE of the switch if they are not discarded for some reason. Similarly, egress frames come from either the MAC relay entity or from an HLE of the switch. A frame is discarded if the checksum is incorrect or if it does not meet the criteria of a valid frame. Examples of invalid frames are frames with an invalid packet format or an invalid virtual local area network (VLAN) ID. VLAN is a technology where a physical network (local area network [LAN]) can be separated into several virtual networks, LANs. VLANs will be discussed later in this chapter.

A MAC entity should have a unique MAC address; thus, an eight-port switch will need eight unique MAC addresses, one for each port. These addresses should not be used by other functions inside the switching device as that may lead to confusion by other switches in the network.

The MAC entity decides whether an ingress frame is addressed to an HLE of the switch. HLEs are identified by multicast MAC addresses. If there is a match, the frame will be sent to the appropriate HLE. If there is no match, the frame will be checked for VLAN conformance. The MAC entity handles the recognition, interpretation, addition, and removal of VLAN tags; and only frames that match the VLAN criteria will be accepted.

**FIGURE 16.1** An Ethernet switch according to IEEE 802.1D.

If it has a VLAN ID, it is checked whether this VLAN ID is valid for the specific port. If so, the frame is forwarded to the MAC relay entity. For egress frames, the MAC entity may add a VLAN tag to the frame.

#### 16.4.2.2 MAC Relay Entity

The MAC relay entity contains the typical switch functions that distribute packets between the switch ports. The main function of a switch is to decide for each incoming packet on which ports to send the packet out again. It does so based on the information found in an address table. This address table contains mappings between MAC addresses and ports; that is, it contains information about which port or ports frames with a certain destination address should be transmitted on. The information in this address table is normally collected by learning from which port traffic with a certain source address is coming in on, but it can also be put there by certain protocols or by manual configuration. The address table contains both unicast and multicast MAC addresses. The address table is more precisely called a filtering database. Based on the information in the filtering database, the switch may decide to send a packet out on one, many, all, or no other ports.

When the MAC relay entity receives a packet with an unknown destination address (i.e., the switch does not know at which port the destination can be found), it normally forwards this frame on all ports. This is similar to how a broadcast frame is handled. Broadcast frames will be forwarded on all ports. When the switch has learned the location of the destination (by receiving a frame from it), an entry in the MAC address table will be made to reflect this. The learned information in the address table will be deleted after the so-called aging time has passed. The aging time is the time passing since a frame from this source has been received. The aging functionality ensures that the address table is not filled up with information that is no longer relevant. The default aging time is 300 s; however, it can be set to as low as 10 s.

The MAC relay entity has (at least) the following functions:

1. Store-and-forward functionality for Ethernet frames
2. Address learning (based on source MAC address)
  - a. Unknown destination addresses are normally broadcasted
3. Frame filtering (based on destination MAC addresses)

Furthermore, the MAC relay entity has several address tables:

1. Unicast MAC address table
  - a. Port versus MAC address relationships
2. Multicast MAC address table
  - a. Port versus MAC address relationships

There are some mandatory entries in the address tables. A certain type of multicast MAC addresses should never be forwarded by the MAC entity. These are multicast MAC addresses in the range 01-80-C2-00-00-00 to 01-80-C2-00-00-0F. These addresses shall be put into a permanent database and shall always be present. Incoming frames with these addresses as destination addresses shall thus never be forwarded by the switch. Such frames are normally associated with HLEs (will be described next) and will be transferred to this part of the switch by the MAC port entity. These frames will only pass into the MAC relay entity if the switch does not support the HLE (protocol) associated with this MAC multicast address. The *never forward* MAC multicast addresses then ensure that such frames are not passed on to any other switch. The logic behind this is that protocols using such MAC multicast addresses as the destination address should only go from one switch to the next (and not do multiple hops) as they are concerned with switch-to-switch information exchange. Transmitting such frames further would lead to confusion by network management tools or degradation in functionality related to, for example, redundancy or synchronization. It should also be noted that frames with these multicast MAC addresses as destination addresses will also pass through so-called blocked ports. Port blocking is discussed later in the availability section of this chapter.

To summarize, the MAC relay entity performs the following functions related to the filtering database:

1. Permanent configuration of reserved addresses
2. Explicit configuration of static filtering information
3. Automatic learning of dynamic filtering information for unicast destination addresses through observation of source addresses of network traffic
4. Aging out of dynamic filtering information that has been learned
5. Automatic addition and removal of dynamic filtering information as a result of Multiple MAC Registration Protocol (MMRP) action

The MAC relay entity then handles all traffic according to the information in the filtering database.

#### 16.4.2.3 Higher Layer Entities

IEEE 802.1D actually requires that at least one HLE be always present, namely, the Rapid Spanning Tree Protocol (RSTP) entity. The RSTP protocol ensures that there are no logical loops in any network as these can lead to forever circulating traffic and network breakdown. RSTP is discussed in more detail later in this chapter.

### 16.5 Networking Protocols

---

A modern Ethernet-based network is a combination of basic switching functionality and a set of network management-related protocols. These network management protocols handle crucial functionality in the system such as network redundancy [6], time synchronization, and handling of multicast and VLAN traffic. A network without such network management protocols will only transport data between publishers and receivers in a very simplistic manner and will not be very robust against errors (hardware errors or user errors). There will also be no additional features such as time synchronization. Thus, a modern switched Ethernet network used in automation has a range of protocols in addition to the application-specific protocols (handling the process-related communication). This part describes protocol adding crucial functionality needed in automation systems; however, there are numerous other technologies that are also highly relevant.

#### 16.5.1 Redundancy

As mentioned earlier, availability is an important requirement in many automation systems. The addition of communication redundancy is a common and important means to achieve higher system availability. This section will discuss communication redundancy solutions applicable for automation networks. Redundancy protocols are used to create fault tolerant networks. There are two principal types of network redundancy solutions:

1. Alternate path operation
  - There are parallel paths between devices, but only one path is active.
  - The alternate path is activated if the primary path fails.
  - Some recovery time is needed, typically 10–200 ms.
  - Examples: RSTP and Media Redundancy Protocol (MRP).
2. Parallel path operation
  - There are parallel paths between devices that are used concurrently.
  - Packet duplication.
  - No packet loss in case of a single failure.
  - Requires special HW and/or SW support in the end nodes.
  - Examples: Parallel Redundancy Protocol (PRP) and High-Availability Seamless Redundancy (HSR).

The type of redundancy protocol to use is determined by the requirements of the control application. The main requirement is that a network failure shall not cause loss of the ability to control or protect the process. Industrial requirements on communication are typically expressed in terms of the recovery time: The recovery time equals the time it takes to detect an error after communication has been lost plus the time needed to reconfigure the network to reestablish communication. For solutions based on simultaneous, parallel communication, the recovery time is zero for a single network failure.

The network recovery time is included in the system recovery time, which is the maximum allowable time the system can be down or nonfunctional, either partly or fully. It is important to realize that the network recovery time typically must be significantly lower than the system recovery time for the system to fulfill the availability requirements.

Industrial requirements on recovery time typically range from seconds down to milliseconds. In some special cases, there may be requirements on zero recovery time; that is, the communication has to be functioning at all time. The requirements often assume that only one failure occurs at any given time. This means that a requirement on zero recovery time typically leads to a need for duplicated communication along two independent paths.

It is worth mentioning that network redundancy is only one part of system redundancy measures. When the availability requirements are sufficiently tough, there may be a need to also have duplicated nodes or fully duplicated systems.

### 16.5.1.1 Spanning Tree Protocol

Before continuing, it is worth taking a short look at the history of network redundancy on Ethernet-based networks. Physical loops were a big problem in the early times of Ethernet usage. Setting up networks with hubs and simple, unmanaged switches could easily lead to physical loops resulting in a situation where broadcasts would circulate forever, rapidly overloading networks into a total crash. The only way to avoid this was through careful manual installation.

It is in practice difficult to avoid loops in medium-to-large-sized networks so the STP was invented to take care of this. STP turns any complex physical network into a logical tree; thus, there is only one available path between any two nodes although several physical paths may exist. STP avoids loops in a network by blocking the traffic on some links (some network management-related traffic still pass through blocked links as mentioned previously). The STP protocol has means to detect a failure of an active path (i.e., a link or a switch) and will, in this case, activate a backup or redundant path so that the nodes can communicate with each other again. With STP, it became possible to design networks with deliberate physical loops to provide communication redundancy.

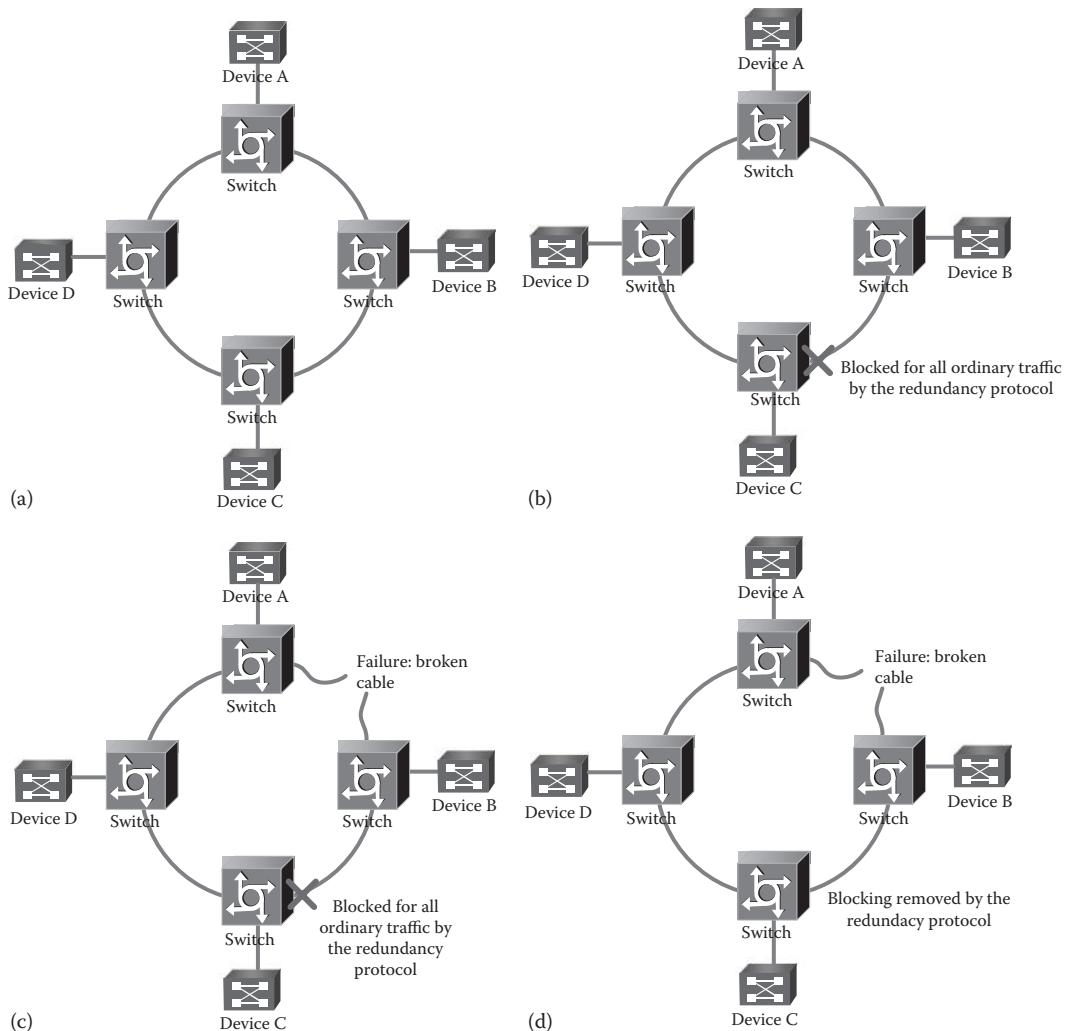

STP was specified in IEEE 802.1D editions prior to 2004. STP is based on time-outs to discover failures in a network, that is, to check that special test packets arrive within a certain amount of time. These time-outs are fairly large, and in practice, the recovery time using STP is typically around 30 s.

RSTP is an evolution of STP, which significantly decreases the network recovery time. In RSTP, recovery is no longer based on the time-outs found in STP but includes a set of new features to achieve lower recovery times. In RSTP, a failure/recovery detection mechanism is utilized, a handshaking mechanism to rapidly agree on new ports states has been included, and the edge port concept for switch ports connected to end nodes (nodes without switching capabilities) in the network has been introduced. These mechanisms mean that recovery is very much faster than in STP. With RSTP, the recovery time may be approximately 1 s, although considerably faster in some cases.

### 16.5.1.2 Other Redundancy Solutions for Industrial Networks

Proprietary network redundancy solutions exist in many flavors, but solutions based on the ring topology are popular in industrial networks used in areas such as process automation. Figure 16.2 shows how a ring topology network running a network redundancy protocol typically handles a cable failure.

Typically every switch manufacturer has its own ring redundancy protocol with quite similar working principles, features, and performance. This presents a problem to the industry due to incompatibility

**FIGURE 16.2** Ring topology network. (a) Initial network with no blocked ports, (b) the redundancy protocol has blocked a port to avoid a logical loop, but all nodes can still communicate with each other, (c) a failure occurs so that switch B cannot communicate with the other switches, and (d) the redundancy protocol removes the blocking, and all nodes can again communicate with each other.

of switches from different vendors. The ring redundancy protocols are usually, to a great extent, based on the features found in RSTP but with optimizations to get deterministic network recovery times. Ring redundancy protocols provide deterministic recovery times ranging from approximately ten to hundreds of milliseconds.

The IEC 62439 High Availability Automation Networks standard suite has recently been developed to offer standardized network redundancy solutions targeting industrial requirements. This standard currently contains the following variants:

- IEC 62439-1 describes an implementation guideline for RSTP used in ring topologies. This results in typical recovery times of 5 ms multiplied by the number of switches in the ring.
- IEC 62439-2 describes MRP, which is a ring redundancy protocol. MRP provides recovery times of 10, 30, 200, and 500 ms for rings with up to 50 devices (only 14 devices for 10 ms recovery time).

- IEC 62439-3 describes PRP and HSR. PRP and HSR provide seamless (0 ms) redundancy for some specific cases (parallel, unconnected networks or ring-shaped networks, both with frame duplication and duplicate removal in the end nodes).
- IEC 62439-4 specifies Cross-Network Redundancy Protocol (CRP), a redundancy solution for duplicated, interconnected networks. CRP offers recovery times of 1 s or somewhat lower.
- IEC 62439-5 specifies Beacon Redundancy Protocol (BRP), a redundancy solution for duplicated networks. BRP provides recovery times of a few milliseconds and upward in duplicated networks, which are interconnected at one place (and with special beacon end nodes on both sides of the interconnection).
- IEC 62439-6 specifies Distributed Redundancy Protocol (DRP), which is a ring redundancy solution. DRP offers recovery times below 100 ms in most situations.

There are several interesting technologies on the long list of nonstandardized redundancy solutions, but the discussion on these is outside the scope of this document.

When it comes to RSTP, current implementations are typically nondeterministic or at least not very fast. Implementations done according to IEC 62439-1 offer deterministic recovery times, but mixing the two types of implementations leads to unpredictable behavior and should be avoided. The IEC 62439-1 RSTP guideline indicates a recovery time of 5 ms per switch for ring networks, but actual implementations may be faster or slower.

The MRP protocol offers recovery times down to 10 ms for a limited number of devices and higher recovery times for up to 50 devices in a ring.

### 16.5.2 Quality of Service

QoS on Ethernet is referring to methods to prioritize traffic through the network to reduce latency and jitter for certain types of traffic, that is, to ensure that high priority packets are not delayed by lower-priority packets queued up in a switch [7]. The IEEE 802.1Q [8] Class of Service (CoS) mechanism allows traffic prioritization on Layer 2 Ethernet. There are eight priority levels, 0–7:

- 7—highest priority (network control, e.g., RSTP packets)
- ...
- 1—lowest priority (background)
- 0—default priority (best effort)

A managed switch can assign packets to priority levels by inspecting Layer 2 information in the packet. The value of the priority code point (PCP) field of the VLAN tag in an Ethernet frame maps directly to the CoS priority level. Untagged frames are assigned the port default priority at egress. The priority level can also be set by the end nodes by adding a VLAN tag or a just a priority tag (VLAN ID = 0).

A managed switch usually has four or more priority queues (e.g., critical, high, normal, and background) allowing the scheduling of packets at egress. The mapping of the CoS priorities to the internal priority levels is configurable on the switch. There are different scheduling algorithms applied, for example, strict priority, weighted fair queuing, and weighted round robin. Some managed switches can also use Layer 3 information, the differentiated services code point (DSCP) information in IPv4 and IPv6 headers, to map to the internal priority levels.

### 16.5.3 Multicast and VLAN Handling

Multicasting means simultaneously sending the same packet to multiple receivers. On an Ethernet network, this is done by using a group or multicast MAC address as the destination address of the Ethernet frame. The network (e.g., the switches) will then distribute the multicast frames to the appropriate devices based on the information in the switch filtering database (a process called multicast filtering).

For unknown multicast MAC addresses (or in switches without support for multicast filtering), this leads to broadcasting of the Ethernet frame on all ports (similar to the handling of unknown unicast MAC addresses).

### 16.5.3.1 Multicast

Multicasting comes in two flavors, either as MAC (Layer 2) multicasts or as IP (Layer 3) multicasts. MAC multicast frames have a group or multicast MAC address as the destination address of the frame. An IP multicast frame, in addition, has an IP group or multicast address as the destination IP address in the IP header of the frame. For IP multicast frames, the MAC multicast address is calculated from the IP multicast address. However, it should be noted that this is not a one-to-one relationship as there are 32 IP multicast addresses per MAC multicast address.

In the simplest scenario, the multicast filtering is set up manually; that is, the switch MAC address database is configured manually (with multicast address–port relationships). This is called static multicast filtering and may work well in small systems but is difficult to manage in larger networks. In addition to being error prone, manual configurations need to be changed when devices are moved, added, or removed; otherwise, the communication may be disrupted.

In modern networks, most of the multicast filtering is handled by a protocol, a process called dynamic multicast filtering. In this way, a device lets the network switches know what multicast addresses it wants to listen to (i.e., what traffic it wants to receive). This is based on the information the device has about available multicast addresses [9].

For MAC multicasts, the associated protocol is the MMRP which is part of a protocol suite that uses the Multiple Registration Protocol framework. The framework defines various mechanisms (e.g., state machines) for common, proper, and robust parameter registration, whereas MMRP is a protocol that defines the actual parameters and their semantics. The problem is that not all managed switches support the MMRP standard. Industrial switches now start to have support for the MMRP standard.

Most managed switches support a feature called Internet Group Management Protocol (IGMP) snooping. IGMP is a standard specifying how a host can register with a router in order to receive specific IP multicast traffic. IGMP snooping is a feature supported in many switches, facilitating IP multicast filtering for bandwidth optimization. Although IGMP is not a Layer 2 technology, it is still important to have support for it in a switch to configure the filtering behavior of the IP multicast frames; otherwise, IP multicasts may be handled as broadcasts.

It should be noted that IGMP is used only by IPv4 and not by IPv6. In IPv6, another protocol, Multicast Listener Discovery (MLD), which is embedded in ICMPv6, does this task. MLD is used by an IPv6 router to discover the presence of multicast listeners on directly attached links and to discover which multicast addresses are of interest to neighboring nodes.

Layer 2 multicasting is used by protocols like PROFINET, PTP, IEC 61850-8-1 GOOSE, and IEC 61850-9-2 Process Bus, whereas Layer 3 multicasting is used in protocols like FF HSE, Ethernet/IP, and IEEE PTP (PTP may use either Layer 2 or Layer 3 multicasting).

### 16.5.3.2 Virtual Local Area Network

VLAN technology, specified in IEEE 802.1Q [8], is used to separate logical segments of a network, which operate on the same physical network. VLANs offer complete and secure isolation of the network traffic on Layer 2.

The fundamental principle of VLANs is to limit the broadcast domain. This means that each domain has its own filtering database in the switch, and Ethernet broadcast frames cannot cross domains. The concept of VLANs is realized by tagging each Ethernet frame with a standardized tag. This tag contains the VLAN number a frame belongs to. In a switch, each port is a member of one or more VLANs. When a frame with a specific VLAN tag and a destination address appears, the address is looked up

in the filtering database of the VLAN specified by the tag. Note that an end device will work in the same way. The Ethernet port of an end device can also be the member of one or more VLANs, and the frames will be handled differently depending on which VLAN they belong to. An untagged frame will always be assigned to the port default VLAN when entering the switch. The frame will also be assigned the port default priority. The ports used for inter-switch links are normally members of all VLANs. These are often called trunk ports. Frames sent out on a trunk port carry the VLAN tag to specify the VLAN membership.

The VLAN concept increases the complexity of loop-prevention technologies such as RSTP. Since the various VLAN domains are separated, an RSTP instance must run in every domain. Multiple Spanning Tree Protocol (MSTP) has therefore been created to accommodate networks consisting of more than one VLAN.

There are two VLAN configuration techniques. The first technique is to set up VLANs manually; that is, a switch port is assigned to a VLAN. Ingress packets will then normally be tagged with the correct VLAN tag. Only egress packets with the correct VLAN tag will be allowed on the port. This is called static VLAN configuration and is normally used when end devices cannot handle VLANs and VLAN tagging.

In networks where the end devices actively take part in the VLAN configuration and handling, the technique of dynamic VLAN configuration can be used. VLAN configuration is then handled by a protocol called Multiple VLAN Registration Protocol (MVRP) to register and deregister the membership of a VLAN. MVRP is also a protocol using the MRP framework and defines the VLAN-related parameters and their semantics.

### 16.5.3.3 Multicasting and VLAN Issues in Automation

Flooding of broadcast, unregistered multicast, and unknown unicast messages, causing the devices to receive unwanted messages originating from other protocols, could be a big problem when different protocols coexist on the same physical network if not managed in a proper way.

First of all, this is a concern when applying protocols that use multicast messages

- IEC 61850 GOOSE (L2 multicast)
- FF HSE (L3 multicast)
- EtherNet/IP (L3 multicast)

All devices connected to the LAN would receive all the multicast messages. A typical automation device is usually not designed to handle this kind of traffic, and would potentially not be able to perform its assigned task.

Secondly, an erroneous device might generate a lot of unwanted messages that could disturb all other devices on the network. This can be managed by applying VLAN separation.

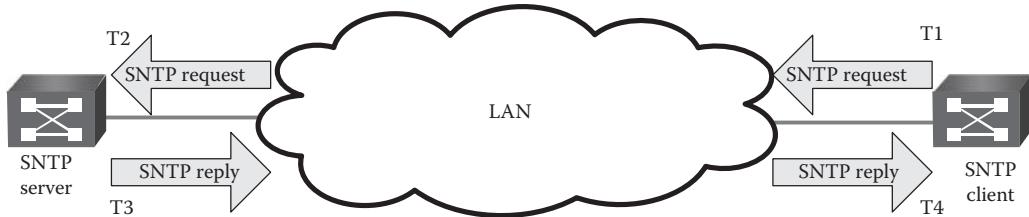

## 16.5.4 Time Synchronization

### 16.5.4.1 Why Is Time Synchronization Important?

Time synchronization is an important requirement in many automation systems. Time synchronization can be solved by using a dedicated signal line with a common clock signal (e.g., pulse per second [PPS]) between the nodes, but this requires additional cabling and hardware in the nodes and is not very feasible for anything but the simplest of systems. The standard approach is therefore to have synchronized clocks in the nodes and run a protocol on the network that enables the synchronization of these clocks [10].

### 16.5.5 Simple Network Time Protocol

There are two relevant standard protocols for clock synchronization across an Ethernet-based network—Simple Network Time Protocol (SNTP) and Precision Time Protocol (PTP—IEEE 1588). SNTP is based on Network Time Protocol (NTP) but is, as the name indicates, a simplified version

**FIGURE 16.3** The request–reply working principle of SNTP.

**TABLE 16.1** Timestamps Used by SNTP

Timestamp Name	ID	When Generated
Originate timestamp	T1	Time request sent by client
Receive timestamp	T2	Time request received by server
Transmit timestamp	T3	Time reply sent by server
Destination timestamp	T4	Time reply received by client

of it. SNTP clients periodically calculate the offset between itself and an SNTP server and adjust their local clocks accordingly. The offset can be calculated with the help of four timestamp values as indicated in Figure 16.3.

The timestamps needed are given in Table 16.1.

The roundtrip delay  $d$  and local clock offset  $t$  are defined as

$$d = (T4 - T1) - (T2 - T3) \text{ and } t = ([T2 - T1] + [T3 - T4])/2.$$

As can be seen from these equations, an SNTP client assumes that the delays are symmetrical in both directions. This is only valid in very simple situations, and thus, the accuracy that can be achieved is limited. SNTP synchronization can be done every 16 s or slower; thus, the drift of the local clock (i.e., the drift of the clock crystals) may be significant during this time if not properly compensated for. The typical synchronization accuracy that can be achieved with SNTP is in the milliseconds range for moderately sized networks. There are numerous SNTP (NTP) time servers on the Internet, and it is normally possible to synchronize a local clock to such a server to an accuracy in the tens of milliseconds range (SNTP is an IP-based protocol).

### 16.5.6 Precision Time Protocol

PTP is using a somewhat different method to synchronize local clocks across a network. PTP has several operating modes. The two most important modes are the following:

1. A hierarchical setup with ordinary clocks and boundary clocks. A boundary clock may typically be a switch that is a clock slave of a clock master on one port and a clock master to all connected devices on all other ports. An end node normally has an ordinary clock that can be either a master clock or a slave clock.
2. A setup where network switches have transparent clocks and the end nodes have ordinary clocks (being either a clock master or a clock slave). The transparent clock's primary mission is to add the residence time of the PTP packets inside the device to a data field inside the packets.

PTP clock masters periodically distribute sync messages containing the transmit time. These may be timestamped accurately in hardware at the clock master, or a follow-up packet containing the accurate

transmit time from the clock master is sent. These packets (sync and possibly the follow-up) propagate across the network to the slave clock. For accurate synchronization, it is necessary to timestamp the receive time in hardware. Transparent clocks add the accurate residence time so that the slave clocks are able to accurately determine the time that has passed since the master clock timestamp. In this way, it is possible to compensate for the drift between the clock master and the slaves. The offset is similarly compensated for with the addition of a request-response packet exchange initiated from the clock slaves (Delay\_request and Delay\_response).

The accuracy of a simple, software-only implementation of PTP may be similar to what can be achieved with SNTP, but PTP has some advantages for automation systems. A main advantage is that there are many hardware components (e.g., CPUs, FPGAs, MACs, PHYs, switch silicon) that come with hardware support for accurate timestamping of PTP packets. This means that PTP can accurately determine the amount of time spent for synchronization packets across a network. This feature enables very accurate time synchronization across a network and can also compensate for asymmetric delays. A PTP-compliant network can be synchronized down to an accuracy of better than 1  $\mu$ s with the assistance of hardware support in all network nodes. Accuracies in the nanoseconds range may even be possible for the most advanced implementations.

It is important to note that while SNTP and PTP can provide the means to synchronize clocks across networks, they do not specify how to update the local clocks. Without taking special care, the result may be that the local clocks of the devices demonstrate significant jumps. As an example, the clock of a device may jump back in time, and the same action may be taken several times. If a clock jumps ahead in time, there is a risk that actions are lost. Thus, it is important to handle the clock update process with care. This is normally handled by implementing some sort of a filtering mechanism so that the clock only adjusts its speed relative to clock master; that is, the clock is only changed in small steps and never back in time.

PTP networks are self-configuring; that is, the devices themselves set up the clock relationships between master clocks and slave clocks. Built-in redundancy ensures that if one clock source fails, then another one will take over. PTP comes as either an Ethernet-based (L2) protocol or an IP-based (L3) protocol. There are many more relevant details of PTP, but these are outside the scope here.

PTP is well established as the time synchronization standard of the future in many domains (both industrial and others) and is already extensively used and fully accepted in industrial networks. Many communication technologies have specified how to use PTP. PROFINET is recommending the usage of IEEE 802.1AS, which is a flavor of PTP. Furthermore, there is a PTP profile called C37.238 developed for usage in IEC 61850 systems.

## 16.6 Future Outlook

---

This chapter has described the key functionality of state-of-the-art automation systems. However, there is continuous development ongoing and therefore no trivial thing to foresee what the future will bring. Perhaps the clearest trend is the move from systems using fieldbuses, proprietary communication solutions, and simple Ethernet communication toward automation systems that are advanced Ethernet-based networks with a wide range of functionality as described in this chapter. There is every reason to believe that Ethernet will take over most of the communication in automation systems in the near future. These Ethernet-based networks will be combined with wireless communication for those few applications that need it (e.g., mobility or applications where it is difficult to install cables). Special solutions such as EtherCAT will also be a part of future systems to handle both the most demanding deterministic applications and systems with a large number of IO devices. This will result in a scalability, flexibility, robustness, and richness of functionality far superior to previous solutions. This will also presumably enable completely new applications and functionality.

It is likely that the number of network management protocols in use in automation systems will increase significantly in the years to come. This, in most cases, means that existing technologies used in other domains (e.g., telecom and data centers) will enter the industrial domain.

There are ongoing changes also to many of the network management-related protocols. PTP is currently in the process of being updated, and the communication profiles for automation systems will be revamped to better fit modern communication networks. RSTP (and most other current network redundancy protocols) provides network redundancy, but it is not using the network in a very efficient manner as only one path is used at any given time. The SPB [2] technology is circumventing this by enabling the use of many paths at the same time. This is mainly developed for load balancing in data centers and similar applications but may also offer the opportunity to have parallel communication in automation networks (thus enabling zero recovery time for communication). There is also a somewhat similar approach called Transparent Interconnection of Lots of Links (TRILL).

Security has not been a topic of this chapter, but automation systems will implement an increasing amount of functionality related to secure communication. Similarly, within the area of safe communication, we will see communication networks completely replacing hardwired signals.

Automation systems are clearly in the middle of a paradigm shift with the transition toward fully Ethernet-based networks with advanced networking functionality. Exactly where this development will go remains to be seen, but there are, for sure, both exciting and challenging times ahead. The winners will be the companies that can utilize modern communication technologies in an optimal way to create superior systems.

### 17.1 Introduction

International fieldbus standardization has always been a difficult endeavor. After a timely start in 1985 and a few enthusiastic years of development, the quest for the one and only comprehensive international fieldbus gradually became entangled in a web of company politics and marketing interests [1]. What followed was a protracted struggle inside CENELEC<sup>\*</sup> and IEC<sup>†</sup> committees that finally ended up in the complete abandonment of the original idea. Instead of a single fieldbus, a collection of established systems was standardized. In Europe, CENELEC adopted a series of multivolume standards compiled from the specifications of proven fieldbus systems. On a worldwide scale, IEC defined a matrix of protocol modules, so-called *types* [2], together with guidelines as to how to combine the various modules into actually working fieldbus specifications [3]. With the adoption of the IEC 61158 standard [2] on the memorable date of December 31, 2000, the fieldbus war seemed to be settled just in time for the new millennium.

At the same time, in the office world, we see the penetration of the networks based on Ethernet and Transmission Control Protocol (TCP)/Internet Protocol (IP). The costs of the network infrastructure in the office world are steadily going down, and it is becoming possible to connect almost anything with everything, anywhere, with the help of the Internet technology. But in the field of automation technology, dedicated fieldbuses are used. The only barrier to access devices in the field of the automation world, from the Internet over a network connection, are the fieldbuses. Therefore, the question is why is it not possible to use Ethernet also in the automation technology?

The adoption of the Ethernet technology for industrial communication between controllers, and even for communication with field devices, supports direct Internet capability in the field area, for instance,

---

† IEC = International Electrotechnical Commission, see [www.iec.ch](http://www.iec.ch).

remote user interfaces via web browser. But it would be unacceptable if the adoption of the Ethernet technology would cause loss of features required in the field area, namely,

- Time deterministic communication
- Time-synchronized actions between field devices such as drives
- Efficient and frequent exchange of very small data records

An implicit but essential requirement is that the office Ethernet communication capability is fully retained so that the entire communication software involved remains usable.

This results in the following requirements:

- Support for migration of the office Ethernet to real-time Ethernet (RTE); the definition is given in the following.
- The use of standard components: bridges, Ethernet controllers, and protocol stacks as far as possible.

To achieve the required higher quality of data transmission with limited jitter and disturbances due to TCP/IP data traffic, it may be necessary to develop further network components. In short, the RTE is a fieldbus specification that uses Ethernet for the lower two layers.

As a matter of fact, neither industrial RTE devices can be as cheap as in the office world (limited by the scale of industrial deployment) nor can plain Ethernet be applied to control applications demanding some sort of hard real-time (RT) behavior; for details of the argument, see [4]. To cope with these limitations, many research projects proposed solutions for the introduction of quality of service, modifications to packet processing in switches, or synchronization between devices.

The IEC/SC65C\* committee, in addition to the maintenance of the international fieldbus and its profile, finished a standardization project and defined additional aspects of RTE. And as in the case of the fieldbus, there are several competing solutions and their proponents represented.

This paper will give an outline of this new document and the requirements specified for the RTE standardization. All solutions in this standard able to handle RT requirements will be presented with their key technical features.

## 17.2 Structure of the IEC Standardization

---

All industrial protocols are defined in IEC 61158 [2]. This document is structured according to the Open System Interface (OSI) reference model in seven parts, as shown in Table 17.1. Inside parts 2–6, all networks are identified by types. So there exist 24 different types of networks in six different parts.

In the IEC 61784 standard, different sets of profiles are collected as listed in Table 17.2. In IEC 61784-1 [3], the profile sets for continuous and discrete manufacturing relative to fieldbus use in industrial control systems are defined. Inside this first profile, some versions based on Ethernet technology are also defined. In the second standard IEC 61784-2 [5], additional profiles for ISO/IEC 8802-3 (Ethernet)-based communication networks in RT applications are defined. To identify all these profile, a classification with communication profile families (CPF) according to Table 17.3 is introduced. Every CPF is free to define a set of communication profiles (CPs). The complete set of CPs and the related types are listed in Table 17.4.

Additional profiles listed in Table 17.2 cover functional safe communications, secure communications, or installation profiles for communication networks. These profiles are also separated according to the same CPF but are not discussed any further in this chapter.

---

\* International Electrotechnical Commission (IEC) is organized in Technical Committees (TC) and Subcommittees (SC), TC65 deals with Industrial-Process Measurement and Control and SC65C with Digital Communication and has the scope to prepare standards on Digital Data Communications subsystems for industrial-process measurement and control as well as on instrumentation systems used for research, development, and testing purposes.

## 17.3 Real-Time Requirements

---

The users of an RTE network have different requirements for different applications. These requirements are defined in [5] as performance indicators (PIs). A list of PIs defines the requirements for a class of applications. Every PI has its limits or ranges, and there exists interdependence between these PIs. Every CP has to define which PIs it fulfills in what conditions.

### 17.3.1 User Application Requirements

The users of an RTE network have different requirements for different applications. One possible classification structure could be based on the delivery time:

- A low-speed class for *human control* with delivery times around 100 ms. This timing requirement is typical for the case of humans involved in the system observation (10 pictures per second can already be seen as a low-quality movie), for engineering, and for process monitoring. Most processes in process automation and building control fall into this class. This requirement may be fulfilled with a standard system with TCP/IP communication channel without many problems.
- In the second class, for *process control*, the requirement is a delivery time below 10 ms. This is a requirement for most tooling machine control system like PLCs or PC-based control. To reach this timing behavior, special effort has to be taken in the RTE equipment: Powerful and expensive computer resources are needed to handle the TCP/IP protocol in RT, or the protocol stack must be simplified and reduced to get these reaction times on simple and cheap resources.
- The third and most demanding class is imposed by the requirements of *motion control*: To synchronize several axes over a network, a cycle time less than 1 ms is needed with a jitter of not more than 1  $\mu$ s. This can only be reached with Ethernet network with a minimal bit rate of 100 Mbit/s, if both protocol medium access and hardware structure are modified.

### 17.3.2 Performance Indicators of the IEC Standard

The following PIs are defined in the CPs for RTE (IEC 61784-2):

- Delivery time
- Number of RTE end-stations
- Basic network topology
- Number of switches between RTE end-stations
- Throughput RTE
- Non-RTE bandwidth
- Time synchronization accuracy
- Non-time-based synchronization accuracy
- Redundancy recovery time

*Delivery time* is the time needed to convey a service data unit (SDU, message payload) from one node (source) to another node (destination). The delivery time is measured at the application layer interface. The maximum delivery time shall be stated for the two cases of no transmission errors and one lost frame with recovery.

The *number of RTE end-stations* states the maximum number of RTE end-stations supported by a CP.

The *basic network topology* supported by a CP comprises the topologies listed in Table 17.5, or as a combination of these topologies.

The *number of switches between RTE end-stations* supported by a CP defines the possible network layout and is also an important indicator.

The *throughput RTE* is the total amount of application data by octet length on one link received per second.

**TABLE 17.5** Possible RTE Topologies

Basic Network Topologie	CP
Hierarchical star	CP m/1
Ring (loop)	CP m/2
Daisy chain	CP m/3

*Note:* A real topology could be any combination of the three basic topologies.

*Non-RTE bandwidth* is the percentage of bandwidth, which can be used for non-RTE communication on one link.

*Time synchronization accuracy* shall indicate the maximum deviation between any two nodes' clocks.

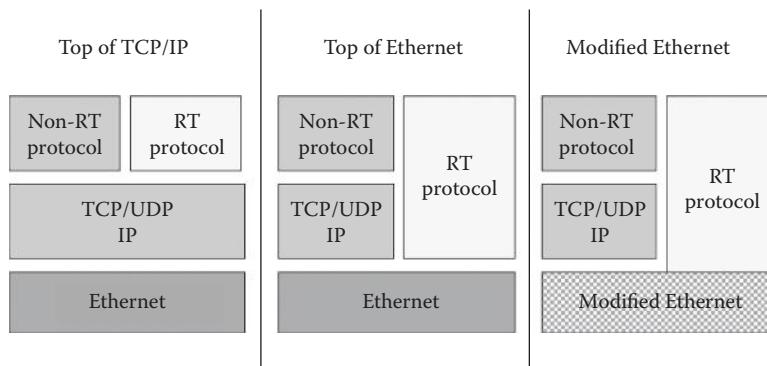

*Non-time-based synchronization accuracy* indicates the maximum jitter of the cyclic behavior of any two nodes, triggered by periodic events over the network for establishing cyclic behavior.

*Redundancy recovery time* indicates the maximum time from a single permanent failure to the network becoming fully operational again. In this case of a permanent failure, the delivery time of a message is replaced by the redundancy recovery time.

## 17.4 Practical Realizations

Standard Ethernet is not able to reach the requirements of the RTE. There exist different propositions to modify the Ethernet technology by the research community [4]. The market has adopted also additional technical solutions. All the solutions included in the standardization are presented here in a short description.

Communication interfaces are structured in different layers. In Figure 17.1, a simplified structure of a communication protocol is described. Common to all Ethernet network is the universal cabling infrastructure. Non-real-time (NRT) applications make use of the Ethernet protocols as defined in ISO 8802-3, and the TCP/User Datagram Protocol (UDP)/IP protocol suite. They use typical IP like, for example, hypertext transfer protocol (HTTP) or file transfer protocol (FTP) for the NRT applications. To build an RTE solution, there are, in principle, three different approaches as shown in Figure 17.1. The first is to keep the TCP/UDP/IP protocols unchanged and concentrate all RT modification in the top layer; here, this solution is called "on top of TCP/IP." In the second approach, the TCP/UDP/IP protocols are bypassed, and the Ethernet functionality is accessed directly ("on top of Ethernet"); in the third approach, the Ethernet mechanism and infrastructure itself are modified to ensure RT performance (modified Ethernet).

**FIGURE 17.1** Possible structures for RT Ethernet.

### 17.4.1 Realization of the “On Top of TCP/IP” Protocols

Several RTE solutions use the TCP/UDP/IP protocol stack without any modification. With this protocol stack, it is possible to communicate over network boundaries transparently, also through routers. Therefore, it is possible to build automation networks reaching almost every point of the world in the same way as the Internet technology. However, the handling of this communication protocol stack requires reasonable resources in processing power and memory and introduces nondeterministic delays in the communication.

In the international standard IEC 61784-2 [5], all CPs have to list also at least one typical set of PIs as defined in the standard. This allows the end user an easier selection of an appropriate network for his application.

#### 17.4.1.1 Modbus/TCP (Profile 15/1 and 15/2)

*Modbus/TCP*, defined by Schneider Electric, uses the well-known MODBUS\* over a TCP/IP network [7], using port 502, and defined as profile 15/1. This is probably one of the most widely used Ethernet solutions in industrial applications today and fulfills the requirements of the lowest class of applications, which we called human control.

MODBUS is a request/reply protocol (send a request frame and get back a reply frame) and offers services specified by function codes to read or write data objects. These data objects can be discrete inputs, coils,<sup>†</sup> input registers, or holding registers. In fact, this protocol is very simple, and the actual definition must be extended with service definitions for the integration in international standards.

In addition to the historical MODBUS protocol, new RT extensions have been defined as profile 15/2. These RT extensions use the real-time publisher subscriber (RTPS) protocol [8]. The RTPS protocol provides two main communication models: the publish–subscribe protocol, which transfers data from publishers to subscribers, and the composite state transfer (CST) protocol, which transfers state information from a writer to a reader.

In the CTS protocol, a CTS writer publishes state information as a variable (VAR), which is subscribed by the CTS readers. The user data transmitted in the RTPS protocol from the publisher to one or several subscribers are called an issue. The attributes of the publication service object describe the contents (the topic), the type of the issue, and the quality (e.g., time interval) of the stream of issues that are published on the network. A subscriber defines a minimum separation time between two consecutive issues. It defines the maximum rate at which the subscription is prepared to receive the issues. The persistence indicates how long the issue is valid. The strength is the precedence of the issue sent by the publication. Strength and persistence allow the receiver to arbitrate if issues are received from several matching publications. Publication relation may be best effort (as fast as possible but not faster than the minimum separation), or strict. In the case of the strict publisher–subscriber relation, the timing is ensured with a heartbeat message sent from the publisher to the subscriber (exact timing is middleware-dependent) and a replied acknowledge message. The RTPS protocol is designed to run over an unreliable transport such as UDP/IP, and a message is the contents (payload) of exactly one UDP/IP datagram.

In the standard, any concrete indication for the values for the PIs is missing. They depend very strongly on the performance and implementation of the UDP/IP communication stack. So it is not possible to define an implementation-independent message delivery time, for instance.

\* Industrial de facto standard since 1979.

<sup>†</sup> In MODBUS, for the representation of binary values, the term coil is used. This is originating from the ladder-logic where the coil of a relay is used to store binary information.

### 17.4.1.2 EtherNet/IP (Profile 2/2 and 2/2.1)

EtherNet/IP,\* defined by Rockwell and supported by the Open DeviceNet Vendor Association (ODVA)<sup>†</sup> and ControlNet International,<sup>‡</sup> makes use of the common interface protocol (CIP), which is common to the following networks: EtherNet/IP, ControlNet, and DeviceNet [9].

The EtherNet/IP communication technology, standardized in IEC 61784-1 as profile 2/2 (using type 2 specifications in IEC 61158), already provides ISO/IEC 8802-3-based RT communication. In full-duplex switched Ethernet, there is no possibility to get delays due to collisions. But in the switching device, Ethernet frames may be delayed, if an output port is busy with the transmission of an Ethernet frame. This may lead to nondeterministic delays, which are not suitable for RT applications. To reduce these delays, a priority mechanism is defined in IEEE 802.3, which allows the sender of a frame to assign a priority to an Ethernet frame. A VLAN<sup>§</sup> tag is added into the Ethernet frame containing a VLAN-ID and a priority level 0–7 of the message. The Ethernet/IP RT messages get the highest priority and are transmitted by the switches before other NRT frames, which results in better accuracy for the RT constraints.

In the CIPsync extensions, the clocks of the devices are synchronized with the IEEE 1588 [10] protocol (accuracy of 0.5 µs). The only problem is that delays may be introduced in the software protocol stack. Based on this time synchronization, the actions in the distributed system are executed based on the planned timing; for example, a device sets its outputs to a defined value not based on the moment a message is received, but on the scheduled time. With this principle, the timing of the application is independent of the delay introduced in the communication network and relies only on the accuracy of the time synchronization. This is defined as profile 2/2.1. When these guidelines are strictly applied, EtherNet/IP is an RT solution usable even for the most demanding classes of applications—compare the range of values in Table 17.6—but it is still not deterministic as a communication network.

CIP defines objects<sup>¶</sup> to transport control-oriented data associated with input/output (I/O) devices and other information that are related to the system being controlled, such as configuration parameters and diagnostics. The CIP communication objects and application objects are grouped in classes. Profiles for different types of applications define the objects to be implemented and their relations.

**TABLE 17.6** Performance Indicators for Ethernet/IP

Performance Indicator	Profile 2/2	Profile 2/2.1
Delivery time	130 µs–20.4 ms	130–190 µs
Number of end-stations	2–1024	2–90
Number of switches between end-stations	1–1024	1–4
Throughput RTE	0–3.44 M octets/s	0–3.44 M octets/s
Non-RTE bandwidth	0%–100%	0%–100%

### 17.4.1.3 P-NET (Profile 4/3)

The P-NET on IP specification has been proposed by the Danish national committee and is designed for use in an IP-environment as profile 4/3. P-NET on IP enables the use of P-NET (type 4 in IEC 61158) RT communication wrapped into UDP/IP packages.

P-NET packages can be routed through IP networks in exactly the same way as they can be routed through non-IP networks. Routing can be through any type of P-NET network and in any order.

A P-NET frame has always two P-NET-route elements constructed as a table of destination and source addresses. In the simple case of a fieldbus solution, these two addresses are the node addresses of the fieldbus network. To allow routing over IP-based networks, these P-NET-route tables are now extended to include also IP addresses in the P-NET-route element. For a fieldbus-based P-NET node, these IP addresses are just another format of addresses. This means that any P-NET client can access servers on an IP-network without knowing anything about IP addresses.

In fact, the P-NET on IP specification just defines how the existing P-NET package is tunneled over UDP/IP networks without any special measures to ensure RT behavior on the Ethernet network. The PIs are listed in Table 17.7.

### 17.4.1.4 Vnet/IP (Profile 10/1)

Vnet/IP\* has been developed by Yokogawa and is included in the IEC document as profile 10/1. The Vnet/IP protocol uses standard TCP/IP protocols for the integration of HTTP or other IPs over the network and special RT extension protocols called Real-time & Reliable Datagram Protocol (RTP).

The Vnet/IP is in fact not an RTE protocol. It just uses the UDP/IP protocol suite to transport the RTP application protocol. No special measures are taken to get a deterministic or even RT behavior. A Vnet/IP network consists of one or more domains connected to each other by routers. The IP unicast and multicast addresses are used as addresses of the data link protocol, and queued communication relations are used.

The minimum cycle time of scheduling of RT traffic is 10 ms, which fulfills the application class of process control. This specification does not cover the limiting of other traffic using the available bandwidth, for example, HTTP or TCP transfer on the same network, which could slow down the RT behavior. The PIs as indicated in the IEC standard are listed in Table 17.8.

At the application layer, different objects like VARs, events, regions, time and network, and the corresponding services are defined. As an example, the VAR object may be accessed over client-server relations with read or write services or publisher-subscriber relations with push or pull mode of operation. In the pull model, the publisher distributes the VAR data periodically by multicasting as requested by a remote subscriber. In the push model, the request is generated locally by the publisher itself.

## 17.4.2 Realization of the “On Top of Ethernet”

These RTE realizations do not alter the Ethernet communication hardware in any way but are realized by specifying a special protocol type (Ethertype) in the Ethernet frame. The standard protocol type for IP is Ethertype = 0x0800. These RTE protocols do use, besides the standard IP protocol stack, their own protocol stack identified with their own protocol type. Table 17.9 lists the different values assigned to this Ethertype for these protocols.

### 17.4.2.1 Ethernet Powerlink (Profile 13/1)

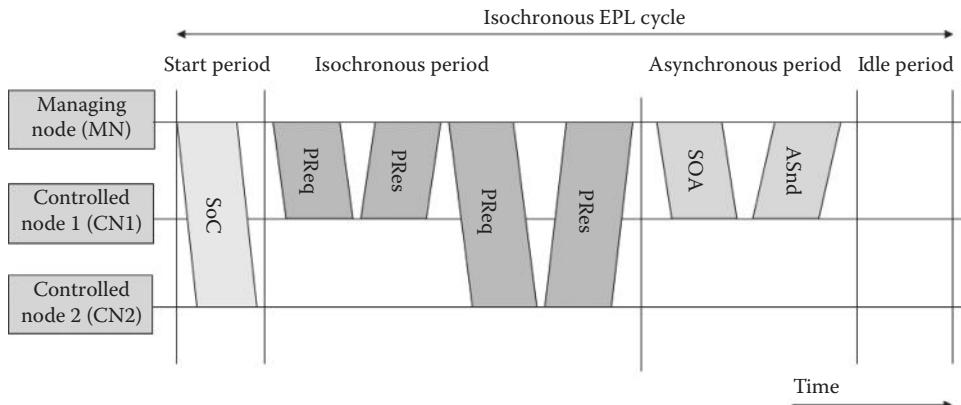

*Ethernet Powerlink (EPL)* was defined by Bernecker + Rainer (B&R) and is now supported by the Ethernet Powerlink Standardisation Group (EPSG).\*

It is based on the principle of using a master–slave scheduling system on a shared Ethernet segment called slot communication network management (SCNM). The master, called managing node (MN), ensures RT access to the cyclic data and lets NRT TCP/IP frame pass through only in time slots reserved for this purpose. All other nodes are called controlled nodes (CN) and are only allowed to send on request by the MN. The MN sends a multicast Start-of-Cycle (SoC) frame to signal the beginning of a cycle. The send and receive time of this frame is the basis for the common timing of all the nodes. It is important to keep the start time of an EPL cycle as exact (jitter-free) as possible. The following time

**TABLE 17.9** Protocol Types for Different RTE Profiles Defined in IEC 61784

**FIGURE 17.2** Ethernet Powerlink timing.

periods exist within one cycle: start period, isochronous<sup>\*</sup> period, asynchronous<sup>†</sup> period, and an additional idle period. The length of individual periods can vary within the preset period of an EPL cycle. In the isochronous period of the cycle, a Poll-Request (PReq) frame is sent unicast to every configured and active node. The accessed node responds with a multicast Poll-Response (Pres) frame. In the asynchronous period of the cycle, access to the EPL network segment may be granted to one CN or to the MN for the transfer of a single asynchronous message only. The preferred protocol for asynchronous messages is UDP/IP. The Start-of-Asynchronous (SoA) frame is the first frame in the asynchronous period and is a signal for all CNs that all isochronous data have been exchanged during the isochronous period (compare also Figure 17.2). Thus, transmission of isochronous and asynchronous data will never interfere, and precise communication timing is guaranteed.

An EPL network is a *protected Ethernet* defined with one controller acting as the MN and several field devices implemented as CNs. In order to protect the SCNM access mechanism of the MN, non-EPL nodes are not permitted within the *protected Ethernet* itself, as they would corrupt the SCNM access mechanism.

Messages exchanged between the MNs of different *protected Ethernet* segments are synchronized based on distributed clock. With the IEEE 1588 [10] protocol, in every MN, a clock is synchronized, and the messages between the different networks are sent based on the synchronized time in the MNs. The MN includes the routing functionality, including the IP address translation from the network to the outside world. With this synchronization mechanism, RTE communication is also possible among different networks. PIs for a small- and a large-size automation system within a *protected Ethernet* are listed in Table 17.10.

The application layer of the EPL is taken from the CANopen standards provided by the CAN in Automation<sup>‡</sup> (CiA) organization [11]. CANopen standards define widely deployed CPs, device profiles, and application profiles. Integration of EPL with CANopen combines profiles, high-performance data exchange, and open, transparent communication with TCP/UDP/IP protocols. These CANopen profiles define process data objects (PDOs) to control the physical process and service data objects (SDOs), which are used to define the behavior of the device as parameters or configuration data. The PDOs are transmitted with the isochronous EPL communication, and the SDOs are transmitted with the UDP/IP protocol. Based on this CP, a variety of CANopen device profiles can be used in an EPL environment without changes.

\* From Latin for iso = the same and chronous = time based, so communication at the same time interval.

† Asynchronous is without any synchronization to a reference.

‡ See [www.can-cia.org](http://www.can-cia.org).

#### 17.4.2.2 TCnet (Profile 11/1)

Time-critical Control Network (TCnet) is a proposal from Toshiba. Like EPL, the TCnet interface goes between the physical and data link layers; the standard MAC\* access CSMA/CD† of Ethernet is modified.

In this proposal, there exists a high-speed-transmission period composed of an RT (in TCnet called *time-critical*) cyclic data service and an asynchronous (in TCnet called *sporadic*) message data service. The time-critical cyclic data service is a connection-oriented buffer transfer‡ on preestablished point-to-multipoint connections on the same local link separated by routers, whereas the sporadic message services are unacknowledged messages on an extended link allowed to go through routers.

At the start of the high-speed-transmission period, a special SYN message is broadcasted to all RTE-TCnet nodes. After receiving the SYN-Frame, the node with the number 1 starts sending its data frames as planned during the system configuration. After completion of the transmission of its data frames, it broadcasts a frame called Completed Message (see CMP1 in Figure 17.3). Node  $n$  upon receiving the CMP ( $n - 1$ ) Completed Message can send out its own data frames. Each node can hold the transmission

**FIGURE 17.3** TCnet timing.

\* MAC = media access control.

† CSMA/CD = carrier sense multiple access with collision detection.

‡ In a buffered transfer, a new message overwrites the old value of the previous message in the receiving buffer. This is in contrast to the (standard) queued transfer; where the messages are kept in the receiver in the same order they are sent. Buffered transfer is more suited for control applications than queued: the control application is interested in the actual buffered value and not in the sequence of values.

**TABLE 17.11** Performance Indicators for TCnet

Performance Indicator	Profile 11/1 <sup>a</sup>	Profile 11/1 <sup>b</sup>
Delivery time	2 ms/20 ms/200 ms	2 ms/20 ms/200 ms
Number of end-stations	24	13
Number of switches between end-stations	0 (3 repeaters)	0 (5 repeaters)
Throughput RTE	7.3/6.4/0.9 M octets/s	5.7/5.1/0.6 M octets/s
Non-RTE bandwidth	0%	<20%
Time synchronization accuracy	—	—
Non-time-based synchronization accuracy	<10 µs	<10 µs
Redundancy recovery time	0 s	0 ms

<sup>a</sup> With no non-RTE bandwidth.

<sup>b</sup> With allocated non-RTE bandwidth.

right for a preset time and must transfer the transmission right to the next node within this time. The node holding the transmission right can send cyclic data and sporadic messages. The cyclic data transmission is divided into high-, medium-, and low-speed cyclic data transmission. Each node sends at least the high-speed cyclic data when it receives the transmission right. The other, lower priority, data are sent only depending on the circumstances. Thus, the cycle time for the high-speed cycle is the cycle of the SYN frame, and the cycle time of the medium-speed or low-speed cyclic data is a multiple of the SYN frame cycle.

TCnet is able to handle redundant transmission media. The RTE-TCnet stack manages the selection of two redundant inputs of received frames and two outputs to two redundant transmission media. In the case of collision on one of the mediums, the transmission is continued on the other. The RTE-TCnet accepts the first incoming frame without transmission error from one of the redundant transmission media. This is the reason why in Table 17.11 the recovery time is set to 0.

The RTE-TCnet application layer service defines the common memory system. The common memory is a virtual memory shared over the RTE-TCnet network by the participating application processes running on each node. The common memory is divided into numbers of blocks with different sizes. One node is the publisher of a block of data and broadcasts this data block to all the others by means of cyclic data service. Each node receives the data block as a subscriber and updates its local copy of the common memory. By this means, each controller can quickly access each other's data by accessing its local copy of the common memory.

#### 17.4.2.3 EPA (Profile 14/1 and 14/2)

The EPA\* protocol (Ethernet for plant automation) profile 14 is a Chinese proposal.

It is a distributed approach to realize deterministic communication based on a time slicing mechanism inside the MAC layer. The time to complete a communication procedure is called communication macrocycle and marked as T. Figure 17.4 illustrates that each communication macrocycle (T) is divided into two phases, periodic message transferring phase (Tp) and nonperiodic message transferring phase (Tn). The last part of each device's periodic message contains a nonperiodic message announcement, which indicates whether the device also has a nonperiodic message to transmit or not. Once the Tp is completed, the Tn begins. All devices that announced (during the periodic message transfer phase) that they have a nonperiodic message to send are allowed to transmit their nonperiodic messages in this phase. Two sets of consistent PIs are listed in Table 17.12.

\* EPA is the trade name of ZHEJIANG SUPCON CO. LTD.

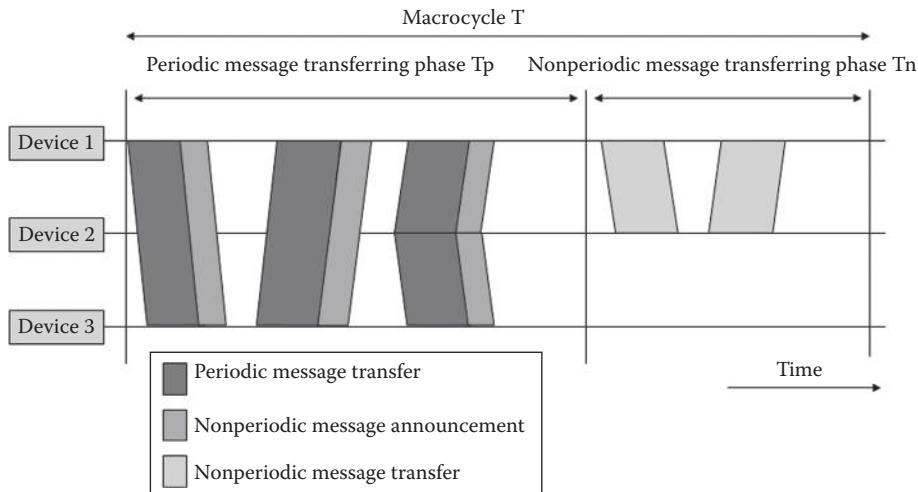

FIGURE 17.4 EPA timing.

TABLE 17.12 Performance Indicators for EPA

Performance Indicator	Profile 14/1	Profile 14/2
Delivery time	5 ms	100 µs
Number of end-stations	32	64
Number of switches between end-stations	4	4
Throughput RTE	1.536 M octets/s	1.536 M octets/s
Non-RTE bandwidth	85%	85%
Time synchronization accuracy	<10 µs	<1 µs
Non-time-based synchronization accuracy	—	—
Redundancy recovery time	<300 ms	<300 ms

In EPA systems, there are two kinds of application processes, EPA function block\* application processes and NRT application processes, which may run in parallel in one EPA system. NRT application processes are those based on regular Ethernet and TCP/IP. The interoperation between two function blocks is modeled as connecting the I/O parameters between two function blocks using EPA application services.

#### 17.4.2.4 PROFINET CBA (Profile 3/3)

PROFINET is defined by several manufacturers (including Siemens) and supported by PROFIBUS International† [12]. The first version was based on component-based automation (CBA) and is included in IEC 61784-1 (type 10 in IEC 61158) as profile 3/3.

The mechanical, electrical, and functional elements of an automation device are grouped together into components. Components have inputs and outputs. The values of the input and output VARs of

\* A function block is an algorithm with its own associated static memory. Function blocks can be instantiated with another copy of the function block's memory. Function blocks are only accessed via input and output variables.

† See [www.profibus.org](http://www.profibus.org).

the components are transmitted over the standard TCP/IP connection using the RPC\* and DCOM† protocol from the office world.

With this RPC and DCOM protocol, it is possible to reach cycle times for what we call the human control application class. If cycle times of less than 100 ms are required, the RT protocol is used. The RT protocol is based on a special Ethertype (see Table 17.9) and frame prioritization (see explanation in the section about Ethernet/IP). In this case, the TCP/IP stack is bypassed, and cycle times of less than 10 ms become possible.

With PROFINET CBA, the end user defines his automation components with the traditional programming and configuration tool for programming logic controller (PLC). These components are represented by one controller in a machine, a fieldbus network, or any device on the fieldbus itself. For the planning of the installation, logical connections between the different components are defined. These connections specify the data type and the cycle time of the transmission. The supported RT or NRT protocols by the components define the possible cycle time, which can be selected in the planning. As PROFIBUS CBA is defined in the first part of IEC61784, there are no PIs published.

### 17.4.3 Realizations of the “Modified Ethernet”

Typical cabling topology of Ethernet is the star topology: all devices are connected to a central switching device. With the introduction of the fieldbuses over 10 years ago in the automation applications, this star topology was replaced by bus or ring topologies to reduce the cabling cost. Likewise, the RTE solutions should allow for bus or ring topologies with reduced cabling effort. To permit this daisy-chained bus topology with switched Ethernet, a switch is needed in every connected device.

Most solutions providing hard RT services are based on modifications in the hardware of the device or the network infrastructure (switch or bridge). To allow cabling according to the bus or ring topology and to avoid the star topology, the switching functionality is integrated inside the field device. The modifications are mandatory for all devices inside the RT segment but allow non-RTE traffic to be transmitted without modifications.

#### 17.4.3.1 SERCOS (Profile 16/3)

The former IEC 61491 [13] standard SERCOS‡ is well known for its CNC§ control optical ring interface. This standard is now split into an application part and a communication part [5]; the communication part is integrated into the IEC 61158/IEC 61784 set. The SERCOS standard is extended to feature an Ethernet-based solution with the name SERCOS III [14] as profile 16/3.

In a SERCOS system, there is always a master station as a controlling device, and one or up to 254 slave devices as axis controllers each with two Ethernet ports. The basic network topology can be either a daisy chain (line structure) or a ring (ring structure). General use switches are not permitted between any two participants. Only the free port of the last slave in a line structure may be connected to a switch if required by the configuration, for example, for communication with devices via TCP/IP or UDP/UDP.

SERCOS III communication consists of two different logical communication channels: the RT channel and the IP channel.

The communication cycle is initiated by the master and consists of up to four master data telegrams (MDTs) and up to four device telegrams (ATs¶) in the RT channel and the IP channel. MDTs are transmitted by the master and received by each slave (see Figure 17.5). They contain synchronization

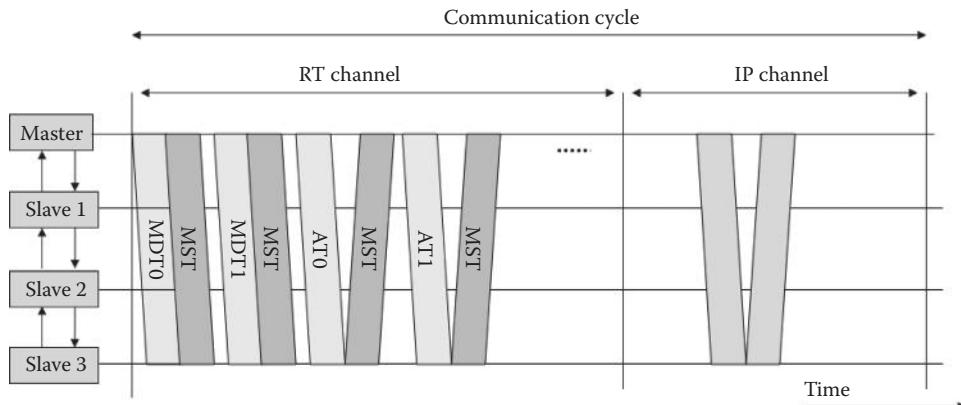

\* A remote procedure call (RPC) is a protocol that allows a computer program running on one host to cause code to be executed on another host without the programmer needing to explicitly code for this (source: wikipedia.org).

† Distributed Component Object Model (DCOM) is a Microsoft proprietary technology for software components distributed across several networked computers (source: wikipedia.org).

‡ SERCOS stands for SEriell Real time COnnection System Interface, see also [www.sercos.org](http://www.sercos.org).

§ CNC stands for computer(ized) numerical(ly) control(ed).

¶ Abbreviated from: device (acknowledge) telegram as AT for historical reasons.

**FIGURE 17.5** SERCOS timing.

information and a data record for each slave containing control information, service channel data, and command values sent from the master to the slaves. The ATs are transmitted by the master as an empty frame with predefined fields but without information. Each slave inserts its data into data fields allocated to it in the ATs. Within their data fields in the telegram, the slaves transmit status information, service channel data, and actual values to the master and to other slaves.

The number and the lengths of the RT data telegrams (MDT and AT) are fixed according to a configuration that is also determined during the initialization.

IP telegrams are standard, NRT IP telegrams that can be used for any purpose, and even be omitted. The IP channel length has a fixed duration and determines the maximum number of IP telegrams that can be sent during this duration.

This sequence of transmitting synchronization, RT data telegrams, and IP telegrams is repeated every communication cycle. Defined values for a communication cycle are 31.25, 62.5, 125, 250 µs and integer multiples of 250 µs up to 65,000 µs. The time slots for the RT channel, the IP channel, and the transmission time of the AT are transmitted during initialization and are therefore known to each slave. In every device, a special software, or for a higher performance, an FPGA,\* will be needed, which separates the RT channel from the IP channel. PIs for two typical setups are listed in Table 17.13.

The application model of SERCOS is based on the drive model<sup>†</sup> with a cyclic data exchange. This exchange includes status and actual values transmitted from the drive to the controller, and commands and set-points from the controller to the drive. The functionality of the drive device is determined by setting different parameters in the model.

#### 17.4.3.2 EtherCAT (Profile 12/1 and 12/2)

EtherCAT<sup>\*</sup> defined by Beckhoff and supported by the EtherCat Technology Group<sup>§</sup> (ETG) uses the Ethernet frames and sends them in a special ring topology [15].

Medium access control employs the master/slave principle, where the master node (typically the control system) sends the Ethernet frames to the slave nodes, which extract data from and insert data into these frames.

From an Ethernet point of view, an EtherCAT segment is a single Ethernet device, which receives and sends standard ISO/IEC 8802-3 Ethernet frames. However, this Ethernet device is not limited to a single

\* FPGA = field-programmable gate array, a gate array is a prefabricated circuit, with transistors and standard logic gates.

<sup>†</sup> A drive model consists of a controller and one or several drives (e.g., motors, servos).

<sup>‡</sup> EtherCAT™ is the registered trade name of Beckhoff, Verl.

<sup>§</sup> See also [www.ethercat.org](http://www.ethercat.org).

Non-time-based synchronization accuracy	<1 µs	<50 µs
Redundancy recovery time	0	0

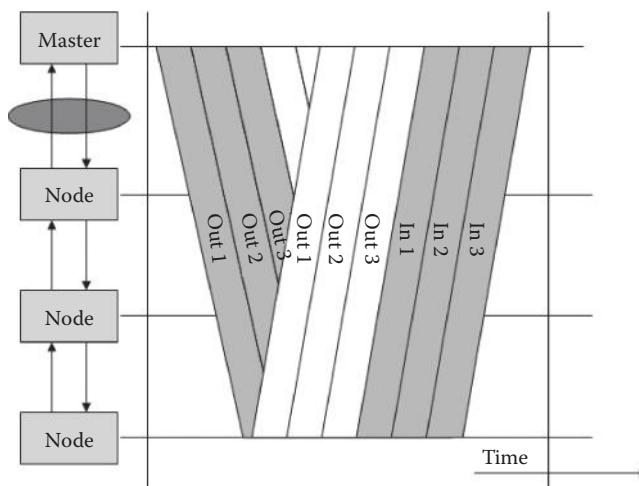

<sup>a</sup> Scenario with minimum cycle time and high-performance synchronization.

<sup>b</sup> Scenario with non-RTE bandwidth and low-performance synchronization.

Ethernet controller with a downstream microprocessor but may consist of a large number of EtherCAT slave devices. These devices process the incoming frames directly and extract the relevant user data, or insert data and transfer the frame to the next EtherCAT slave device. The last EtherCAT slave device within the segment sends the fully processed frame back so that it is returned by the first slave device to the master as the response frame.

The EtherCAT slave node arrangement represents an open ring bus. The controller is connected to one of the open ends, either directly to the device or via Ethernet switches utilizing the full duplex capabilities of Ethernet; the resulting topology is a physical line (see Figure 17.6). All frames are relayed from the first node to the next ones. The last node returns the telegram back to the first node, via the nodes in between.

In order to achieve maximum performance, the Ethernet frames should be processed “on the fly.” This means that the node processes and relays the message to the next node in the line as the message is being received, rather than the other (slower) option of waiting until the message is fully received. If the “on the fly” method of processing is implemented, the slave node recognizes relevant commands and executes them accordingly while the frames are passed on to the next node. To realize such a node, a special ASIC\* is needed for medium access, which integrates a two-port switch into the actual device.

**FIGURE 17.6** EtherCAT timing.

\* Application-specific integrated circuit.

**TABLE 17.14** Performance Indicators for EtherCAT

Performance Indicator	Profile 12/1	Profile 12/2
Delivery time	<150 µs	<519 µs
Number of end-stations	180	650
Number of switches between end-stations	NA	NA
Throughput RTE	10.75 M octets/s	10.5 M octets/s
Non-RTE bandwidth	50.6%	55.9%
Time synchronization accuracy	—	≤1 µs
Non-time-based synchronization accuracy	10 µs	10 µs
Redundancy recovery time	60 µs	200 µs

The nodes have an addressable memory that can be accessed with read or write services, either each node consecutively or several nodes simultaneously. Several EtherCAT telegrams can be embedded within an Ethernet frame, each telegram addressing a data section.\* The EtherCAT telegrams are either transported directly in the data area of the Ethernet frame or within the data section of a UDP datagram transported via IP. The first variant is limited to one Ethernet subnet, since associated frames are not relayed by routers. For machine control applications, this usually does not represent a constraint. Multiple EtherCAT segments can be connected to one or several switches. The Ethernet MAC address of the first node within the segment is used for addressing the EtherCAT segment. The second variant via UDP/IP generates a slightly larger overhead (IP and UDP header), but for less time-critical applications, such as building automation, it allows using IP routing. On the master side, any standard UDP/IP implementation can be used on the EtherCAT devices.

For messages, a mailbox mechanism with read and write services is used; for process data output and input, buffered data services are defined.

The performance of the EtherCAT system (when configured to run “on the fly”) may reach cycle times of 30 µs if no standard (non-RTE) traffic is added. The maximum transmission unit (MTU) of Ethernet with 1514 bytes corresponding to approximately 125 µs at 100 MBd in the non-RTE phase would enlarge the EtherCAT cycle. Two examples of consistent sets of PIs are shown in Table 17.14. But in EtherCAT, Ethernet telegrams are divided into pieces and reassembled at the destination node, before being relayed as complete Ethernet telegrams to the device connected to the node (see Figure 17.6). This procedure does not restrict the achievable cycle time, since the size of the fragments can be optimized according to the available bandwidth (EtherCAT instead of IP fragmentation). This method permits any EtherCAT device to participate in the normal Ethernet traffic and still have a cycle time for RTE with less than 100 µs.

Similar to EPL, EtherCAT uses the CANopen application layer. The PDOs are mapped to the input and output buffer transfer, which is the same as what is used for EPL. The SDOs, however, are mapped to the mailbox messaging mechanism, rather than the IP protocol, which EPL uses.

#### 17.4.3.3 PROFINET IO (Profile 3/4, 3/5, 3/6)

PROFINET is defined by several manufacturers (including Siemens) and supported by PROFIBUS International† [16]. A second step after the PROFINET CBA definition was the definition of an application model for PROFINET IO based on the well-proven PROFIBUS DP (type 3 of IEC 61158, profile 3/1). The devices are IO controllers to control IO devices with cyclic, buffered data communication. An IO supervisor is used to manage the IO devices and IO controllers in a system.

The exchange of data between the devices may be in different classes of communication service like isochronous RT (IRT), RT, or NRT. NRT traffic is standard TCP/UDP/IP and may also be PROFIBUS

\* A data section is a set of memory variables (e.g., inputs or outputs).

† See [www.profibus.org](http://www.profibus.org).

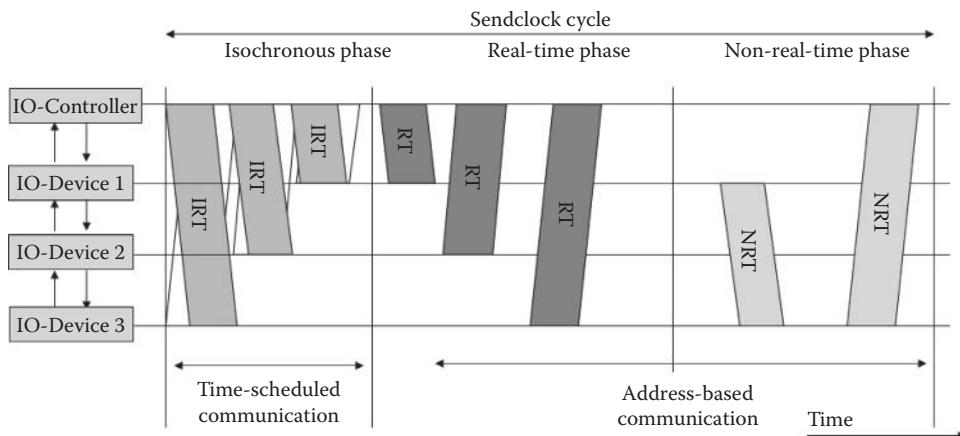

FIGURE 17.7 PROFINET timing.

CBA traffic. In a system with high isochronous cycle requirements, only special PROFINET switching devices are allowed. The Ethernet communication is split into send clock cycles, each with different time phases as presented in Figure 17.7. In the first time phase called isochronous phase, all IRT frames are transmitted. These frames are passed through the switching device without any interpretation of the address information in the Ethernet frame. The switches are set according to a predefined and configured timetable: on every offset time (see Figure 17.7), the planned frame is sent from one port to the other one without interpretation of the address. For even shorter cycle times down to 31.25 µs, these IRT frames are packed in one frame, and every IO device removes its output data and inserts the input data (dynamic frame packing). In the next time phase called RT phase, the switching devices change to address-based communication and behave as standard Ethernet switches. In this addresses-based phases, RT frames are transmitted followed by NRT Ethernet frames (see also Figure 17.7). All PROFINET switching devices are synchronized by means of a modified IEEE 1588 mechanism with “on the fly” stamping [17], to have their cycles and IRT timetables synchronized with 1 µs jitter.

PROFINET CBA and IO do not need any special hardware for RT communication. To ensure good performance, PROFINET IO needs a 100 Mbit/s switched full duplex Ethernet network. For IRT, a special PROFINET-Ethernet switch is needed. It is recommended to integrate this special PROFINET-Ethernet switch in every device to allow all possible Ethernet network topologies as listed in Table 17.15.

The PROFINET specification includes a concept allowing one to integrate existing fieldbuses with proxy devices. A proxy device represents a field device or a fieldbus with several field devices, on the PROFINET network. The user of the PROFINET does not see any difference, if the device is connected to Ethernet or to the fieldbus. This proxy technology is very important to allow for a migration of the

TABLE 17.15 Performance Indicators for PROFINET IO

Performance Indicator	Profile 3/4 and 3/5	Profile 3/6
Delivery time	128 ms	31.25 µs–1 ms
Number of end-stations	60	10–64
Number of switches between end-stations	10	10–63
Throughput RTE	2.324 M octets/s	3.324 M octets/s
Non-RTE bandwidth	23.5%	0%–23.5%

Non-time-based synchronization accuracy	—	—
Redundancy recovery time	<200 ms	0 ms

existing fieldbus installations to new Ethernet solutions with PROFINET. Initially, proxies are defined for INTERBUS (type 8 in IEC 61158) and PROFIBUS (type 3 in IEC 61158), but today, proxies are also defined for DeviceNet, AS-Interface, and other networks in the field.

## 17.5 Summary—Conclusion

---

During the standardization process, there was a long discussion: why is it not possible to reduce the number of technical solutions to three or four RTE profiles? But there was a common understanding from the manufacturers that it is not up to the engineers in the standardization groups to take such decisions. It is agreed that the market should decide which system will be successful in the field. So the problem of selecting a good solution is finally moved to the end user.

This set of standards has been published first in 2007 with 16 different types of networks, was updated in 2010, and will be actualized in 2013 with up to 24 different types of networks. So in fact, the number of different industrial network in the standards is increasing by more than one new network protocol every year. At the moment, there is no upper limit visible for this development.

### 18.1 Introduction

---

Ethernet for Control Automation Technology (EtherCAT) [ETG12] is a high-performance Ethernet-based fieldbus system. The main reason for its development was the adoption of Ethernet in automation applications, where short cycle times and low communication jitters are required. Nowadays, EtherCAT is a popular solution for enabling access to field devices by control applications in industrial environments, including motion-control systems. Communication equipment and devices are available off-the-shelf, which are based on purposely developed hardware [ET1100].

The EtherCAT protocol is an open standard currently managed by the EtherCAT Technology Group (ETG). Its specification has been integrated into the international fieldbus standards IEC 61158 [IE158] and IEC 61784 [IE784]. EtherCAT is based on a master/slave approach and relies on a ring topology at the physical level. Only one master is allowed in the network, and this is suitable, for instance, to connect a control unit (e.g., a programmable logic controller [PLC]) to decentralized peripherals (sensors, actuators, drives, etc.). By using suitable gateways, EtherCAT can interoperate with both conventional Transmission Control Protocol (TCP)/Internet Protocol (IP)-based networks (intranets) and other real-time Ethernet (RTE) solutions, such as EtherNet/IP and/or PROFINET.

The master node is in complete control of the traffic exchanged over the EtherCAT network. In particular, it is the only device that can take the initiative in the communication; hence, it is responsible for initiating all data exchanges with the slaves. Each slave processes the received frame in order to extract/insert data from/into it. Then, the frame is forwarded to the next slave in the ring.

**FIGURE 18.1** EtherCAT typical topology, with the *on-the-fly* frame processing.

Unlike Ethernet switches and bridges, slaves do not manage frames according to a conventional store-and-forward approach, which implies receiving the frame, decoding the related protocol control information, and sending the message out. Every frame, instead, is processed on-the-fly by the slave data link layer. In order to ensure high performance, frame processing and relaying take place at the same time so that these operations have to be carried out in hardware. This explains why specialized components are used for slaves, which are known as EtherCAT slave controllers (ESCs) [ET1100] (Figure 18.1).

## 18.2 Physical Layer

The physical layer of EtherCAT relies on the proven fast Ethernet transmission technology, which enables high data rates that are more than adequate to the communication needs of next-generation industrial plants. A low-cost solution, namely, EBUS, is also foreseen for modular devices, which is able to coexist with conventional Ethernet seamlessly and does not impair performance in any way. Although the use of switches is not recommended to ensure real-time behavior, the EtherCAT network architecture is quite flexible and can also stretch over wide areas.

### 18.2.1 Communication Support

Though EtherCAT is correctly listed among the industrial Ethernet solutions available today, it actually supports two different types of physical layers, namely, Ethernet and EBUS. The first alternative relies on the conventional 100 Mb/s full-duplex Ethernet technology (either 100BaseTX or 100BaseFX), according to the popular IEEE 802.3 standard [8023]. It is typically used for connecting the master to the network segment to which slaves are attached. Indeed, the whole EtherCAT segment (also known as *Type 12 segment*) is seen as a single, large Ethernet device by the master, which *concurrently* receives and sends Ethernet frames by exploiting full-duplex transmissions. However, this *device* does not consist of a single Ethernet controller but includes a (possibly very large) number of EtherCAT slaves connected

so as to form a ring topology. Ethernet is also used to interconnect slave devices, for instance, when they are located in distinct racks or fastened to different mounting rails.

The transmission medium, in this case, consists of a Cat 5 twisted pair (either shielded or unshielded, depending on the amount of electromagnetic interference) although higher category cables are also allowed. Both classic RJ45 (8P8C) and circular M12 D-code connectors can be used.

The Ethernet transceivers (PHYS) needed to interface ESCs to Ethernet have to satisfy a number of requirements in order to be used in EtherCAT. In particular, they must be able to provide either a standard media-independent-interface (MII) or a reduced one (RMII) and have to support the MII management interface, auto-negotiation, and auto-crossover.

Conversely, EBUS can be used only as a backplane bus and is not intended for wire connections. EBUS, in fact, was mainly conceived to interconnect modules in modular devices. It is worth noting that, unlike other fieldbuses that enable a modular design for devices, the sequence of logical bits that EtherCAT transmits over EBUS is exactly the same as for Ethernet. This means that switching from Ethernet to EBUS (and vice versa) can be done quickly, efficiently, and inexpensively (in practice, only transceivers have to be replaced).

EBUS is an inexpensive physical layer that features reduced pass-through delays inside the slaves. Typically, frames experience delays on the order of  $120 \div 500$  ns [PRY08,CEN10] when propagating through EBUS interfaces, whereas longer latencies (about 1  $\mu$ s) are introduced by Ethernet interfaces. EBUS uses the Manchester (biphase L) encoding scheme and marks the start and end of Ethernet frames with a pair of delimiters, namely, the start of frame (SOF) and end of frame (EOF) identifiers. The beginning of a frame is defined by a Manchester code violation with a positive level following an idle condition. A bit at the logical value “1” follows, which is the first bit of the Ethernet preamble. Then, bits of the whole Ethernet frame are transmitted up to the cyclic redundancy check (CRC). The frame ends with a Manchester violation with negative level, followed by a bit at the logical value “0,” which is, in practice, the first bit of the subsequent IDLE phase.

EBUS uses low-voltage differential signaling (LVDS), and the bit rate is selected equal to 100 Mbit/s to match the fast Ethernet specification. The EBUS protocol simply encapsulates Ethernet frames; thus, it can carry any kind of Ethernet message besides EtherCAT.

### 18.2.2 Network Topology

The topology of a communication system is one of the crucial factors for its successful adoption in industrial environments, since it affects a number of key elements such as cabling, diagnostic features, redundancy options, and hot-plug-and-play features. The star topology, commonly used for switched Ethernet, implies significant cabling and infrastructure costs; hence, line or tree topologies are usually preferable in factory networks. Typically, slave devices in EtherCAT segments are connected in linear structures and exploit a daisy chain wiring scheme. Every slave is provided with (at least) two Ethernet ports, to connect downstream and upstream devices. The last slave in the segment performs a loopback function and returns the frame in the opposite direction to the master. The master is the headend of the structure and requires one Ethernet port only.

Each slave relays all frames it receives to the next device in the EtherCAT segment. Because of the daisy chain connection and loopback, all the slaves in the segment form an open ring. The master transmits frames at one of the ends of this open ring and receives them at the other end, after they have been processed by every slave. This means that on the whole the physical topology of an EtherCAT network is actually a ring.

Thanks to the full-duplex capabilities of Ethernet, which uses two pairs of wires housed in the same cable to carry out communications in both directions simultaneously, the resulting topology resembles, nevertheless, a physical line, as in most legacy fieldbuses. The reduction of wiring complexity helps in making the network deployment easier and lowers the installation costs at the same time.

In principle, branches can be introduced anywhere in an EtherCAT segment, by using devices equipped with three or more ports (EtherCAT couplers). This kind of devices are provided, for example,

with two Ethernet ports and one EBUS interface for direct connection of input/output (I/O) modules (also known as EtherCAT terminals) and can be used to enhance the basic line structure setting arbitrarily complex tree networks topologies. It is worth noting that, in this case, every slave device located at the end of a branch has to close the ring on its own using the loopback function.

The maximum number of addressable devices in EtherCAT is quite large, since  $2^{16}$  nodes for each segment are allowed. The limit depends on the data link layer, and in particular on the address field, which is encoded on 16 bits. In the same way, the maximum network extension is usually able to satisfy the requirements of most real applications. The limitation, in this case, is mainly due to the maximum distance allowed between any two adjacent nodes (i.e., the length of the cable), which in turn depends on the underlying transmission support (up to 10 m for EBUS and up to 100 m for Ethernet connections). This means that the whole network size is practically unlimited: in theory, up to  $2^{16}$  devices can be connected in daisy chain using 100 m Ethernet cable segments.

### 18.2.3 Device Architecture

Many asymmetric communication technologies conceived for industrial environments have different internal architectures for masters and slaves, and this is true for EtherCAT devices too.

EtherCAT masters (EMs) rely on standard communication hardware (full-duplex Ethernet network interface controllers) and dedicated software, even though open-source solutions based on Linux-like operating systems are also available. On the contrary, purposely designed hardware components (ESCs) have to be necessarily used for slaves. In order to reduce the implementation costs, frame processing by ESCs occurs in one direction only, which is known as *processing path*. The reverse direction, known as *forwarding path*, is needed to propagate frames in the ring. From a logical point of view, ESCs exhibit an active behavior only on the processing path (frame modifications on the forwarding path are not allowed), but at the physical layer, they behave as repeaters in both directions. Consequently, they are able to regenerate electrical signals so that network equipment like stand-alone repeaters is no longer necessary. This also reduces connection costs and complexity in large installations.

Most ESCs are internally equipped with two or more ports, depending on device complexity. For example, the Beckhoff ET1100 [ET1100] is provided with four separate ports, which can be individually configured to operate as either EBUS or MII. Port 0 is the *upstream* port whereas the others are used for *downstream* connections and to forward signals. Each port implements two functions, called *auto-forwarder* and *loopback*. The auto-forwarder block performs frame checks, such as CRC error detection, at the physical level and manages the error count. It is also responsible for taking timestamps on frame receptions, a mechanism which is needed, for instance, by the clock synchronization protocol. The loopback function, instead, forwards frames to the next logical port if the related link is not available. In this way, the ring is automatically closed in the case of faults affecting either devices or links.

## 18.3 Data Link Layer

---

The data link protocol of EtherCAT was designed to maximize the utilization of the Ethernet bandwidth and to grant a very high communication efficiency. As mentioned earlier, the access mechanism of EtherCAT is based on a master/slave approach, where the master node (typically the control unit, e.g., a PLC) sends Ethernet frames to slave nodes. Slaves, in their turn, either extract data from the frame payload or insert information by overwriting part(s) of the payload itself.

### 18.3.1 Frame Format

Messages sent over the network are standard Ethernet frames, with EtherCAT frames (also known as *Type 12 frames*) encapsulated in the data field. Consequently, they include the conventional fields:

preamble (8 bytes), destination and source MAC addresses (6 bytes each), EtherType (2 bytes, set to 0x88A4 to distinguish them from non-EtherCAT frames), frame check sequence (Fcs, 32 bits), and the interframe gap.

An EtherCAT frame, in turn, contains a frame header (2 bytes) and one or more EtherCAT datagrams, also known as *Type 12 Data Link Protocol Data Units* (DLPDU) according to the data link layer standard specifications. In this way, the large data field made available by conventional Ethernet can be better exploited to increase the communication efficiency. DLPDUs are packed together, one after the other, without intermediate gaps. The payload of the Ethernet frame ends with the last DLPDU, unless its overall size is 63 octets or less. In this case, the frame is padded to 64 octets in length, as required by the Ethernet specifications. The standard Ethernet CRC closes the frame and is used by each device (either master or slave) to check the integrity of the message. Thanks to the EtherType field, EtherCAT can coexist, in theory, with other Ethernet protocols.

Each DLPDU corresponds to a separate EtherCAT command and consists of three sections: header, data, and counter field. Commands are used to perform data exchanges: basically, they are issued by the master for reading or writing specific memory areas in the slave devices.

Ethernet frames, and in particular DLPDUs they embed, are processed in sequence by slaves. Each slave recognizes its commands of interest and executes them while the frames are passing through. Because of the physical ring topology, a frame is returned to the master after being processed by all the slaves. This procedure exploits the full-duplex mode of Ethernet, which means that the two communication directions can work independently.

Several DLPDUs can be embedded in the same Ethernet frame, each one addressing different devices and/or memory areas. As shown in Figure 18.2, DLPDUs are transported either (a) directly in the data field of the Ethernet frame or (b) within the data section of a datagram, by means of the User Datagram Protocol (UDP).

The first variant is limited to a single subnetwork, since Ethernet frames are not relayed by routers. Usually, this is not a limitation at all, for machine control applications. Direct Ethernet encapsulation is by far the most widespread EtherCAT solution at the shop floor of factory automation systems. In theory, multiple EtherCAT segments can be connected to a single master through one or more switches, and the MAC address of the first node in each segment is used for addressing the segment itself. However, this approach can affect the real-time properties of the communication.

On the one hand, the second variant, which relies on UDP and the IP, implies lightly larger overheads (because of the IP and UDP headers) and is also limited by routers, which are typically unable to guarantee a real-time behavior. On the other hand, this solution also enables IP routing; hence, it is suitable for applications having loose timing requirements, such as in process automation. Any standard UDP/IP implementation can be used in this case on the master side.

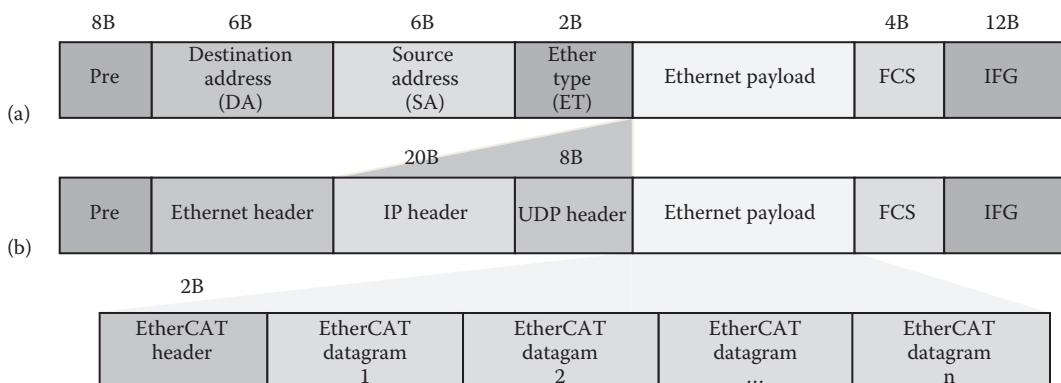

FIGURE 18.2 EtherCAT frame structure.

### 18.3.2 DLPDU Format

As shown in Figure 18.3, each DLPDU consists of a number of fields. The initial fields (up to IRQ included) can be assumed to belong to the header part, which has a fixed size (10 bytes). The variable-sized data area is placed immediately after the header and includes the information to be exchanged, often referred to as *data link service data unit* (DLSDU). The last field in the frame is the *working counter* (WKC), used mainly for checking whether a command has been successfully executed by the relevant slaves.

Table 18.1 summarizes sizes, formats, and meanings of the DLPDU fields.

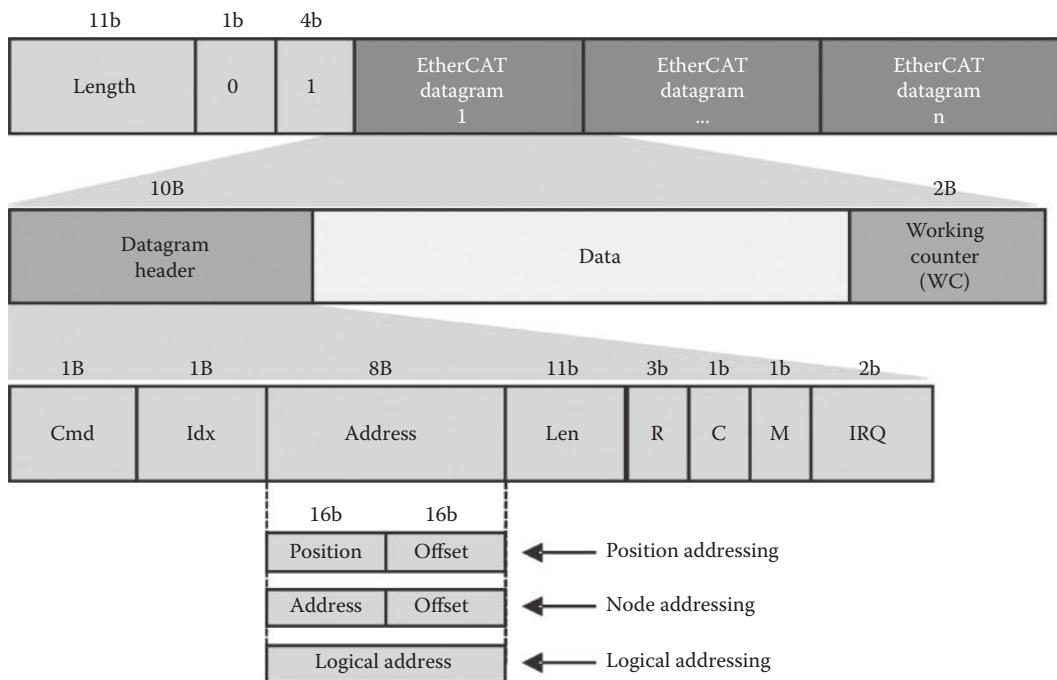

FIGURE 18.3 EtherCAT datagram structure.

TABLE 18.1 Generic Type 12 DLPDU Format

Field	Type	Meaning
CMD	Unsigned8	Service command (0–14, values from 15 to 255 are reserved).
IDX	Unsigned8	Index for identifying duplicate/lost DLPDUs.
Address	DWORD	Address (auto-increment, configured station address, broadcast, or logical address [see below]).
LEN	Unsigned11	Length of the DATA field.
R	Unsigned3	Reserved 0x00.
Circulating frame (C)	Unsigned1	0x00: Frame is not circulating. 0x01: Frame has already circulated once.
NEXT (M)	Unsigned1	0x00: this is the last DLPDU in the EtherCAT frame. 0x01: more DLPDUs follows in the EtherCAT frame.
IRQ	WORD	External Event Request registers of all slaves combined via OR.
DATA	OctetString LEN	Data (DLSDU).
WKC	WORD	Working counter.

The service command (1 byte) is encoded in the CMD parameter. Different types of command exist, which can be used to carry out highly optimized read and write operations on slave devices. Generally speaking, they can be grouped according to the access type:

- *Read* (RD) is used by the master to read memory areas or registers from slave devices.
- *Write* (WR) is used by the master to write to memory areas or registers of slave devices.
- *Read/Write* (RW) is used by the master to carry out both a read and a write operation at the same time; in this case, reading is performed by the slave before writing.
- *Read/Multiple Write* (RMW) is a quite peculiar service, where the addressed slave carries out a read operation while all other slaves are performing a write action.

The IDX field (1 byte) is used by the master to identify a given DLPDU. This is useful, for instance, to pair a frame returned on the forward path with those sent on the processing path, when more frames are allowed to travel along the ring at the same time. This field shall be left unchanged by the slaves.

The address field (4 bytes) can contain different information, encoded as either a single 32 bit double word or two 16 bit words, according to the addressing mode chosen for the DLPDU. A more detailed description is provided in the next section.

The parameter LEN (11 bits) is the size in bytes of the DATA field included in the DLPDU.

The *circulating frame* (C) bit is used to cope with failures of links between slaves. Because of the loop-back function (which forwards Ethernet frames to the next internal port if the current port is neither connected nor available), if a part of the network is cut off from the master, it becomes an insulated ring. If no action is taken, frames that are currently traveling there might continue to circulate. To prevent endless frame circulation, a slave with no active link to the master has to remove frames from the insulated ring according to the following rules:

- If the C bit of the DLPDU is 0, the C bit is set to 1.
- If the C bit of the DLPDU is 1, the frame is not processed but it is destroyed.

The NEXT field (also called Mbit) specifies whether the DLPDU is the last one in the frame or another DLPDU follows.

An important mechanism is implemented through the IRQ field. EtherCAT event requests are used to inform the master of slave events. On each slave, the *External Event* register is combined, using a logical “AND” operation, with a predefined *External Event Mask* register. This mask is used for selecting interrupts that are relevant to the master. The resulting bits are combined with the IRQ field in the incoming DLPDU using a logical “OR” operation, and then written into the IRQ field of the outgoing DLPDU. This implements a quasi-asynchronous event notification mechanism. It is worth noting that, when using the IRQ mechanism, the master is not able to single out what slave(s) originated the interrupt.

Process data that have to be read or written (DLSDU) are placed in the DATA field. When a slave modifies any field in the DLPDU (a quite frequent event), the CRC field has to be recomputed and updated so that it looks correct to the following slaves.

Finally, the WKC field is used as a further error detection mechanism. Basically, it counts the number of devices that were successfully addressed by the DLPDU. Each addressed slave, when reading/writing data to/from the DLPDU, increments the WKC in hardware. In most control applications, each DLPDU has an expected value for WKC, which is known in advance and depends on the number of involved slaves. Therefore, the correctness of datagram processing can be checked by the master by comparing the value of the WKC field in the received DLPDU with the expected value.

WKC is incremented by one in the case at least 1 byte/bit of the data field has been successfully accessed by the slave for read, write, and read/multiple write commands. In the case of read/write commands, instead, WKC is incremented by two for successfully written data and, additionally, by one for a successfully read operation.

### 18.3.3 Addressing

Different addressing modes are supported for accessing information in the slaves, as shown in Figure 18.3. The DLPDU header contains a 32 bit address field, which is used for both *physical* and *logical* addressing.

#### 18.3.3.1 Physical Addressing

In physical addressing, the address field is split into two 16 bit words: the first one, the address position (ADP) encodes the address of a slave device in the EtherCAT segment, while the second, the address offset (ADO) refers to either a physical memory location or a register in the slave device.

This solution enables up to  $2^{16}$  slave devices in the network, each one associated to a local memory as wide as  $2^{16}$  cells. In other words, every slave is assigned its own 64 kB physical address space. The first 4 kB block (address range from 0x0000 to 0x0fff) is used for *registers* and user memory. The remaining space (from address 0x1000 onwards) is the 60 kB *process memory*. Its actual size, however, depends on the specific device considered. The address space of any ESC is directly addressable by both the EM and the attached microcontroller. In physical addressing, each DLPDU refers to a specific memory area (or register) in either a single slave or all slaves at the same time (broadcast). For this reason, this mechanism is mostly suitable for transferring parameterization information to devices.

Basically, slaves can be physically addressed in two different modes, namely, position and node addressing, which rely on the information included in the ADP field. A third mode is also available for dealing with broadcast DLPDUs. In practice, the following alternatives are possible:

- *Position (or auto-increment) addressing*: In this case, each slave device is identified via its physical position in the EtherCAT segment. When processing a DLPDU that makes use of this kind of addressing, each slave increments the ADP field by one. When a DLPDU is received with the ADP field set to 0, the device assumes to be the intended destination. As a consequence, the master has to preset ADP to a negative value that corresponds to the absolute position of the target slave (the first slave, which is next to the master, is conventionally assumed to have position 0). For instance, an initial ADP value equal to -2 identifies the third slave in the segment. Because of the mechanism, which updates the address field while the frame is traversing a device, the DLPDU is said to adopt auto-increment addressing. Position addressing should be used only during the start-up phase to scan the EtherCAT segment and can be adopted occasionally to detect new slaves attached to the segment. This is because problems may arise if some network branches are temporarily closed because of link errors. In this case, in fact, a wrong count could lead to address a wrong slave, possibly disrupting the correct system operations.
- *Configured addressing*: In this case, slave devices are identified by means of node addresses (*configured station address* and *configured station alias*) that are assigned at start-up. This choice grants that, even if the segment topology is changed and/or devices are added to/removed from the network at runtime, every slave can nevertheless be safely accessed through the same predefined address. In this working mode, every slave compares the ADP field in the DLPDU with its own configured address(es). If a match is found, the device is the intended destination. Node addressing is typically used for accessing (already configured) devices individually. Each EtherCAT slave can be assigned a pair of station addresses. Assignment can be done by either the EM (configured station address), during the data link start-up phase, or the application running on the slave (configured station alias), for instance, by reading the address value from an internal nonvolatile memory during the device initialization.
- *Broadcast*: In this case, all slaves in the EtherCAT segment are addressed and shall execute the command encoded in the DLPDU. As for position addressing, the ADP field is incremented by one by each slave during the DLPDU propagation so that the master can eventually obtain the number of slaves that are present in the network. It is worth noting, however, that the ADP field is not checked by slaves in this case. Broadcast addressing is used, for instance, to initialize the same memory area in all slaves with the same value at the same time by means of a single command.

Specific areas in the local memory of the target node(s) are then addressed via the ADO field in the DLPDU. In particular, ADO represents an offset into the physical address space of the device and is useful to access a single block of data starting at a given memory location.

### 18.3.3.2 Logical Addressing

The EtherCAT data link communication services enable the individual addressing of several slaves by means of a single Ethernet frame carrying multiple DLPDUs. The main benefit is a significant improvement of the communication efficiency with respect to conventional solutions where every request (and the related reply) is encoded into a separate frame. The typical Ethernet overhead for frame transmission and protocol control information is quite large, and improvements are surely welcome. However, when dealing with simple devices characterized by very small process data (e.g., for 2 bit digital I/O modules), the overhead introduced by DLPDUs based on physical addressing might be still considered excessive.

This problem can be lessened by adopting the EtherCAT logical addressing mode. In logical addressing, the exchanged information is identified by using the 32 bits in the address field as a whole (ADR). In practice, a logical address space is defined for the EtherCAT segment, which is shared by all devices. When using the logical addressing, the resulting utilization can exceed 90% of the available bandwidth, even when data are exchanged with devices that produce/consume only 2 bits of user data.

Logical addressing requires that slaves include suitable *fieldbus memory management units* (FMMUs), which have to be implemented in hardware in the ESC. An FMMU is similar to memory management unit (MMU) of modern processors and takes care of translating the logical address to a physical address in the device local memory. FMMUs enable individual address mappings for each device.

In contrast to conventional MMUs, which typically map whole memory pages, FMMUs also support bit-wise mapping. This is the reason why, for instance, 2 bits of a specific input device can be mapped individually (and practically anywhere) in the logical address space. If an EtherCAT command is sent to read/write, the logical memory area assigned to the 2 bits (instead of addressing an EtherCAT device explicitly), the FMMU in the related device is able to transfer 2 bits of data from/to the memory and the right position in the payload of the DLPDU. The same happens to other slaves, when they use the logical address within the same DLPDU. Therefore, the combined adoption of FMMUs and logical addressing enables the exchange of data segments that span across several slave devices. As shown in Figure 18.4, a single command is able to address data arbitrarily distributed within several slaves. Clearly, this boosts the communication efficiency significantly.

The access type supported by each FMMU is configurable and can be read, write, or read/write. The configuration of FMMU entities in the slaves is carried out by the master during the data link start-up phase. In particular, the following items are configured for each FMMU to specify how the address translation has to be performed:

- (Bit-oriented) start address in the logical address space
- (Bit-oriented) start address in the device's physical memory
- Size of the translated memory area
- Direction of the mapping (input or output)

When a DLPDU with logical addressing is received, the slave looks for an address match via its FMMU. If any correspondence is found, it transfers data between the local memory position and the data field of the DLPDU.

### 18.3.4 Commands

Generally speaking, EtherCAT commands are obtained by combining an access type (read, write, read/write, or read/multiple write) and an addressing mode (auto-increment, configured, logical, or broadcast). However, not all possible combinations are actually allowed. The legal EtherCAT commands are listed in Table 18.2.

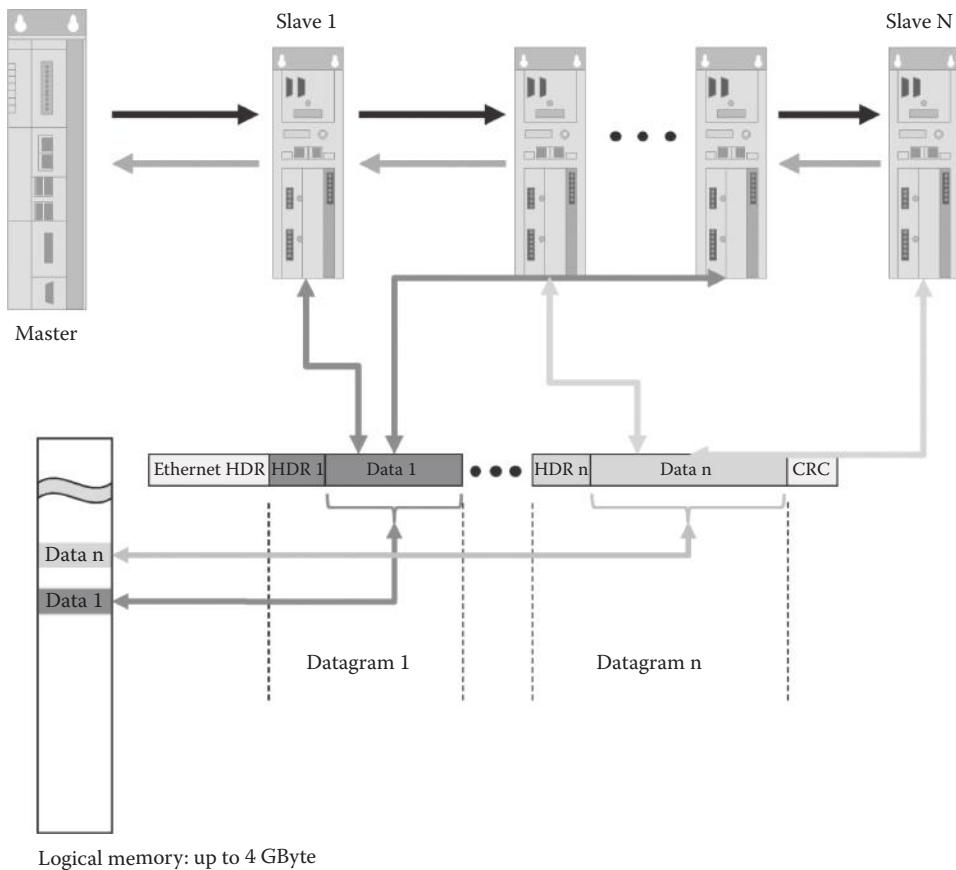

FIGURE 18.4 FMMU mapping example.

TABLE 18.2 EtherCAT Commands

Access Type	Command	CMD	Encoding
Read	Auto-increment physical read	APRD	1
	Configured-address physical read	FPRD	4
	Broadcast read	BRD	7
	Logical read	LRD	10
Write	Auto-increment physical write	APWR	2
	Configured-address physical write	FPWR	5
	Broadcast write	BWR	8
	Logical write	LWR	11
Read/Write	Auto-increment physical read/write	APRW	3
	Configured-address physical read/write	FPRW	6
	Broadcast read/write	BRW	9
	Logical read/write	LRW	12
Read/Multiple Write	Auto-increment physical read/multiple write	ARMW	13
	Configured-address physical read/multiple write	FRMW	14

Read commands (APRD, FPRD) are used to extract information at the specified (ADO) offset in the memory of the slave(s) addressed by ADP and to copy it in the data field of the DLPDU, which will eventually reach the master. Write commands (APWR, FPWR) carry out data exchanges in the opposite direction, while read/write commands (APRW, FPRW) are used for indivisible read and write operations. In this case, in fact, the contents of the DLPDU data field and the addressed memory location are swapped simultaneously.

Logical commands behave almost the same. It is worth remembering that multiple slaves can be involved in the execution of the same command when using logical addressing, depending on the FMMU configuration. As a consequence, the content of the data field in the DLPDU is either obtained by gathering information from the physical memory of several devices (LRD) or scattered over a number of different slaves (LWR). As mentioned before, the logical read/write command (LRW) carries out both operations at the same time.

Broadcast write commands (BWR) are straightforward: as expected, the same value overwrites the memory area addressed by ADO in all slaves. Broadcast read commands (BRD), instead, exploit Boolean operators; while processing an incoming DLPDU, every slave carries out a bitwise “OR” operation between the value found in its memory area addressed by ADO and the data field in the incoming datagram. Then, the result is inserted into the data field of the outgoing DLPDU.

The broadcast read/write command (BRW) combines read and write operations, so that the slave memory content is changed to reflect incoming data. However, according to data sheets [ET1100], this last service is typically not used.

Read/multiple write commands (ARMW and FRMW) complete the set of available services. Only singlecast physical addressing can be used in this case, namely, auto-increment or configured. Read/multiple write operations are quite peculiar and are exploited by EtherCAT in well-defined contexts (i.e., they are not intended for general-purpose data exchange services). In particular, the addressed slave carries out a read operation, whereas all other slaves execute a write operation triggered by the frame reception. If the addressed slave is the first one in the segment, such a mechanism permits a specific value to be read from its local memory and propagated to all the other slaves with a single command. This is profitably exploited, for instance, by the clock synchronization mechanism for distributing the reference time (further details will be discussed in the next sections).

### 18.3.5 SyncManager

The ESC memory is used for exchanging data between the EM and the application running on the slave. The master can access the memory through the network by using the data link layer services, whereas the local application makes use of the *process data interface* (PDI) provided by the ESC. As a consequence, problems may arise if concurrent accesses are carried out without any restriction. In particular, the consistency of data is not guaranteed by the basic data link communication services, unless a mechanism like semaphores is implemented in software for dealing with data exchanges in a coordinated way. Moreover, both the EM and the application running in the slave have to poll the memory explicitly, in order to determine when it is no longer used by the competing entity.

EtherCAT provides a mechanism for slave memory access control, which is based on *SyncManagers*, and was designed bearing in mind concurrency issues. SyncManagers are implemented in hardware in the ESC and enable consistent and secure data exchanges between the EM and the local application, together with the interrupt generation to notify both sides of changes.

SyncManagers are configured by the EM. The communication direction can be selected, as well as the communication mode. Each SyncManager uses a buffer in the local memory area for exchanging data and transparently controls all accesses to the buffer. The buffer must be accessed beginning with the start address; otherwise, the access is denied. Once access to the start location is granted, the whole buffer can be accessed, either as a whole or in a number of strokes. Accessing the last location also

concludes the whole operation. Buffer changes caused by the master are accepted by the SyncManager only if the frame FCS is correct. This also means that such buffer changes take effect immediately after the reception of the end of the frame.

SyncManagers support two communication modes:

1. *Buffered mode*: In this case, the interaction between the producer and the consumer of data is uncorrelated, and each entity can access the buffer at any time. The consumer is always provided with the newest data. In the case data are written into the buffer faster than they are read out, old data are simply discarded. The buffered mode is typically used for cyclic process data. This mechanism is also known as 3-buffer mode, because the SyncManager manages three buffers of identical size (denoted as 0, 1, and 2). One buffer is allocated to the producer (for writing), another buffer to the consumer (for reading), and a third buffer helps as intermediate storage. Reading or writing the last byte of the buffer results in an automatic buffer exchange. It is worth noting that both the EM and the local application must always refer to buffer 0 when accessing memory. It is up to the SyncManager redirecting accesses to the right buffer.
2. *Mailbox mode*: In this case, a handshake mechanism is implemented for data exchanges, which prevents buffer overwriting and ensures that no data will be lost. Just one buffer is allocated for each mailbox; moreover, reading and writing are enabled alternatively. The mechanism implemented by mailboxes is straightforward. At first the producer writes to the mailbox buffer. When done, the SyncManager locks it for writing and enables read access to the consumer. Only when the consumer has finished reading data out of the buffer, the producer is granted write access again. At the same time, the mailbox turns to the locked state for the consumer. The mailbox mode is typically used for application layer (AL) protocols, where the time taken to exchange information typically is not very relevant.

## 18.4 Distributed Clocks

---

An important mechanism included in the EtherCAT specification is the distributed clocks (DC) synchronization protocol, which enables all slave devices to share the same system time with high precision and accuracy. Synchronization errors are typically well below 1  $\mu\text{s}$  [CEN12]; in this way, all devices can be synchronized, and consequently, distributed applications are synchronized as well. Possibly, the master can also be synchronized, even though this option requires additional capabilities.

### 18.4.1 Main Features

The DC mechanism provides a number of features that are very useful for distributed control applications, the most important being

- Synchronization of the slaves (and the master) clocks
- Generation of synchronous output signals (*SyncSignals*)
- Precise timestamping of input events (*LatchSignals*)
- Generation of synchronous interrupts
- Synchronous digital output updates
- Synchronous digital input sampling

DC is placed above the EtherCAT data link protocol, and its implementation is not mandatory. For this reason, both DC-enabled and non-DC-enabled devices can quietly coexist in the same network. It is worth noting that DC is not a general-purpose synchronization protocol, since it relies on specific features of EtherCAT, such as its ring topology, on-the-fly datagram processing, and hardware timestamping capabilities.

To better understand the DC mechanism, the following terms and definitions are needed:

- The *system time* is a 64 bit value representing the time (in nanoseconds) elapsed since 0:00 h of January 1, 2000.
- Typically, the *reference clock* is the slave device with DC capability that is connected closer to the master. Optionally, the reference clock can be adjusted to an extern *global* reference clock, for example, to an IEEE 1588 grandmaster clock. The reference clock provides the system time to all other devices in the EtherCAT segment.
- Each DC-enabled device has a *local clock* that, if not suitably controlled, runs independently of the reference clock.
- The *master clock* is used to initialize the reference clock. Typically, it is the clock of the EM, but it is also possible (and sometimes recommended) to bind it to a global clock reference (IEEE 1588, GPS, etc.), which is made available to the master either directly or through a specific EtherCAT slave.
- The *propagation delay* is the time spent by frames when passing through devices and cables.
- The *offset* is the difference between the local clock of a given slave device and the reference clock. It is due to several elements, such as the propagation delay from the device holding the reference clock to the considered slave, the initial difference of the local clocks resulting from the different instants at which devices were powered on, the skew between oscillator frequencies, and so on. The offset is compensated locally in each slave.
- Because the oscillator periods of local and reference clock sources are subject to small deviations (different quartzes are used), the resulting *drift* has to be compensated regularly.

## 18.4.2 DC Mechanism

The clock synchronization process consists of the following three main actions:

1. *Propagation delay measurement*: The master sends a synchronization DLPDU at certain time intervals, and each slave stores the time of its local clock; after collecting all timestamps, the master, which is aware of the network topology, computes the propagation delay for each segment.
2. *Offset compensation*: Because the local time of each device is a free-running counter, which typically does not have the same value as the reference clock, the master computes the offset between the reference and local clocks separately for each DC-enabled slave. Then, the offset is written to a specific register of the slave, in order to compensate differences individually. At the end of this step, all devices share the same absolute system time.
3. *Drift compensation*: After propagation delays have been measured and the offsets between clocks compensated, the drift of every local clock is corrected through a time control loop (TCL). This mechanism readjusts the local clock by regularly measuring its difference with the reference clock.

Details on these actions are provided in the following. For the sake of clarity, from now on, DLPDUs will be referred to simply as datagrams.

### 18.4.2.1 Propagation Delay Measurement

As mentioned before, each slave device introduces small frame processing/forwarding delays, caused by both internal and communication link mechanisms. For this reason, the propagation delay between the reference node and any slave has to be evaluated carefully. This procedure, which is the first action carried out by DC, consists of three main steps. First, the master sends a broadcast message (i.e., a datagram processed by all slaves). Second, each slave stores the value of its local clock when the first bit of that message is received. This operation is performed for each port of the device, on both the processing and forwarding paths (Figure 18.5). Finally, the master collects timestamps and computes the path delays, taking into account the topology of the network.

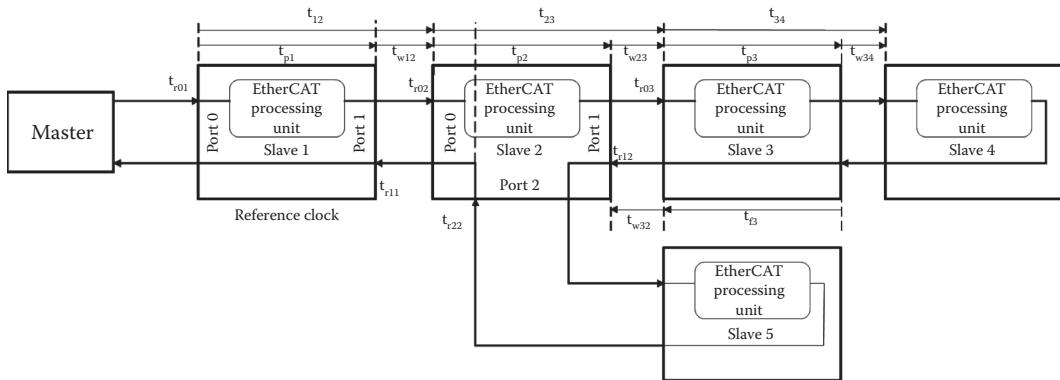

FIGURE 18.5 Time measurement in the DC mechanism.

A synchronization of slave devices is not necessary for the correct operation of the procedure, because only local clock values are used.

The computation of the propagation delay ( $t_{\text{PropagationDelay}}$ ) for each slave is based on the differences between receive times at the device ports. Delays introduced by nodes without DC capabilities are taken into account as well. To better understand the propagation delay measurement, a sample EtherCAT network is shown in Figure 18.5. The node that is closer to the master (Slave 1) has been selected as the reference clock. Propagation delay computation makes use of the main elements summarized in Table 18.3.

The algorithm starts when the master sends a set of datagrams to reset the slave DC registers. After this initialization phase, the master transmits a pair of datagrams to each slave: the first message forces the ESC in the device to record timestamps related to the reception of the frame on its different ports, while the second is used to read timestamps back. For simple devices with only two ports, this means that timestamps are taken in both directions; that is, a first timestamp is acquired when the message is received on the processing path, while a second is recorded on the reception of the same frame on the forwarding path.

In sample network in Figure 18.5, Slave 2 records timestamp  $t_{r02}$  when the frame reaches its Port 0,  $t_{r12}$  when the frame is received back from Slave 3, and, finally,  $t_{r22}$  when the message is returned by Slave 5. Since timing information is taken using the same internal clock, differences between each pair of timestamps can be evaluated properly. Differences are then used to evaluate all delays (processing, forwarding, and wire contributions) and to compute the resulting propagation delay for the slave. It should be noted that the forwarding delay for the first slave (Slave 1 in Figure 18.5) cannot be computed in this way, as timestamps are recorded only for incoming messages. A possible solution is to assume that it is the same as the other  $t_{fx}$  or, alternatively, it can be measured once and for all (at least in theory) when the device is designed and manufactured. The compensation is then performed directly by the master, likely by using a predefined fixed value.

TABLE 18.3 Definition of DC Timing Parameters

$t_{px}$	Processing delay of slave x
$t_{fx}$	Forwarding delay of slave x
$t_{xy}$	Propagation delay from slave x to slave y
$t_{wxy}$	Wire propagation delay from slave x to slave y (symmetry assumption)
$t_{rk_y}$	Receive time on port k of slave y, recorded on the DC receive time register

### 18.4.2.2 Offset Compensation

The second main action carried out by DC is the offset compensation. Local clocks ( $t_{LocalClock}$ ), if not synchronized, are free-running counters. At system start-up, they are likely to have different values from the reference clock so that an offset compensation is needed. The technique adopted in EtherCAT to evaluate offsets is based on the same timestamps collected by the master during propagation delay measurement. In fact, after the previous phase has finished, the master is also able to compute the offset of each local clock with respect to the reference time ( $t_{Offset}$ ). This value is then written into a specific register (*system time offset*) of the slave and then used to adjust the local time. At this point, when the initialization phase is concluded, each DC slave can determine its own copy of the system time autonomously, by using the local time and offset values.

### 18.4.2.3 Drift Compensation

Finally, DC has to deal with oscillator drifts. The natural drift of every local clock (which depends on variations between the reference and local clock quartz) is corrected by means of a TCL algorithm implemented into each ESC. The master periodically distributes the system time ( $t_{ReceivedSystemTime}$ , as read from the reference clock) to all slaves in the network. The algorithm in each slave compares the received system time to its local copy. In evaluating the difference  $\Delta t$ , propagation delays have also to be taken into account:

$$\Delta t = (t_{LocalClock} + t_{Offset} - t_{PropagationDelay}) - t_{ReceivedSystemTime}$$

In automation systems, adjusting the clock with abrupt increments (or, even worse, decrements) is typically not tolerable. The clock discipline algorithm defined by DC, namely, TCL, is also able to cope with this requirement. If  $\Delta t$  is positive, the local time is running faster than the system time and has to slow down. On the contrary, when  $\Delta t$  is negative, the local time is too slow and needs to speed up. In this way, the monotonic property of time is assured for each DC-enabled slave. After the initialization of delays and offsets, the master tries to compensate the static clock deviations quickly, that is, by sending a high number of commands (e.g., fifteen thousands) in separate frames. In other words, first the control mechanism takes care of the static deviations to obtain synchronized DCs, then compensation frames are sent cyclically to correct dynamic clock drifts.

### 18.4.3 External Synchronization

The ability to synchronize to an external time source, so as to define clear timing hierarchies for the whole control system, is quite desirable in current industrial plants. This feature has been recently introduced in EtherCAT so that the time alignment of separate EtherCAT systems is now possible. The basic idea is having the DC time controlled directly by an external device. A possible solution makes use of special devices that provide a common DC reference time to different network segments. In practice, the EBUS is cross-connected to an Ethernet segment, and the user can decide what side (either EBUS or Ethernet) hosts the reference clock with the highest priority. The connecting device is then responsible for sending reference clock correction values to the EM with the lower priority.

Moreover, when the reference time in an EtherCAT system has to be adjusted to a higher-level clock, an external synchronization device can be used that supports synchronization protocols different from DC. For example, some devices are now available that can work with an external Precision Time Protocol (PTP) clock source. In principle, several other popular synchronization protocols and clock sources can be also used, for example, GPS, radio clocks, Network Time Protocol (NTP), and Simple Network Time Protocol (SNTP).

Another remarkable feature has been recently introduced in EtherCAT to cope with systems that demand increased availability; it consists of an optional redundancy mechanism that enables the on-the-fly replacement of devices without having to shut down the network and makes the system resilient to slave failures.

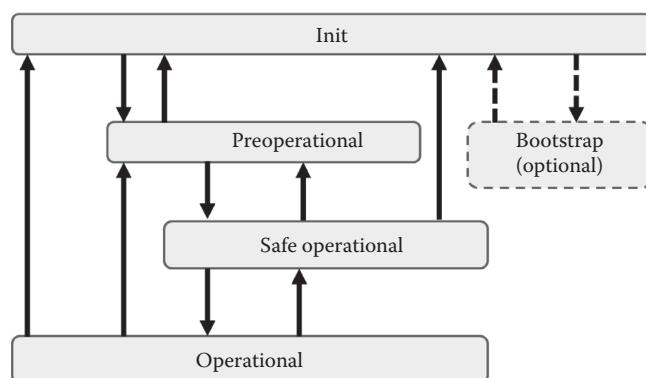

## 18.5 Application Layer

The AL of EtherCAT implements a state machine, which describes the behavior of a device by means of its states and events that trigger transitions between states. In particular, the state machine is responsible for coordinating master and slave applications during the start-up and operational phases. Depending on the current state, different functions are enabled in the EtherCAT slave. Different commands have also to be sent to the device in each state by the EM, in particular, during the boot sequence of the slave. Commands are acknowledged by the local application after the involved operations have been completed. Unsolicited changes of the local application state are also possible. Moreover, simpler devices, which do not include a microcontroller, can be configured to follow the state machine logic through an emulation mechanism. In this case, any state change has to be accepted and acknowledged.

The state machine is controlled and monitored using some registers included in the slave. The master controls the state transitions by writing to the AL control register. In turn, the slave updates information about its current state by writing in the AL status register, which is also used for error notification by means of suitable error codes written in the register itself.

As Figure 18.6 shows, an EtherCAT slave shall support four basic states and, possibly, one optional state:

- *Init*: EtherCAT slaves enter this state at power-on. In this situation, the master initializes the SyncManager channels for mailbox communications.
- *Preoperational*: Mailbox communications are enabled in the preoperational state, but process data communications are not. The EM initializes the SyncManager channels for process data, the FMMUs and the PDO mapping mechanism, if supported.
- *Safe operational*: In this state, mailbox and process data communications are enabled, but the slave outputs are kept in a safe state, while inputs are updated cyclically.
- *Operational*: In this state, slaves can transfer data between the network and their I/O logic. Mailbox and process data communications are completely enabled. The operational state is the normal working condition for slaves after completing the bootstrap sequence.
- *Bootstrap* (optional): The bootstrap state is mainly aimed at downloading the device firmware. In the bootstrap state, mailboxes are active but restricted to file access via EtherCAT services.

**FIGURE 18.6** EtherCAT state machine.

### 18.5.1 Application Protocols

An important characteristic of EtherCAT is its ability to support multiprotocol higher-level communications using standardized mailboxes. This aspect is particularly appealing when options are offered for popular solutions such as the following:

- *CANopen over EtherCAT* (CoE): This option offers a way to access a CANopen object dictionary (OD) and to exchange CANopen messages according to event-driven mechanisms.
- *Ethernet over EtherCAT* (EoE): This option allows to tunneling standard Ethernet Frames in EtherCAT.
- *File access over EtherCAT* (FoE): This option enables the download/upload of firmware and other files.
- *Servo drive profile over EtherCAT* (SoE): This option is useful to grant access to the device profile of SERCOS.

Supporting popular communication protocols helps in improving compatibility and efficiency of data exchanges between new and old components in automation systems; to this purpose, EtherCAT makes use of well-known and established technologies. For instance, the *CoE* protocol enables the adoption of the complete CANopen profile family in EtherCAT networks. Besides this feature, the service data object (SDO) transport protocol allows the transmission of objects of any size and is equivalent to its CANopen counterpart so that it is possible to reuse existing protocol stacks. Data are organized in process data objects (PDOs), which are transferred using the efficient support of EtherCAT. Moreover, an enhanced mode is defined that overcomes the 8 byte limitation of CAN and enables the readability of the whole object list.

Another appealing feature an industrial Ethernet solution should provide is the support to standard IP-based communication protocols (i.e., TCP/IP and UDP/IP) and all higher-level protocols that rely on them, such as HTTP, FTP, SNMP, etc. To this purpose, the *EoE* feature exploits a mechanism where Ethernet datagrams are tunneled and reassembled in a device, before being relayed as complete Ethernet frames. This procedure has no impact on the achievable cycle time, because the size of fragments can be optimized according to the available bandwidth.

The *FoE* is an EtherCAT service that can be used to download a file from a client to a server or to upload it in the opposite direction. The protocol is similar to the trivial file transfer protocol (TFTP), and both sides are allowed to initiate a read or write request via the corresponding command. This service is typically used to update the device firmware.

Finally, the *Servo drive profile over EtherCAT* (SoE) service enables the use of the SERCOS device profile and is suitable for demanding applications that rely on popular drive technology.

## 18.6 EtherCAT Master Characteristics

---

Functionalities of the EM are usually implemented in software. EM coordinates activities of slaves through a control application, mainly by reading and writing data stored in their local memory. In addition, EM manages some network mechanisms (concerning, for instance, clock synchronization) and checks the availability of the system by monitoring the state of slaves (for both detection and active reaction to faults). The master is also responsible for the slave configuration during the network start-up, and it often offers additional features such as the automatic discovery of the network topology and/or support to make the network configuration and reconfiguration easier. Other useful features provided by some EMs are high-level functionalities, such as communications between EMs (carried out at the cell level) that allow interconnecting separate subsystems (at the field level), each one consisting of one EM and a number of connected slaves.

The most critical task carried out by EM is probably dealing with the control loop, which is entered after the configuration of slaves. This is because, in an EtherCAT network, the level of determinism achieved by the master directly affects the real-time performance of the whole control application.

In the following subsections, the concept of control loop is briefly introduced. Then, the main features of two categories of EMs, namely, commercial and open source, as well as their points of strength and weakness, are discussed.

### 18.6.1 Control Loop

The master enters the cyclic control loop at the end of the configuration phase, after fundamental operations such as the discovery of the network topology and the transmission of configuration data to slaves have been completed. The control loop is a cyclic task with its own predefined period ( $T_{CYCLE}$ ), which, independently of its complexity, has unavoidably to read and write data from/to the slaves according to the (well-defined) control algorithm. Besides datagrams (i.e., DLPDUs) needed by the control application, additional messages are exchanged over the network under the EM control, to provide essential network services such as synchronization and fault detection.

A distinguishing feature of EtherCAT is its ability to enable very short cycle times  $T_{CYCLE}$  (that can be as short as 500  $\mu$ s or even less), so this technology is also suitable for motion control and other high-precision applications.

Figure 18.7 shows a very basic structure for an EM control loop, where pseudo-code is used to highlight its main phases. The `receive_frame` function is where EtherCAT frames, received through the EM network interface, are made available to the application. This involves a specific sequence of actions: extracting datagrams from the frame, extracting process data from each datagram, and, finally, storing process data into the relevant variables into the process image (collectively represented by the “data” variable in the picture). The functional block `execute_control_application` is where the control algorithm is executed, so as to compute new values (`new_data`) for commands and state variables. Data to be sent to actuators are first encoded into suitable datagrams and then collected into a single frame, which may also include other datagrams added by EM for management purposes. At this point, the frame is sent over the EtherCAT network (function `send_frame`). The `wait` function in Figure 18.7 reminds that the execution of the control loop must occur exactly once on every  $T_{CYCLE}$ , so some waiting time could be necessary before starting a new iteration.

The timing diagram in Figure 18.8 depicts some iterations of the control loop. In the diagram,  $t_{CPU}$  represents the time spent by the CPU in the master to execute the code of the control loop (i.e., the `receive_frame`, `execute_control_application`, and `send_frame` blocks in Figure 18.7). The  $t_{NET}$  interval, instead, is the overall time spent by the network interface to send an EtherCAT frame over the network, including the time needed by the frame to traverse all the slaves on the processing path and come back on the forwarding path (propagation delay). To keep the diagram simple, the time needed to store the frame received from the network interface into the EM memory is also included in  $t_{NET}$ .

```
while (TRUE) {
    wait(time = time + TCYCLE);
    data = receive_frame();
    new_data = execute_control_application(data);
    send_frame(new_data);
}
```

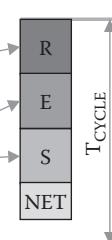

FIGURE 18.7 Pseudo-code of a typical EM control loop.

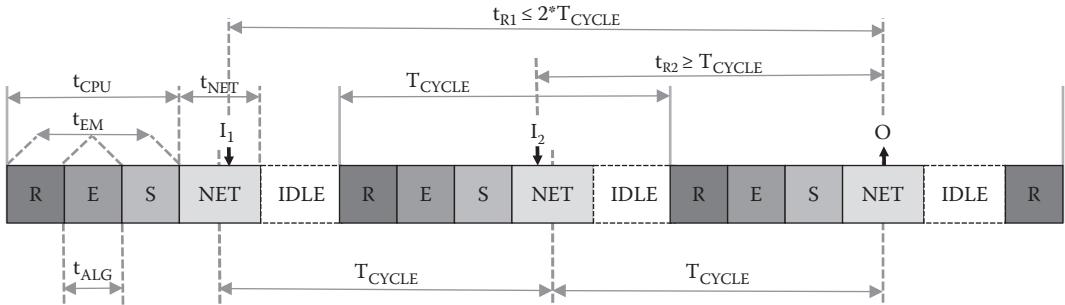

FIGURE 18.8 EtherCAT control loop timing diagram.

Slaves copy sampled input data from their local memory to EtherCAT datagrams in a time interval included in  $t_{NET}$ , and the same happens for output data, which have to be transferred from datagrams to slaves' registers.

The *reaction time*  $t_R$  is the time required by the control application to react to a variation of sampled input data, by writing commanded output data accordingly. Figure 18.8 shows that  $t_R$  is less than or equal to  $2*T_{CYCLE}$  (the time interval between  $I_1$  and  $O$  in Figure 18.8 depicts the worst case). However, when the sampled input signal is made available by the slave in time for being included in the datagram containing the read command,  $t_R$  is just a bit larger than  $T_{CYCLE}$  (time interval between  $I_2$  and  $O$  in Figure 18.8). Summing up, the reaction time  $t_R$  is bound by the inequality  $T_{CYCLE} < t_R \leq 2*T_{CYCLE}$ .

It is worth remarking that the results hold if the input and output operations are performed by the same slave and the execution time of the control algorithm is constant. On the contrary, other factors have to be taken into account, such as the propagation delay on the processing path for the portion of EtherCAT network segment between the involved slaves, and/or the amount of indeterminism introduced by the control algorithm. For instance, when the cycle time is  $T_{CYCLE} = 500 \mu s$ , the maximum reaction time is  $t_R = 1 ms$ , but this is true if and only if the inequality  $t_{CPU} + t_{NET} \leq T_{CYCLE}$  holds.

When DC is used to synchronize the clock of EtherCAT slaves, they can execute a given action at a predefined instant in time. In this case, the maximum reaction time actually increases, because all slaves must receive the related command (included in one or more the datagrams) before the programmed actuation time.

Because of the intrinsic determinism of EtherCAT, the time  $t_{NET}$  does not vary across subsequent iterations of the control loop. In practice,  $t_{NET}$ , which depends on the frame size and other parameters, can be computed analytically [CEN10b].

Unfortunately, the  $t_{CPU}$  time interval is not deterministic. Its duration basically depends on two factors, that is, the time spent by the CPU to execute the control algorithm ( $t_{ALG}$ ) and delays introduced by EM and its operating system ( $t_{EM}$ ).  $t_{ALG}$  is mostly affected by the code implementing the control algorithm. In most cases, an upper bound on the execution time can be evaluated, either analytically or experimentally. On the contrary, no reasonable bound can be found a priori for  $t_{EM}$ . For this reason, the inequality  $t_{CPU} + t_{NET} \leq T_{CYCLE}$  might not hold in some circumstances.

$t_{EM}$  takes into account the time needed by the protocol stack to send and receive EtherCAT frames and also includes operating system latencies caused by interacting tasks, context switching, and scheduling. To keep  $t_{EM}$  bounded, EM implementations usually rely on hard real-time operating systems and protocol stacks. Software drivers for interfacing to the Ethernet controller are often rewritten, in order to ensure that such a requirement is met.

Besides the functionalities a given EM is able to provide, the quality of an EM largely depends on its ability to transfer EtherCAT frames with high determinism. The EM performance analysis presented in [CER11], for instance, shows that jitters on the order of  $10 \mu s$  can be obtained for a nominal cycle time equal to 1 ms, provided that hard real-time operating systems and protocol stacks are used. EMs based

on non real-time operating systems and protocol stacks are usually not suitable for EtherCAT, since in such conditions  $t_{EM}$  is not bounded, and delays larger than 1 ms can be commonly experienced. In these cases, the actual determinism featured by EtherCAT can be even worse than non real-time industrial Ethernet solutions, such as EtherNet/IP.

### 18.6.2 Commercial versus Open-Source Implementations

As already pointed out, the most important requirement for EM is determinism. Even though the determinism achieved by an EtherCAT network is largely enabled by the slave hardware (i.e., by the precision of the DC synchronization mechanism and the ability of slaves to process datagrams on-the-fly), the master plays an important role as well, because all actions summarized in Figure 18.7 have to be completed in a single iteration of the control loop in order to ensure a predetermined and constant cycle time.

In addition, a wide range of other features differentiate EM products today available off-the-shelf. Even though hardware prototype implementations that are based on field programmable gate array (FPGA) boards are described in the scientific literature, EMs are usually implemented as software components. In [MAR12], for example, a mixed hardware-and-software-based architecture was presented that enables the transmission of EtherCAT frames with jitters shorter than 10 ns. The whole system behavior was also sped up significantly, by performing several time-consuming EM operations directly in hardware. Although promising, FPGA-based EM architectures are just prototypes, and, as far as we know, they are not used in real-world EtherCAT applications at the present day. For this reason, the remaining part of this section focuses on software-based EMs.

A number of software EMs are currently available, and designers and systems integrators can choose between commercial and open-source licenses. Commercial products are usually more user-friendly, bug-free, full-featured, and well documented, but open-source products can also be selected, in some situations, for a number of complementary reasons.

On the one hand, Beckhoff TwinCAT [TWIN3] is the most popular commercial EM solution, produced by the company that developed EtherCAT. Other interesting commercial products are NI EM and KPA EM, produced by National Instrument and Koenig-pa GmbH, respectively.

On the other hand, the most popular open-source EM is certainly EtherLab, developed by Ingenieurgemeinschaft IgH and freely downloadable [ELAB]. Another popular open-source solution is the Simple Open EtherCAT Master (SOEM). Unfortunately, SOEM cannot be used in applications demanding high determinism and low  $T_{CYCLE}$ , since its implementation is not real-time.

Regardless of the specific implementation, the two EM categories exhibit very different characteristics. In Table 18.4, the most significant differences between commercial and open-source EMs are highlighted, pointing out strengths (+) and weaknesses (-). The absence of weak points for commercial EMs in the table does not mean absence of defects, since open-source EM strengths have to be considered as weaknesses for commercial EMs and vice versa. A more detailed comparison between the two categories can also be found in [SCA12].

**TABLE 18.4** Commercial versus Open-Source EMs

Commercial	Open Source
+ Easy-to-use	+ Cost (less expensive)
+ Programming languages compliant with IEC 61131-3	- (Usually) nonstandard programming languages
+ Many libraries	+ Customizable code and (usually) better performance
+ Documentation	- Limited hardware support
+ Integrability	- Some EtherCAT features not implemented

Commercial EMs are usually easy to use, if compared with their open-source counterparts. The network configuration, programming interface, and all configurable features are accessible via a graphical user interface (GUI), which allows reducing the time needed to learn the programming and configuration environment also for not experienced programmers and, consequently, shortens the *time-to-market* of applications.

The biggest advantage of open-source EMs is that they are generally free of charge. For this reason, if a large number of control applications have to be developed, costs for the longer learning time can be compensated by adopting the open licensing scheme.

At the beginning of 2013, the new version of the IEC standard 61131-3 [IEC13] was released, which defines five programming languages to be used with PLCs. This edition replaces the previous version published in 2003. All most important commercial tools for EtherCAT programming (and for the vast majority of other industrial Ethernet protocols as well) are now IEC 61131-3 compliant.

Two textual and three graphical languages are included in the IEC 61131-3 standard:

- *Instruction list* (IL) is a low-level programming language, with a level of abstraction similar to assembler.
- *Structured text* (ST) resembles high-level programming languages like C or C++.
- *Ladder diagram* (LD) allows to represent the program as a sequence of digital circuits, including contacts, coils, and specific blocks like counters, timers, etc.
- *Function block diagram* (FBD) is based on block diagrams, where blocks are connected through oriented arcs. It describes how inputs, through the blocks, are transformed into outputs.
- *Sequential function chart* (SFC) represents the control program as a sequence of states (*steps*) with associated *actions* activated by given conditions (*transitions*).

ST and LD are currently the most used languages. ST has a higher level of abstraction and is suitable for large projects, while LD is well known to technicians working in the industrial automation field. A typical situation found in many projects are programs developed with mixed languages, that is, LD for low-level functions and ST for more complex functions (it also acts as the *glue* for putting different subroutines together).

Unfortunately, open-source EMs seldom support IEC 61131-3-compliant programming languages. This drawback limits the code reusability and portability on other EMs and PLCs and requires, in general, longer training times. However, it may also lead to a better optimization of the produced code.

In most open-source solutions, the programming language used to develop the actual control application is the same as the one adopted for implementing the EM. This means that the EM code, which is freely released in the source form, can be possibly modified to meet specific design requirements. This often results in a more efficient EM (where, for instance, some unused features are disabled at compile time), which sometimes is able to show an improved determinism (the EM can be calibrated with respect to the hardware of the PLC, e.g., by modifying the driver of the network interface card or the operating system scheduler). By contrast, some particular features of EtherCAT may sometimes be unavailable in open-source EMs, and enhanced determinism can be achieved only with the aid of specific hardware components (i.e., selected network interface cards).

The documentation, as well as the availability of a large number of libraries (to ease the implementation of the algorithms used in industrial control systems), is certainly one of the most significant advantages of commercial EMs.

Finally, the ability to integrate a number of subnetworks at the cell level is important in large industrial plants, in order to coordinate the production processes. In this context, the availability of a well-engineered application programming interface (API) for enabling communications between PLCs can make the difference, especially when different industrial Ethernet technologies have to be integrated in the same plant. Open-source EMs often offer communication services that are limited to the field level segment of the network (i.e., in the case of EtherCAT, the segment between EM and its slaves), while no API is provided for communications at the cell level (i.e., between different EMs).

In conclusion, the choice of the master should not be underestimated, since it can strongly constrain the project, and in particular its maintainability and characteristics, in terms of both functionalities and performance of the control application. Since in most situations, applications cannot be easily migrated from one EM to another, requirements about performance, desired features, and costs must be carefully considered during the initial design phase.

### 18.6.3 EtherCAT Application Example

This section focuses on a simple example of a typical EtherCAT application, so as to offer the reader a flavor of EM configuration and programming. The same application has been implemented with both a commercial (TwinCAT) and an open-source (EtherLab) EM solution. In the case of TwinCAT, two programming languages have been employed, namely, the LD and ST.

The sample application considered here is a frequency divider. Its goal is switching the level of a digital output (DO) each time three rising edges are sampled from a digital input (DI)—for instance, by pressing three times a push button connected to DI. The EtherCAT network involved in this example consists of a single EM (a standard PC, which runs either TwinCAT or EtherLab), one DI slave (Beckhoff EL1202 [EL1202]), and one DO slave (Beckhoff EL2202 [EL2202]).

The EM, independently from its implementation (TwinCAT/EtherLab), must be properly configured before entering the application loop that executes the control algorithm. The configuration takes place by means of a graphical interface in TwinCAT or relies on specific textual commands in the case EtherLab is used. Each EtherCAT slave hosts an OD, containing a number of entries that are addressed through a 16 bit index and an 8 bit subindex. OD entries allow accessing the slave registers that need to be read/written by the program.

In the configuration phase, EM sets up process data in each slave to specify what information is transferred over the network during every iteration of the control loop, in agreement with the application requirements. These PDOs are embedded in EtherCAT datagrams and transferred by means of an EtherCAT frame. In practice, they are the process data that are used by the control application to perform its task.

The final step of the configuration phase is linking process data to the variables in the process image used by the application in the control loop. A detailed analysis of the configuration steps is not reported here: a thorough description of TwinCAT can be found in the public software documentation, while additional details about the configuration phase for both the EMs taken into account are included in [SCA12].

#### 18.6.3.1 Ladder Diagram

A program written in TwinCAT LD consists of two parts: declaration of variables and code. Declaration of variables is performed by means of an IEC 61131-3-compliant textual programming language. For instance, the variables used in the frequency divider example are shown in Figure 18.9.

```

1 : VAR
2 :      (* Process variables *)
3 :      input AT %IX0.0 : BOOL;
4 :      output AT %QX0.0 : BOOL := FALSE;
5 :      (* Internal variables *)
6 :      switch : BOOL := FALSE;
7 :      enable : BOOL := TRUE;
8 :      (* Function block: CTU counter *)
9 :      counter : CTU;
10: END_VAR

```

**FIGURE 18.9** Declaration of variables for the application example.

Process variables input and output (lines 3 and 4 in the picture) are two Boolean values representing the input DI and output DO; they are linked to the process data in the EtherCAT frame as defined in the configuration phase of the EM. Symbols %I and %Q are used for input and output process variables, respectively. X is one of the possible sizes for process variables (X: bit, B: byte, W: word, and D: double word), while the numbers in the format B.b specify the position of the variable in the process data memory. B and b stand for the byte and bit number, respectively (e.g., address X12.3 selects bit number 3 of byte number 12). Such an addressing method is used to make control application variables largely independent of the underlying communication technology used to interconnect PLCs and remote devices (either a fieldbus or industrial Ethernet).

In Figure 18.9, switch and enable are two internal variables, while counter is a function block, that is, a complex *object* with its own attributes and static variables, which retain their values between successive executions. Variables can be initialized at the same time when they are declared: for instance, output is initialized to 0 (FALSE), which means that the initial value of the DO slave is reset.

Figure 18.10 shows the LD implementation of the application, as well as the most common symbols used in this language, namely, *contacts* and *coils*. In the LD model, current flows through the circuit from left to right. The basic components are contacts and coils, and each component is associated to a variable. When the variable associated to a contact is TRUE, the current flows through the contact; otherwise, when it is FALSE, the current flow is blocked. When current flows through a coil, the variable associated to that coil is set to TRUE; otherwise its value is FALSE. The symbol “/” over a contact or a coil inverts the behavior of that component; for example, in the case of a contact, the current flow is blocked if the variable associated with the contact is TRUE. An LD program is executed from top to bottom.

Other more complex components are also defined in the LD programming language, which are known as function blocks, the most important being *timers* and *counters*. A count up (CTU) counter is shown in the first row of Figure 18.10. Each time a rising edge is sampled by the CU input of the CTU counter, the CV value of the counter (an unsigned integer variable) is increased by one. When the value of CV is greater than or equal to PV, the output Q is set to TRUE (so that the current flows out from Q). When the current flows through the RESET input, the CTU counter stops counting, and the CV value is set to FALSE. Moreover, the output Q stops emitting the current flow.

The first row of the program in Figure 18.10 means that each time the value of the process variable input is TRUE, the current reaches the input CU of the CTU counter, and thus, the CV value is incremented by 1. When the value CV equals 3 (the value of PV), the current exits from output Q and crosses the two coils associated with the switch and enable variables (both variables are set to TRUE).

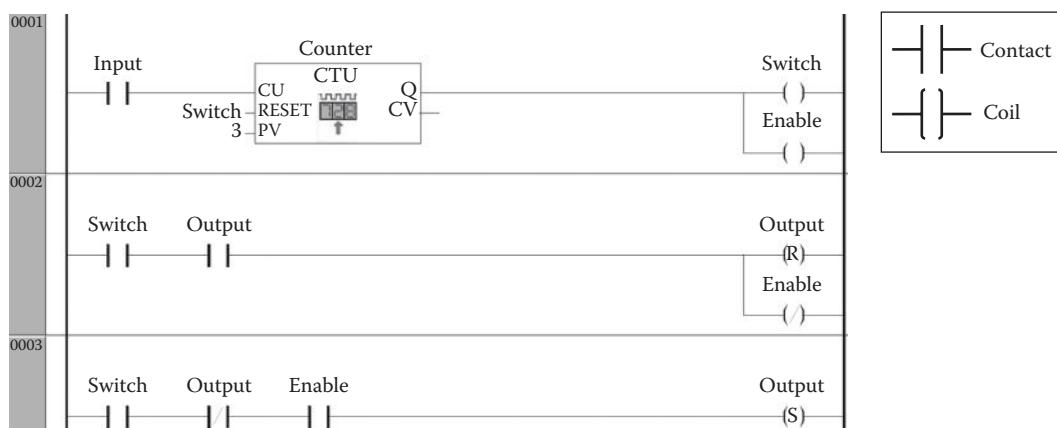

FIGURE 18.10 The example application in ladder diagram.

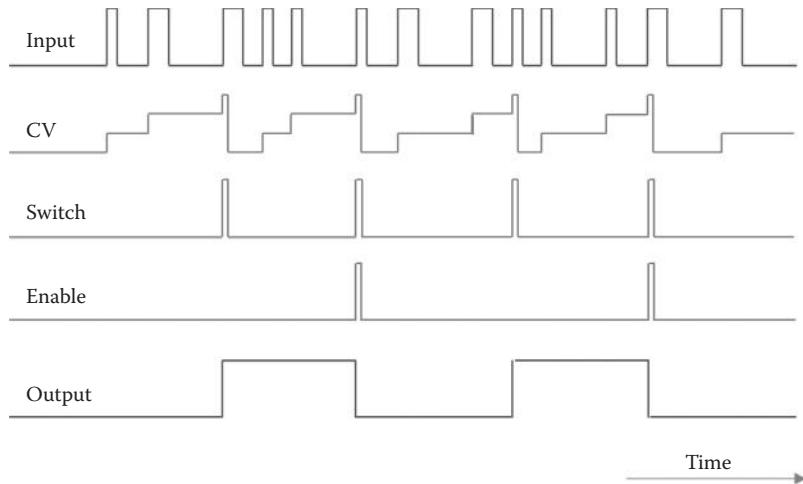

FIGURE 18.11 Timing diagram of the LD program.

The two contacts in row 2 build an AND operator. When both variables `switch` and `output` are TRUE, current flows through both coils associated to the `output` and `enable` variables. The idea behind this scheme is that, when the counter reaches the value of `PV` (i.e., when `switch` is TRUE), the program switches the `output` variable, and, consequently, also the DO output is switched.

The code in row 2 reverts the output from TRUE to FALSE. The coil with the “R” symbol has a specific behavior: when traversed by a current flow, it resets to FALSE the associated variable. The “S” coil in row 3 is needed to set the associated variable to TRUE. These behaviors are different when compared with classical coils, because actions are performed only in the presence of current flows. In summary, the second row of the LD code sets the variable `output` to FALSE and the `enable` variable to FALSE if the `switch` and `output` variables are both TRUE. The `enable` variable is set to FALSE in order to disable the third row of code in the case a change of `output` has just been performed in the same execution cycle.

The third row of the code is similar to the second and manages the transition of the `output` variable from FALSE to TRUE. Indeed, if a transition of the `output` is required (`switch` is TRUE), the `output` variable is FALSE, and the second row has not changed the `output` yet (`enable` is TRUE), the `output` variable is set to TRUE. In the following cycle, `switch` remains TRUE, the counter is reset, and, since no current exits from the contact Q, the `switch` and `enable` variables are set to FALSE.

A possible example of timing diagram for the variables involved in the example is shown in Figure 18.11.

### 18.6.3.2 Structured Text

The implementation of the same example in the TwinCAT ST programming language is shown in Figure 18.12.

From a lexical and syntactical point of view, ST resembles the typical high-level programming languages used in computer engineering. The part of the program reserved to variable declaration (lines 2–9) has exactly the same syntax as LD. Code lines 10–14 perform the detection of a rising edge in the `input` variable. If the current sampled value is TRUE and the value sampled in the previous cycle was FALSE (line 11), a rising edge is detected, and the variable `counter` is incremented by 1 (line 12). The `counter` variable has the same meaning as the CTU counter in the LD program.

When three rising edges are detected (line 16), the output is switched (lines 17–21), and the `counter` variable is reset to 0. From this point on, the program is put into the initial state, and therefore, it can start counting rising edges again.

This example is useful to understand that, although LD and ST are actually different, their complexity is comparable. Usually, ST is more suitable for large projects since it is more expressive and complete.

```

1 : PROGRAM MAIN
2 : VAR
3 :     (* Process variables *)
4 :     input AT %IX0.0 : BOOL;
5 :     output AT %QX0.0 : BOOL := FALSE;
6 :     (* Internal variables *)
7 :     old_input : BOOL := FALSE;
8 :     counter : INT := 0;
9 : END_VAR

10: (* Detection of a rising edge *)
11: IF input = TRUE AND old_input = FALSE THEN
12:     counter := counter + 1;
13: END_IF
14: old_input := input;

15: (* Output switching *)
16: IF counter = 3 THEN
17:     IF output = TRUE THEN
18:         output := FALSE;
19:     ELSE
20:         output := TRUE;
21:     END_IF
22:     counter := 0;
23: END_IF

```

**FIGURE 18.12** Structured text of the sample application program.

than LD. Moreover, ST can be easily mastered by programmers that are used to classical high-level programming languages, such as C, C++, Java, Ruby, Python, etc.

#### 18.6.3.3 EtherLab C

The same frequency divider has also been implemented by using EtherLab on a Linux-based PC. The EtherLab EM follows a completely different approach with respect to TwinCAT. Indeed, the programming language is C, and the configuration phase is performed directly in the control program by means of C functions and without any graphical interface aid. The configuration phase, not described for reasons of space and because not particularly interesting, consists in a sequence of commands to associate the control application with the EM and activate it and in a mapping between the required entries in the slaves' OD and a memory area in the PC (accessible by the control application).

At the end of the configuration phase, a memory pointer (`domain_pd`) allows the control application to access the memory areas associated to the input of the DI and to the output of the DO terminals. The offsets of these process data with respect to the memory address `domain_pd` are `DI_offset` and `DO_offset` for the input and the output, respectively. The EtherCAT control task must start after the configuration phase. The timing of the control task can be dealt with in EtherLab by using either POSIX system calls, in the case of not demanding applications, or specific services offered by the underlying hard real-time operating systems for increased accuracy.

The control task corresponds to the function `cyclic_task()`, whose body is reported in Figure 18.13. It is periodically executed on every  $T_{CYCLE}$ , and it is scheduled by using a timing function similar to `wait` in the pseudo-code in Figure 18.7. Inside the control task, two other functions, `ecrt_master_receive(master)` and `ecrt_domain_process(domain)`, at lines 7 and 8, are used to receive and extract process data from the EtherCAT frame. Data extracted from the datagrams are then stored in the process memory area pointed by the global variable `domain_pd`.

```

1 : int counter = 0;
2 : int old_input = 0;
3 : int input;
4 : int output = 0;

5 : void cyclic_task() {
6:     /* Receive new process data */
7:     ecrt_master_receive(master);
8:     ecrt_domain_process(domain);

9 :     input = EC_READ_BIT(domain_pd+DI_offset, 0);
10:    /* Detection of a rising edge */
11:    if (input==1 && old_input==0) {
12:        counter = counter + 1;
13:    }
14:    old_input = input;

15:    /* Output switching */
16:    if (counter==3) {
17:        if (output==1) {
18:            output = 0;
19:        }else{
20:            output = 1;
21:        }
22:        counter = 0;
23:    }
24:    EC_WRITE_BIT(domain_pd+DO_offset, 0, output);

25:    /* Send new computed process data */
26:    ecrt_domain_queue(domain);
27:    ecrt_master_send(master);
28: }

```

**FIGURE 18.13** C code of the sample application program.

In line 9, a bit is read from the process memory at position domain \_ pd+DI \_ offset and stored in the input variable. The new value of the variable input is then used by the control algorithm (lines 11 to 23) to check if the output variable has to be switched again. As for ST in TwinCAT, the counter variable keeps track of the number of input rising edges. When counter reaches the value 3 (line 16), the output variable, and thus the value of the DO output, is inverted and the new value is then written in the process memory (line 24). Process data are finally embedded in datagrams (line 26) and sent to the slave devices in the EtherCAT frame (line 27).

### 19.1 Introduction

---

Ethernet POWERLINK (EPL) represents a prominent example of real-time Ethernet (RTE) communication networks. It belongs to the IEC 61784 International Standard [1], where it is referred to as the Communication Profile (CP) #1 within the CP Family #13.

EPL was originally designed by B&R GmbH [2] and the first version was released in 2001. Later on, the Ethernet POWERLINK Standardization Group (EPSG) [3] was in charge of continuing its management and published the first EPSG Draft version of EPL as an open standard in 2003 fostering for a free distribution of its specifications as well as for the open-source distribution of the protocol source code. The current version of this communication standard [4] can actually be downloaded from the EPSG website.

EPL is able to provide the real-time capabilities required by critical processes, control tasks, and management functions typical of the industrial scenario [5]. As a matter of fact, EPL, which is compliant with the Industrial Automation Open Network Alliance (IAONA) real-time class 4 (highest performance) recommendations, is able to cope with communication cycles in the order of hundreds of microseconds, ensuring, at the same time, jitters below 1  $\mu$ s.

Also, the EPL application layer is based on the popular and settled CANOpen standard [6] (practitioners often refer to EPL as *CANOpen over Ethernet*). This feature ensures, at the high layer of the protocol stack, compatibility with several other industrial communication devices.

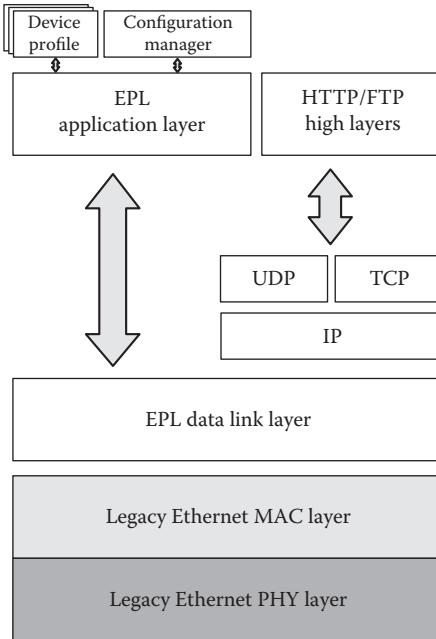

### 19.2 Ethernet POWERLINK Protocol

---

A schematic representation of the EPL protocol stack is provided in Figure 19.1.

#### 19.2.1 Low Layers Specifications

At the lowest protocol layers, EPL makes use of legacy Ethernet to access the medium, while real-time capabilities are provided by the purposely developed EPL data link layer (EPL DLL) protocol, which is placed on top of the standard Ethernet Medium Access Control (MAC) [7]. Therefore, communications

**FIGURE 19.1** EPL protocol stack.

on the medium borrow the features provided by Ethernet MAC. Particularly, the transmission medium is accessed exploiting the well-known Carrier Sense Multiple Access with Collision Detection (CSMA/CD) scheme. The EPL reference physical layer is the IEEE 802.3 100BASE-X, used in the half-duplex transmission mode. In practice, the popular 100BASE-TX based on copper wires and the 100BASE-FX fiber-based channel are encompassed, even if the former is the most common choice in real applications. Nevertheless, it is worth noticing that the EPL standard itself foresees that any advancement in the Ethernet specifications (as, e.g., the adoption of Gigabit Ethernet) can be exploited in order to enhance performance.

In the legacy installation case, when copper wires are employed, both RJ-45 and M12 connectors are encompassed and can be used depending on the environment characteristics, following the installation guidelines of IAONA [8]. EPL also provides recommendations on the type of cables to be adopted in network installations. Particularly, AWG26 twisted pair cables with a protection foil shielding (S/UTP, commonly known as Cat5e) shall be used to increase immunity to noise in the potentially harsh industrial environment.

### 19.2.2 Application Layer

The EPL application layer provides services to the applications by means of *service objects*. From this point of view, the application layer may be seen actually as a collection of objects that, indeed, are listed in a dedicated structure called the *object dictionary*.

Services may be either local or remote. The former type involves only the local objects of a node. These services may be started either by a *request* primitive issued by a specific application or by a local service object, which detects an event and communicates it to the addressed application via the *indication* primitive. Conversely, remote services involve objects that reside on peer nodes connected to the network and may be either nonconfirmed or confirmed. An application that requires a nonconfirmed service issues, at first, a request primitive to a local service object that, in turn, forwards the request to the peer object(s) via an *indication* primitive. On the other hand, confirmed services are peer-to-peer relationships that involve only two service objects, one per each network node.

The EPL application layer ensures data can be exchanged according to several communication models. Particularly, as it will be shown in the following of this chapter, the available relationships are master/slave, client/server, and producer/consumer.

### 19.2.3 Network Operation

An EPL network comprises two different kinds of nodes, namely, managing node (MN) and controlled nodes (CNs). The former is a device that actually implements both automation and control tasks, taking care, at the same time, of all network management aspects. CNs represent the other entities in the network, which are devices like, for example, sensors and actuators, equipped with communication capabilities. The cyclic exchange of data between MN and CNs is at the basis of the EPL operation.

The free distribution of the EPL specification, as well as the open-source nature of the software codes for both MN and CN, has boosted the implementation of different kinds of these devices, which are hence off-the-shelf available by several vendors, covering the whole range of industrial automation systems, including programmable logic controllers (PLC), several types of sensors and actuators, computer numerical control (CNC) machines, etc.

Each EPL network is managed and supervised by exactly one MN, whereas it can encompass up to 240 CNs deployed in various topologies. To ensure real-time behavior for transmission of time-critical data and, at the same time, to provide mechanisms to allow noncritical communications (traffic based on IP protocol, like UDP, HTTP, or FTP requests) a slot communication network management (SCNM) scheme is defined by EPL. Specifically, operations on the network rely on a fixed-duration periodic cycle, which is mainly split in a first isochronous part, where real-time data are exchanged following a publish/subscribe relationship with CNs, followed by a second asynchronous section. This latter has been conceived for either the transmission of asynchronous real-time data or the seamless integration with general purpose IT applications via the transmission of common TCP-IP (Transmission Control Protocol-Internet Protocol) messages. In practice, a strict time division multiple access (TDMA) technique is at the basis of SCNM, where the MN is in charge of managing the access to the channel. In this way, though legacy CSMA/CD is in use to resolve medium contentions and collisions, traffic will never interfere, also in the case, nonswitched Ethernet configurations are employed.

A schematic representation of the EPL cycle is given in Figure 19.2.

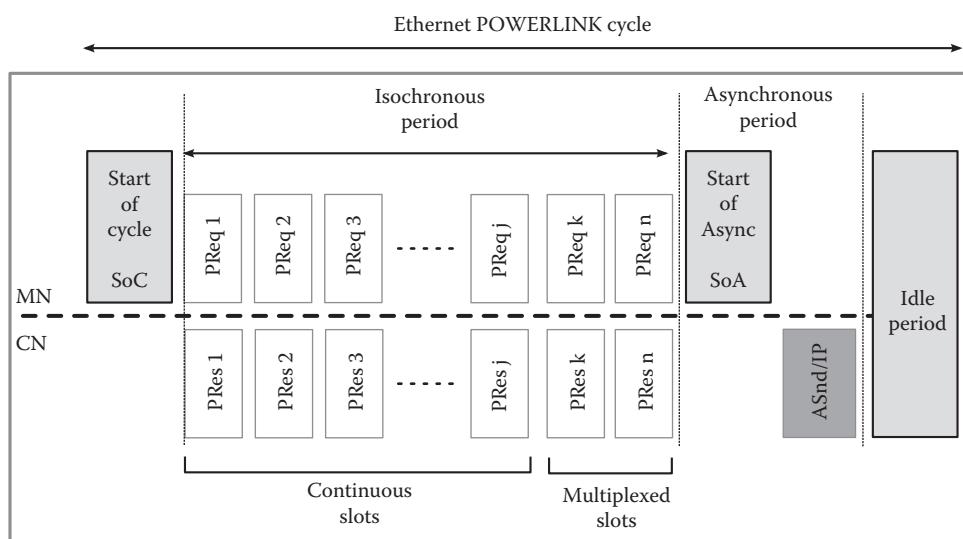

FIGURE 19.2 Ethernet POWERLINK cycle.

The beginning of the EPL cycle is triggered by the MN through the broadcast frame SoC (start of cycle). To maintain a fixed cycle time, the SoC frame is issued on a precise periodic basis, keeping jitter on it as low as possible; this also serves to the purpose of providing time synchronization for all the devices.

After the SoC frame has been issued, the *isochronous period* is entered. In this key part of the cycle, the MN polls each CN by means of the poll request (PReq) frame, which is sent only to the selected CN and can carry output data for it. The accessed CN responds to this query by issuing a poll response (PRes), which is instead a multicast frame carrying input data, made available to all nodes in the network. During this phase, the MN also gathers requests for asynchronous transmissions, which may be solicited by any of the CNs by means of the PRes messages and/or by the MN itself. When the last CN has been polled, the MN has the opportunity to send a PRes frame. According to the protocol specification, such a frame is broadcast, and it is intended to send data to groups of CNs.

Once the isochronous period is concluded, the MN sends a broadcast frame called start of acyclic (SoA), which informs all CNs about the start of the *asynchronous period*. This second phase ensures the transmission of only one asynchronous message by a selected node. The SoA frame is also used to inform which node, among those that previously issued a request, has been selected for the acyclic communication. The choice is based on a priority selection scheme. Acyclic traffic is allowed to serve two different types of transmissions. Specifically, the selected node may transmit either a legacy Ethernet message or an EPL-specific ASyncSend frame. The former type is introduced to allow for general-purpose IT traffic from any source of data, even though the EPL specifications recommend the use of UDP/IP protocol pair since UDP, with respect to the more popular TCP, requires a lower overhead. The second type refers to a particular message purposely defined by the EPL protocol for the exchange of acyclic process data, such as alarms. It is therefore specific of the protocol, and it may be transmitted either to a single node or to a group of nodes.

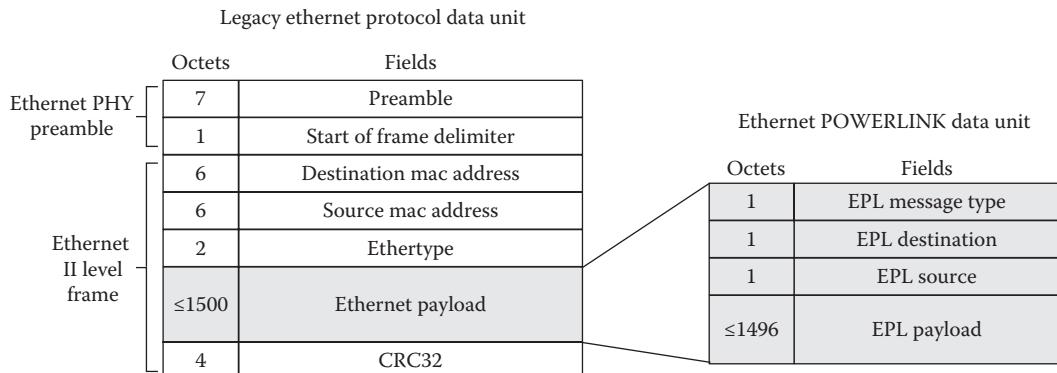

After both the SoA and acyclic frames have been transmitted, the *idle period* is entered. Here, all the stations wait for the new cycle to start, that is, to receive a new SoC frame from the MN. The purpose of this final period is to ensure that all the message transmissions scheduled during the other periods are concluded before the end of the EPL cycle, and hence, no activity is present on the network during this phase.

The structure of the cycle described earlier represents the baseline scheme defined by the EPL standard. However, a noteworthy feature provided by the protocol is the possibility to poll a subset of the CNs at a predefined multiple of the cycle time. That is, the standard defines two communication classes. The first class is the one just described, referred to as *continuous polling*. CNs belonging to this class are polled at every EPL cycle. The other class enables *multiplexed polling*, where data from a subset of CNs are gathered at a multiple  $n$  of the cycle time. Both continuous and multiplexed CNs coexist in the isochronous period, as described in Figure 19.2. The multiplexed CNs are hence adequately distributed in slots in such a way their polling period is respected and the duration of the isochronous period is kept as low and uniform as possible.

#### 19.2.4 Encapsulation of EPL Frames

The EPL DLL protocol is placed on top of the MAC layer of the IEEE 802.3 standard. Consequently, any EPL message is encapsulated within a legacy Ethernet II frame, as shown in Figure 19.3. The field Ethernet Type is used to specify that the (Ethernet) frame is actually employed by EPL setting its content to the hexadecimal value 88ABh.

An EPL message is inserted at the beginning of the DATA field of the Ethernet frame and is composed mainly by four consecutive fields. The first octet identifies the *Message type*. In this field, the first bit is reserved (typically set to 0), and the other 7 bits are actually used. The EPL DLL protocol encompasses six main message types, relevant to the messages already mentioned in the quoted protocol description (SoC, SoA, etc.), each one identified by a unique hexadecimal code, as shown in Table 19.1.

**FIGURE 19.3** Ethernet POWERLINK message encapsulation.

**TABLE 19.1** Ethernet POWERLINK Message Types

Ethernet POWERLINK Frame	MAC Transfer Type	Hexadecimal Code
Start of cycle	Multicast	01 <sub>h</sub>
Poll request	Unicast	03 <sub>h</sub>
Poll response	Multicast	04 <sub>h</sub>
Start of asynchronous	Multicast	05 <sub>h</sub>
Asynchronous send	Multicast	06 <sub>h</sub>

The second and third octets contain, respectively, the *Destination Address* and *Source Address* of the EPL nodes (clearly, they have no relation with the addressing mechanism of Ethernet). Finally, the *Data* field carries the actual message payload, and, on the basis of the message type, it may contain a further internal subdivision to accommodate for message-specific fields.

### 19.3 Ethernet POWERLINK Topologies

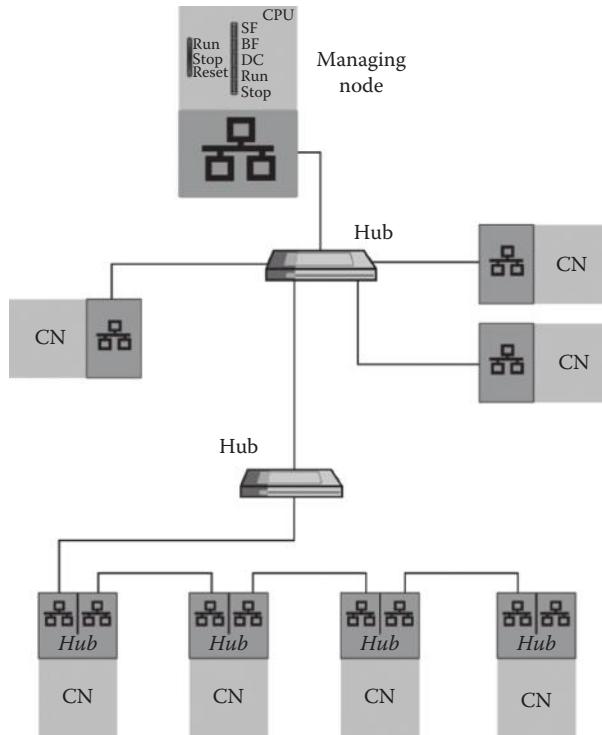

EPL recommends the use of Ethernet hubs in order to cope with the tight timing requirements that are often imposed to the network. However, switches may be employed as well, taking into account their behavior, with particular attention to the additional delays they introduce.

Indeed, hubs are able to provide low path delays (lower than 460 ns) and a very limited jitter (according to the EPL specification, typically no more than 70 ns), while switches are usually characterized by worse performance figures.

The typical fields of application for EPL networks often require the deployment of complex topologies, where several hub levels are introduced. For this reason, hubs may be integrated into the CN network interface card, thus reducing the number of needed components and simplifying the network installation. Specifically, as outlined in Figure 19.4, this allows for the deployment of networks that comprise traditional star topologies combined with linear chains of CNs.

The strict determinism implemented by EPL through the SCNM also ensures the absence of frame collisions on the medium. This allows to deploy even more complex topologies, since the typical Ethernet constraint on the maximum round-trip time being limited to 5120 ns (for the 100BASE-TX physical layer) no longer applies to EPL networks. Thus, for example, linear chains of CNs benefit of this relaxed timing constraint since, in general, they may introduce considerable round-trip times that could exceed the Ethernet upper bound.

Conversely, further timing constraints are introduced by the EPL specifications. Indeed, time-outs are used in the polling mechanism (during the isochronous period, in particular) as a mean to detect either

**FIGURE 19.4** Example of Ethernet POWERLINK network using combined topologies.

node failures or transmission errors. Particularly, after sending the PReq frame toward a CN, the MN starts a timer whose default value (for the 100 Mbps transmission speed) is set to 25  $\mu$ s. The corresponding PRes from the addressed CN should be received within this time-out time to avoid misbehavior of the EPL network in the subsequent cycles. Therefore, the latency for a round-trip time between the MN and any of the CNs is upper-bounded by this time-out value. However, since this latency is strictly dependent on both the employed components and the adopted topology, the EPL protocol allows a per-node configuration of the time-out. Also, a global network-wide different time-out selection is possible.

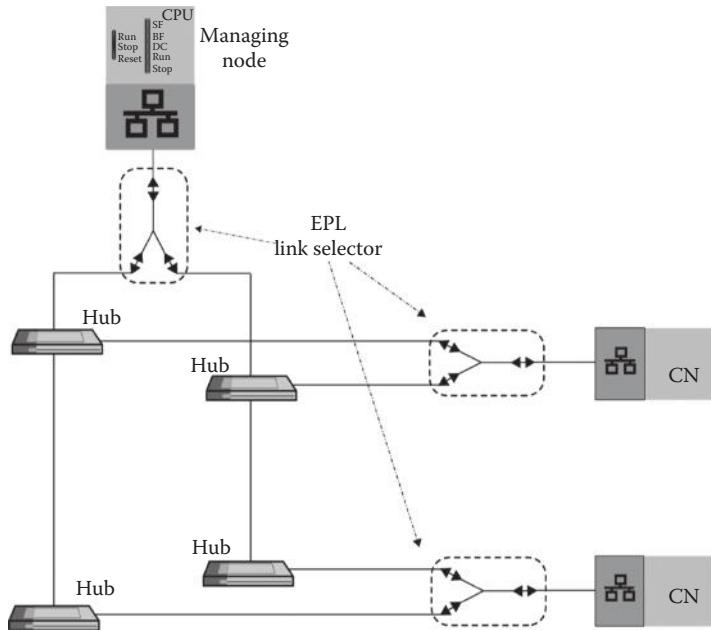

## 19.4 Ethernet POWERLINK Redundancy

The EPL standard aims at providing a reliable and robust RTE network. To this extent, the POWERLINK High-Availability Service [9], provided as an amendment document to the main specifications, focuses on possible failures of any of the network devices, providing suitable methods to ensure even in those situations a full network functionality. To this purpose, the amendment requires that very fast switch-over times be guaranteed in case a failure occurs, including, in particular, a hot standby function. The POWERLINK High-Availability services implement two specific means for achieving the quoted goals, namely, medium redundancy and MN redundancy. Moreover, a further optional technique, referred to as ring redundancy, may be adopted.

### 19.4.1 Medium Redundancy

A schematic representation of this redundancy technique implementation is given in Figure 19.5.

As can be seen, all devices connected to the EPL network are provided with a second, redundant, cabling. During the normal operation of the network, stations (both MN and CNs) transmit data on

**FIGURE 19.5** Example of Ethernet POWERLINK medium redundancy.

both links. A link selector feature should be implemented on each device to decide what is the suitable reception link to be used. The decision relies on a predefined algorithm that can be based on either a single attribute (e.g., the message arrival time) or a set of attributes (e.g., the link quality and the cyclic redundancy codes of the received messages).

Furthermore, the link selector of each CN is required to introduce in the PRes frame the information about the status of both its links. The MN may use the gathered link status information to provide the application it handles with a snapshot of the *quality of the network*. As a final comment, this redundancy feature requires that the operations of the link selector do not introduce a variation in the path delay, measured between any two nodes in the EPL network, larger than 5.76 µs (transmission time of a 64-byte frame on a Fast Ethernet network).

#### 19.4.2 Managing Node Redundancy

This second approach faces the high-availability service from the application layer perspective. Basically, it extends the MN functionality by introducing the redundant managing nodes (RMNs), which are devices with MN capabilities contemporaneously present on the network. This allows defining two new entities, namely, the active managing node (AMN) and the standby managing node (SMN). The former actually represents the legacy MN, and, as such, it implements all its functionalities. Conversely, SMNs are RMNs that are connected to the network and, from the application point of view, behave like legacy CNs. They constantly monitor the network and retrieve information about the current status of all participants. If the current AMN experiences a failure, it is immediately substituted by one of the SMNs, and the takeover shall not require more than an EPL cycle time.

Finally, MN redundancy requires that an election algorithm be implemented to select the SMN that should take over the AMN functionalities, in the case more than one SMN is available. This feature is actually based on priorities assigned to each of the SMNs, which can be either derived from the SMN node address or set through a purposely defined engineering tool.

## 19.5 Ring Redundancy

Though the earlier-described methods realize a full redundant network principle, optionally, the MN could provide also a basic ring redundancy feature. This relies on the fact that a ring cabling structure intrinsically provides two independent transmission paths linking any two nodes in the network.

Figure 19.6 provides an example of application of ring redundancy. As can be observed, in this case, each device is equipped with two independent Ethernet ports.

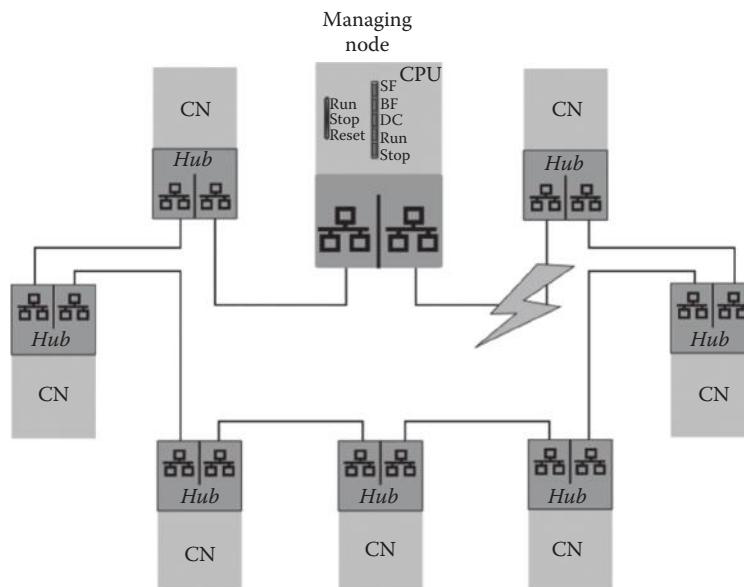

Under regular network conditions, each frame issued by the MN will traverse the ring until it reaches the MN again, which will identify the message as *recently sent* and simply discard it. Under faulty conditions, instead, the frame is not received back at the MN, and a previously set time-out time will expire, thus signaling a connectivity loss, due, for example, to a cable break.

As a consequence, in the next EPL cycle, the MN will transmit on both available connections. If it subsequently detects a frame collision, then it will conclude that the ring connectivity has been reestablished so that it can return to transmit on only one transmission path.

It is worth remarking that this represents an optional feature for EPL networks, which should not be confused with the full redundancy introduced with the techniques discussed in the previous sections. However, this method reveals very interesting in the industrial environment since these networks are subjected to harsh stresses, for instance, caused by high temperature variations, extreme humidity conditions, presence of dust, and movement of parts.

### 19.5.1 OpenSAFETY Protocol

In the context of RTE networks, the main purpose of a safety protocol is to ensure data transfer integrity. Particularly, data duplications, loss of frames, and/or manipulations must be absolutely avoided. Also, a safety protocol should be able to detect excessive delays in data transmission as well as corrupted frames. Typically, only some critical segments of a network are subjected to safety-related control activities, and the implemented safety protocol activates appropriate functions when triggered by a fault situation, leading in extreme cases to the safe shutdown of the plant.

**FIGURE 19.6** Example of Ethernet POWERLINK ring redundancy.

To provide an adequate solution to the aforementioned requirements, the EPL Safety Working Group developed the OpenSAFETY protocol, which is now part of the IEC 61784-3 International Standard. OpenSAFETY was originally defined as EPL Safety application layer, released by EPSG in 2007 as an *open* standard. Subsequently, it has been approved by TÜV Rheinland Group in 2008, as being suitable for safety-sensitive applications belonging to the IEC 61508 Safety Integrity Level 3 (SIL 3).

OpenSAFETY, however, has not been exclusively designed for EPL. Indeed, it may be adopted by any other RTE network such as, for example, EtherNet/IP, Sercos, and Modbus, as it is actually independent from the underlying real-time transport protocol, exploiting the *Black channel* principle. This feature derives from the complete implementation of the standard at the application layer, which ensures the so-called OpenSAFETY layer may be, in principle, introduced in the protocol stack of any other RTE network.

A basic method to detect corrupted frames as well as to increase transmission reliability is represented by the use of dedicated frame formats. In particular, user data are duplicated in two adjacent subframes within the same frame. Each one is protected by a checksum calculated differently for both subframes. OpenSAFETY allows a maximum payload data of 354 bytes. At reception, both subframes are independently checked for integrity against their respective cyclic redundancy check (CRC). Further, they are compared to ensure data have been correctly received.

Moreover, as further safety measures, the transmission times of frames and the processing times are taken into account by the protocol, in order to adequately detect delivery failures.

The communication model of the OpenSAFETY protocol relies on the producer/consumer paradigm, in that any safety node (SN, a node part of the safety-controlled network) can be a producer and/or consumer of safety-related information.

In a single OpenSAFETY network, referred to as a safety domain (SD), a unique safe configuration manager (SCM) is responsible for the monitoring of attached SNs, storage of each SN parameters, and node addressing. Indeed, the unique identifier for an SN is provided by the safety address (SADR).

For each SD, there exists only one SCM, to which a maximum of 1023 SNs can be attached. In the case of large OpenSAFETY networks, up to 1023 SDs can be defined, which can extend over several, possibly unrelated and inhomogeneous, networks. In this case, the communication among SDs is ensured by specifically designed OpenSAFETY Domain Gateways (SDGs), which appear as simple SNs from the SD point of view.

## 19.5.2 Basic Performance Analysis

This section serves the purpose of presenting the major guidelines to be accounted for the performance analysis of communication networks based on the EPL standard, highlighting the existing relationships between protocol design parameters and key performance indicators.

Actually, in the context of RTE networks, performance indicators have been defined by the IEC 61784-2, international standard that introduces some general-purpose metrics as well as specific indicators for each CP.

In the case of EPL, however, some additional complementary indicators may be considered. Namely, cycle time and jitter are indicators of prominent importance for networks like EPL whose operation is based on a periodically repeated cycle. Also, the latency introduced on the delivery of acyclic messages represents a further meaningful metric to be assessed.

### 19.5.2.1 Cycle Time

From the analytical point of view, the EPL cycle time, which is trivially determined by the time periods shown in Figure 19.2, can be expressed as

$$T_C = T_{SoC} + T_{Isoc} + T_{ASync} + T_{Idle} \quad (19.1)$$

where the four addends represent the durations of, respectively, start, isochronous, asynchronous, and idle periods of the EPL cycle.

The duration of the start period is simply determined by the transmission of the Cycle frame.

The isochronous period is usually the most weighting part of a cycle, and its duration is determined mostly by the time needed to access all the configured CNs. This involves sending of PReq/PRes frames, communication latencies (due, e.g., to network topology), and, finally, component latencies.

The asynchronous period has typically a short duration since, after the SoA frame has been issued by the MN, at most one asynchronous transmission is allowed. The longest duration of such a period can be hence calculated considering that, in any case, the transmitted asynchronous frame cannot exceed a 1500 byte payload.

Finally, the idle period is not related to the transmission of any frame. However, to achieve the best performance, such a period has to be kept as short as possible.

The minimum value that can be set for the cycle time,  $T_C^{min}$ , represents a meaningful metric that gives an indication of the achievable performance, helps the design stage of the network, and provides a significant basis for the calculation of other performance indicators. From Equation 19.1, it is clear that, for a given network configuration, the minimum cycle time is achieved when the duration of the idle period is set to zero, and, moreover, the acyclic transmission does not take place. This means that in Equation 19.1,  $T_{Async}$  is determined by the transmission of only the SoA frame that, actually, has the same length of the SoC frame. This latter is a minimum size Ethernet frame, and at the transmission rate of 100 Mbps, the time necessary to transmit any of the SoC and SoA frames is  $T_{SoC} = T_{SoA} = 5.12 + 0.64\mu s = 5.76\mu s$ , where the second addend ( $0.64\mu s$ ) accounts for the transmission of the Ethernet preamble.

After the transmission of the SoC frame, the MN shall wait for a predefined time, called  $t_{SoC-PReq\_MN}$ , which represents the minimum delay between the end of SoC transmission and the start of the isochronous period. According to the EPL specification, this time has a minimum value equal to an Ethernet interframe gap ( $T_{EthIFG}$ ). Hence,  $t_{SoC-PReq\_MN} = 960$  ns. The same value of time can be accounted for the gap after the transmission of the SoA frame.

Consequently, the analytical expression of the minimum cycle time, calculated from Equation 19.3 with the aforementioned assumptions, is given by

$$T_C^{min} = 2 \cdot (T_{SoC} + T_{EthIFG}) + T_{Isoc} \quad (19.2)$$

The duration of the isochronous period can be calculated from the times necessary to poll the CNs, which comprise the transmission time of both the PReq and PRes frames, plus the mandatory gap times to be waited between these frames (which, again, are specified to be equal to an Ethernet interframe gap).

Finally, the calculation of  $T_C^{min}$  has to take into consideration both the physical propagation times and the latency introduced by the hubs present in the path between MN and CNs. The propagation delay can be usually approximated by 5 ns per each meter of cable, whereas, the latency introduced by a hub,  $T_{Hub}$ , is usually not greater than 460 ns.

Thus, the analytical expression of the minimum EPL cycle time results:

$$T_C^{min} = 2 \cdot (T_{SoC} + T_{EthIFG}) + \sum \left\{ T_{PReq} + T_{PRes} + 2 \cdot [T_{EthIFG} + T_{propag} + (N_{Hub,n} \cdot T_{Hub})] \right\} \quad (19.3)$$

### 19.5.2.2 Jitter

This indicator is defined as the maximum deviation of the periods of cyclic operations from their nominal values. For example, the polling of a continuous CN is expected to take place with a period equal to the EPL cycle time whereas, in practice, it may be subjected to even minimal fluctuations.

In an EPL network, two main causes of jitter can be identified, namely, the jitter introduced by the MN and that due to the network components.

The former is strongly related to the specific physical device employed as well as to the protocol implementation. On the other hand, the jitter introduced by network components is peculiar of the components themselves (e.g., hubs) being practically independent from the EPL protocol rules.

Limiting the discussion about the jitter introduced by components to the case of hubs, the general expression for the upper bound of the jitter introduced in the path between the MN and a CN is given by

$$J_{TOT} = J_{MN} + N_{Hubs} \cdot J_{Hub} \quad (19.4)$$

where the jitter introduced by the MN is indicated as  $J_{MN}$ , whereas the jitter contribution of a single hub is accounted by the term  $J_{Hub}$ , under the simplifying assumption that all hubs are homogeneous with respect to their jitter performance. Finally,  $N_{Hubs}$  represents the maximum number of hubs in the MN-CN path.

To better highlight the importance of component selection and of topology design in the field of EPL-based RTE, two meaningful (even simple) examples could be introduced, though they remain representative only of a qualitative analysis of this topic. Considering a basic star topology network in which a single hub connects MN and all the CNs. The term  $J_{MN}$  accounts for 50 ns, as indicated by the EPL specification, whereas the jitter contribution of a hub is on the order of 70 ns, resulting in an upper bound for the jitter of 120 ns.

In a slightly more complex topology, where two hubs are introduced, the maximum jitter is, trivially,  $J_{TOT} = 190$  ns, which however highlights the fundamental impact of the topology on this performance figure.

### 19.5.2.3 Acyclic Traffic

The main factors affecting the latency of asynchronous messages are both the cycle time and the scheduling algorithm implemented on the MN to select the asynchronous request to serve in the current cycle.

Actually, referring to the worst case, a CN that has asynchronous data to transmit issues its request through the PRes frame when it is polled. The MN receives this request and processes it, using a pre-defined scheduling mechanism based on assigned priorities (the asynchronous request, however, could be of higher priority for more time-critical events). Simplifying and assuming that all requests have the same priorities, the result is that the latency for asynchronous messages increases linearly with the number of requests. Hence, the EPL capability of providing low cycle times reveals an even more important feature, since it ensures reduced latencies for asynchronous requests.

Finally, the latency of acyclic messages could be reduced adopting techniques requiring slight modifications to the protocol. For example, multiple asynchronous send (ASend) transmissions could be allowed in the same cycle, provided that there is enough bandwidth to accomplish with them. Another possible way of achieving better latencies would consist in reserving part of the EPL asynchronous period exclusively for alarms, as addressed in [10].

### 20.1 General Overview

---

When Ethernet was introduced some 40 years ago, only few would have envisioned the extraordinary success story that would follow. While, at first, Ethernet grew to become the dominant communication standard in the office and IT communication, it quickly entered new application domains, and whenever it did, chances were high that it proved to be a mainstream alternative to niche and potential proprietary protocols. There are a variety of reasons why Ethernet manages over and over again to enter new application domains and become the leading communication technology in the new field. However, one main factor that has contributed to the vast distribution and application of Ethernet is its steady and incremental standards improvements and the industry support that comes hand in hand with that.

The IEEE is the natural home of Ethernet and bridged networks in general; and two main working groups maintain and extend Ethernet's leading position as a communication protocol: IEEE 802.3 and IEEE 802.1. IEEE 802.3 is primarily concerned with standardizing the physical (PHY) and media access control (MAC) layers of Ethernet, while IEEE 802.1 is standardizing general architectures for local area networks (LANs) and metropolitan area architectures (MANs) that use IEEE 802 technology. These general architectures include security mechanisms, interworking of LANs, MANs, and wide area networks (WANs), as well as the overall network management. The protocols and mechanisms that 802.1 develops operate above the MAC layer.

In the IEEE, working groups are split into task groups, and this chapter will mostly focus on the mechanisms and protocols developed by the IEEE 802.1 *time-sensitive networking* (TSN) task group, previously known as the *audio/video bridging* (AVB) task group. As the name suggests, this task group standardizes protocols and mechanisms that improve the real-time behavior in the IEEE 802 family of protocols and technology and, thus, are of immediate interest as industrial communication technologies.

The AVB task group has had its roots in the *residential Ethernet* study group and became later a task group in IEEE 802.1. Today, it is common to refer to the output of the AVB task group as *AVB*. The following four items are considered to be its building blocks:

1. 802.1AS Timing and Synchronization for Time-Sensitive Applications in Bridged Local Area Networks: a protocol and technique to synchronize local clocks in the network to each other
2. 802.1Qat Stream Reservation Protocol (SRP): a protocol that allows applications to dynamically reserve bandwidth in the network
3. 802.1Qav Forwarding and Queuing Enhancements for Time-Sensitive Streams: an enhancement over strict priority-based forwarding and queuing mechanisms that establishes fairness properties for lower priority traffic in the network
4. 802.1BA: list of standards and definition of profiles for AVB systems

IEEE 802.1AS and IEEE 802.1BA are stand-alone IEEE standard documents released in 2011, while 802.1Qat and 802.1Qav are amendments to the IEEE 802.1Q standard, which is considered one of, if not the, central standard documents of IEEE 802.1. These amendments have been incorporated into IEEE 802.1Q-2011 (the most recent version of IEEE 802.1Q at the time of this writing), but for simplicity, the community sometimes continues to refer to the amendment tags.

While AVB equipment is now entering and is about to enter the market for audio and video applications in various domains (e.g., professional theater equipment, in-car information, and entertainment), the task group has broadened the target market for the IEEE 802.1 technology toward industries that demand even more time-sensitive and reliable networks. Therefore, the audio/video bridging task group was renamed to time-sensitive networking in 2012. As of today, the following items are discussed to form the core of TSN:

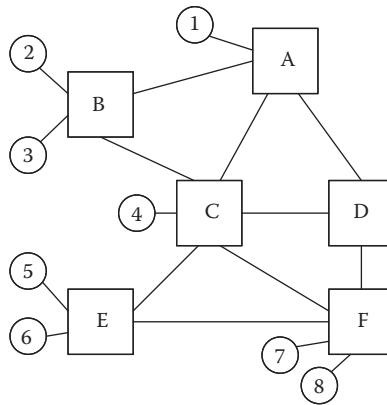

- 802.1ASbt Timing and Synchronization: Enhancements and Performance Improvements.
- 802.1Qcc Stream Reservation Protocol: Enhancements and Performance Improvements.
- 802.1Qbv Enhancements for Scheduled Traffic: The developed mechanisms will allow a basic form of time-triggered communication in which the outgoing queues from bridges will be drained according to an a priori known schedule. The bridges will execute the schedule synchronously with respect to the IEEE 802.1AS timebase.
- 802.1Qbu Frame Preemption: A mechanism that allows to preempt a frame in transmit to intersperse another frame. While this mechanism was originally intended to improve transmission latency, its primary application will be in combination with scheduled traffic to allow more efficient bandwidth utilization.
- 802.1Qca Path Control and Reservation: Protocols and mechanisms to set up and manage the active communication paths in the network. In particular, it will be possible to set up redundant communication paths between sending and receiving end stations. The concurrent transmission of replicated copies of frames will raise the reliability of frame transmission.
- 802.1CB Frame Replication and Elimination for Reliability: Complementary to the capability of transmitting frames concurrently over redundant communication paths in the network, the TSN task group will also standardize mechanisms to eliminate redundant copies of frames, for example, at the receiver or at bridges directly connecting to a receiving end station.

In this chapter, we will describe the basic IEEE 802.1 technology and elaborate on the AVB and TSN protocols and mechanisms outlined earlier in more detail. We will use the term *TSN/AVB network* to reflect both the new target markets of time-sensitive networks, such as industrial control applications, and the original target markets of audio and video applications.

## 20.2 Basic Technology

---

A TSN/AVB network is composed of two types of components: end points and bridges. Frequently, the commercial term *switch* is used synonymously for a bridge. End points will typically be the computational nodes that host and execute applications. As these end points need to exchange information,

**FIGURE 20.1** An example of the physical topology of a TSN/AVB network consisting of eight end stations (labeled 1–8) and six bridges (labeled A–F).

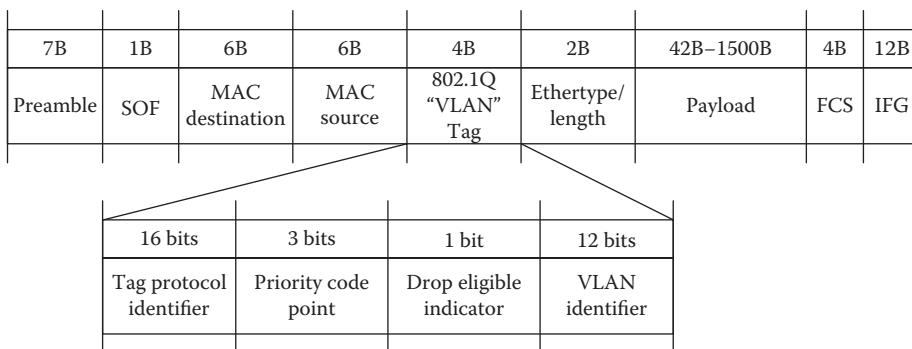

they are connected to each other either directly or indirectly using one or many bridges. An example physical topology of a network consisting of eight end stations (represented by circles) and six bridges (represented by boxes) is depicted in Figure 20.1.

End points and bridges are connected to each other with bidirectional communication links, and for the sake of simplicity, we will assume in the remainder of this chapter that these links are either 100 Mbit/s or 1 Gbit/s Ethernet connections and omit that the 802.1 technology supports also other communication technologies through well-defined interfaces. End points and bridges connect to the links through physical *ports* and communicate solely by the exchange of Ethernet frames. The structure of an Ethernet frame is depicted in Figure 20.2.

End points may send or receive Ethernet frames, or both. Bridges control the forwarding of the frames between end points. In particular, a bridge needs to address two main tasks in frame forwarding:

1. Switching: When a bridge receives an Ethernet frame on a port (the incoming port), it needs to decide to which ports the frame shall be forwarded on to (the outgoing ports).
2. Traffic shaping: When more than one frame is ready for forwarding at an outgoing port, the bridge needs to serialize this set of frames.

Switching and traffic shaping use the information transported in the Ethernet frame: for the switching task of an incoming Ethernet frame, the bridge will take the media access control (MAC) destination and the virtual local area network (VLAN) identifier into account to decide to which outgoing ports

**FIGURE 20.2** Structure of an Ethernet frame and detailed representation of the IEEE 802.1Q VLAN tag.

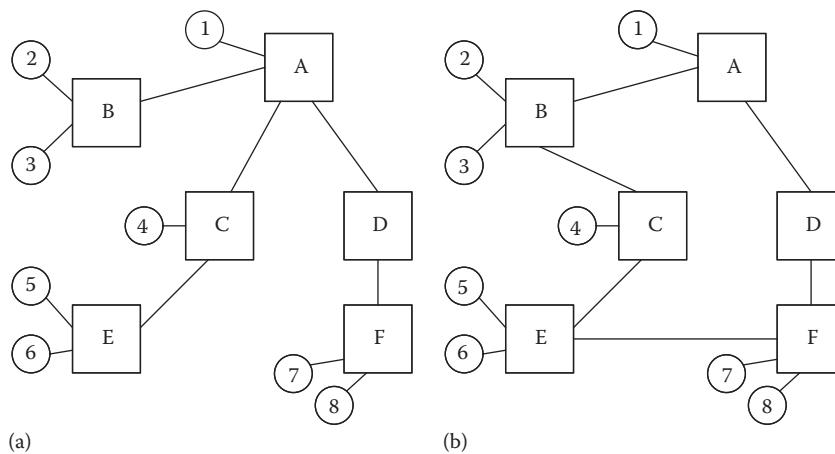

the frame needs to be forwarded. For the traffic shaping, the bridge only uses the priority code point (PCP) information in the VLAN tag. The relation between incoming port and outgoing port for a given Ethernet frame as well as the particular traffic-shaping mechanism that needs to be applied is locally stored in the *forwarding information base* (FIB) of a bridge.

It is also common to distinguish the *control plane* from the *data plane* inside a bridge. In simple terms, the control plane is the collection of protocols and mechanisms that populate the FIB, while the data plane refers to the mechanisms that use the information in the FIB to handle the actual data transfers like the buffer and queue management mechanisms.

Sometimes, the physical topology of a network forms a graph that contains loops. As a bridge only uses the Ethernet MAC destination address and the VLAN identifier for the switching task, loops in the graph potentially lead to repeated circulations of Ethernet frames along these loops. To avoid this problem, the bridges use protocols like spanning tree or shortest path bridging that establish a loop-free *active topology* on top of the physical topology. These protocols are considered to be part of the control plane of a bridge. Given the physical topology in Figure 20.1, after the execution of a spanning tree protocol, the active topology may be the one established in Figure 20.3a. If end point 1 needs to communicate with end point 6, it will send its frames to bridge A. Bridge A will learn from the MAC source address in these frames to which port end point 1 is connected to (and update its FIB), but it may not (yet) know the location of end point 6. Hence, bridge A forwards the frame to all ports in the active topology except the one to which end point 1 is connected to. Bridges B, C, D likewise forward the frame and learn the MAC address relation to the incoming port. In the next step, bridges E and F learn the address of end point 1 and their local port on which the frame has been received, and finally, bridge E delivers the frame to end point 6. The active topology avoids circulation of the frame from end point 1, which would happen otherwise if bridge C would forward the frame also to bridge B and bridge B again to bridge A.

Complementary to the dynamic way to establish the active topology and address learning, networks can also be engineered, for example, for active redundancy reasons. Figure 20.3b depicts an engineered ring topology on top of the physical topology in Figure 20.1. Obviously, the ring topology is not loop-free as it only consists of a single loop. Hence, to avoid the problem of circulating frames, great care must be taken in the proper configuration to set up disjoined active paths between senders and receivers. We will continue this discussion in Section 20.3.4.

The bridges in the network will typically be used to transmit frames from many end points and, consequently, become a shared resource. Traffic-shaping mechanisms decide the sequence in which the frames will be forwarded in case several frames are competing for transmission on the same outgoing port.

**FIGURE 20.3** Possible logical topologies on top of the physical topology in Figure 20.1. (a) Dynamically generated spanning-tree topology and (b) engineered ring topology.

For example, in Figure 20.3a, end points 1 and 4 may need to send a frame each to end point 6. Thus, both frames need to use the connection from bridge C to bridge E. In case both frames are ready to forward at about the same point in time, bridge C needs to decide which frame goes first. This decision can be random or follow a particular traffic-shaping mechanism.

The traffic-shaping mechanisms standardized by IEEE 802.1 operate on classes of frames rather than on individual frames; that is, they operate *per-class* rather than on *per-flow*. The frames are classified based on the PCP in their VLAN tag, and as the PCP has a size of 3 bits, it is common that bridges implement eight outgoing queues (one queue per priority) per outgoing port. The simplest traffic-shaping mechanism is *strict priority*: when multiple frames are ready for forwarding, the bridge will select the frame with the highest priority to transmit next. Should several frames with the same priority be ready for forwarding, the bridge will process them in first-in first-out order. This strict priority traffic-shaping mechanism has several drawbacks, and we will discuss more advanced traffic-shaping mechanisms in Section 20.3.3.

TSN and AVB build on the protocols and mechanisms discussed earlier to enhance the real-time and reliability properties of IEEE 802.1 networks. We continue in the next sections with a more detailed discussion of the specific TSN and AVB protocols and mechanisms.

## 20.3 TSN/AVB Protocol Services

---

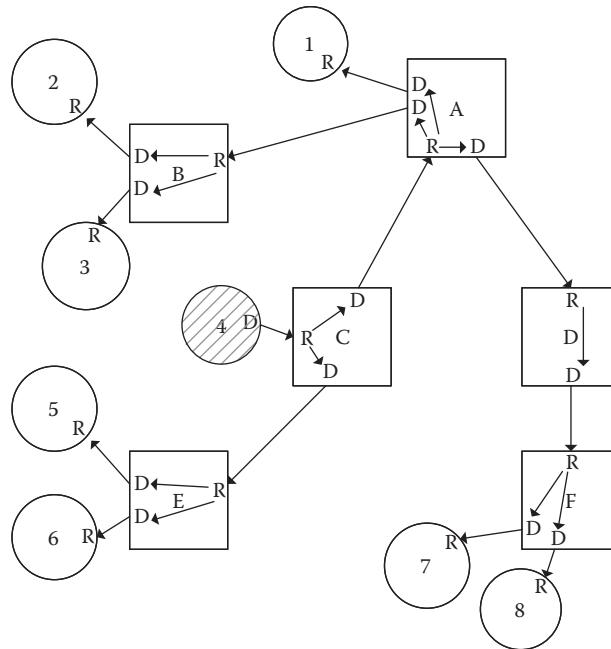

In this section, we discuss the SRP to dynamically reserve communication bandwidth in a TSN/AVB network, the TSN/AVB clock synchronization protocol, traffic-shaping algorithms, and a current proposal to redundancy management in TSN. Finally, we also give a brief overview of the IEEE 1722 standard, which defines OSI layer 2 protocols for TSN/AVB. A detailed description of how to configure and use AVB in a systems context is standardized in IEEE 802.1BA.

### 20.3.1 Stream Reservation Protocol

SRP is responsible for reserving bandwidth between two AVB-capable devices. SRP itself uses an already existing protocol, the MRP defined in IEEE 802.1Q. Basically, MRP enables to register (and deregister) so-called attributes and distribute them across all ports in a network, or sections of the network confined by a VLAN. This way application-specific configuration information can be distributed, and managed, as registration and deregistration of attributes are handled. Applications of the MRP are the multiple stream reservation protocol (MSRP), the multiple VLAN reservation protocol (MVRP), or the multiple multicast reservation protocol (MMRP). Examples of attributes are MAC addresses, VLAN ID, or stream information in MSRP.

The way MRP works is very simple: every MRP participant periodically sends his registered attributes to the neighboring devices. In particular, a network node that needs to communicate new configuration data declares an attribute (declaration) by sending the information to all its available network ports. When an MRP participant receives information about an attribute, it registers the attribute. The attribute is then, again, declared at the recipient, and therefore, the process propagates from device to device through the network. Using the spanning tree, MRP makes sure the network does not get congested by MRP messages bouncing between neighbors. Figure 20.4 pictures the principle of the MRP operation. In this scenario, end station 4 is the source of the attribute declaration. As depicted, the attribute is registered and declared along the active topology of the network.

AVB uses the MSRP, an application of the MRP to declare streams and propagate the information about streams throughout the network. Using MSRP, the whole set of network nodes is divided into two groups: so-called *talkers* and *listeners*. A talker is a device providing information, like a microphone. A listener is a device consuming the provided information, like a loudspeaker. A talker advertises its stream by registering a *talker advertise* attribute using MRP. So eventually, every participating device will know about the stream and its properties.

**FIGURE 20.4** Example of MRP declaration/registrations as they propagate through the network.

The *talker advertise* attribute contains the following information: StreamID, DataFrameParameters, TSpec, PriorityAndRank, and AccumulatedLatency. StreamID represents a system-wide unique identifier, consisting of the MAC address of the talker and a 16 bit StreamID. DataFrameParameters specifies the destination MAC address StreamDA and the VLAN ID of the stream. TSpec defines the maximum frame size MaxFrameSize of a frame in this stream (excluding media specific overhead) and the maximum number of frames MaxIntervalFrames a talker may send within a *class measurement interval* (CMI). CMI is specified by the *traffic priority class*, where AVB so far defines two classes, A and B, and CMI is 125 µs for class A and 250 µs for class B.

AccumulatedLatency specifies the maximum latency a stream can encounter during the traversal of the network, a value that should not change during the lifetime of the stream reservation; if the value has to be increased (e.g., due to a wireless link), the *talker advertise* attribute will be changed to a *talker failed* with the appropriate error code. PriorityAndRank contains information about the priority of the stream and its rank, a 1 bit field to indicate a critical stream, for example, a speaker system for emergency announcements in a public building.

An example of a *talker advertise* message containing the attributes discussed earlier is depicted in Figure 20.5.

With the information from the *talker advertise* attribute, it is possible to calculate the required bandwidth, BW, for this stream using Equation 20.1:

$$BW = \frac{Tspec_{MaxIntervalFrames}}{CMI} \times 8 \times (Tspec_{MaxFrameSize} + Overhead_{mediaSpecific}) \quad (20.1)$$

For the captured stream depicted in Figure 20.5, using Equation 20.1 results in  $\frac{1}{125\mu s} \times 8 \times (224 + 42) = 17.024 \text{ Mbit/s}$ .

FIGURE 20.5 Example of a talker advertise message captured with Wireshark.

SRP itself does not specify how the payload of AVB/TSN frames is constructed but relies on other protocols like IEEE 1722 and IEEE 1722.1.

The registration of the talker advertise attributes in an AVB network will typically involve the following steps (Figure 20.6): First, a *talker* declares that it has a stream ready to transmit and registers a *talker advertise* attribute, which in turn gets propagated through the whole network. If a listener is interested in this stream, it can register a *listener ready* attribute (containing the correct stream id). Again, this information will be propagated across the network and eventually reach the talker. The path is constructed on a hop-by-hop basis, as each registers and declares the attribute for the corresponding port. When a bridge device registers a *listener ready* attribute, it knows that a listener exists at this specific port and can check if enough bandwidth is available. This way MSRP can make sure that sufficient bandwidth is available across the whole path of the stream. If an error occurs during this reservation process, a bridge can declare a *listener failed* or *talker failed* attribute and provide an error code to define the cause, so all devices will eventually get informed about the failed stream reservation. As soon as the talker receives a *listener ready* declaration, the talker can be sure that sufficient bandwidth is available along the stream path, and at least, one listener is ready to receive streamed data. The streaming itself is done via higher level protocols like IEEE 1722.

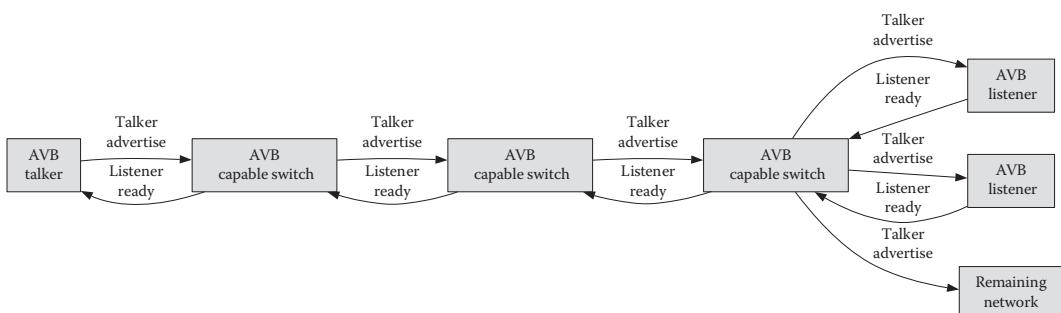

FIGURE 20.6 Example of talker advertise and listener ready propagation through an AVB network.

### 20.3.2 Clock Synchronization Protocol

The purpose of a clock synchronization protocol is to bring local clocks in the end stations and bridges into close agreement, such that at any point in real-time, two nonfaulty clocks in end points or switches will read approximately the same local computer-time. The clock synchronization protocol of TSN/AVB is standardized as IEEE 802.1AS and is significantly overlapping with the IEEE 1588 standard. We give an overview of IEEE 802.1AS and currently discussed improvements to it in the following. A more detailed introduction to IEEE 802.1AS is given by Garner et al. in [3].

From a literature point of view, IEEE 802.1AS specifies a classical master–slave clock synchronization protocol in which one component (end point or bridge) acts as the master clock toward which all clocks of the other components are synchronized to. In IEEE 802.1AS, the master is called the *grandmaster* and forms the root of a *synchronization spanning tree* that connects all the local clocks of the components. For example, the spanning tree depicted in Figure 20.3a may also be the synchronization spanning tree for the IEEE 802.1AS clock synchronization protocol. In this example, bridge A may act as the grandmaster clock that provides its local time to all other bridges (B–F) and end points (1–8). In summary, IEEE 802.1AS specifies protocols:

- To select a grandmaster out of a set of grandmaster-capable components
- To periodically synchronize to the grandmaster clock
- To measure the forwarding delays in the bridges
- To measure the communication delays of frames on the communication links

For grandmaster selection, IEEE 802.1AS uses the best master clock algorithm (BMCA): components that are capable of acting as grandmaster clocks in the system will announce their presence in so-called “announce messages.” A receiver of the announce messages can directly compare these messages with each other and select the *best* announce message using a standardized assessment scheme. Consequently, the component that sent the best announcement message will become the grandmaster in the network and the root of the synchronization spanning tree.

The grandmaster will, then, periodically distribute its local time (the `preciseOriginTime-stamp`) to the network along the synchronization spanning tree using two messages: the `Sync` and the `Follow_up` messages. The `Sync` message is a time-critical message, and each component precisely timestamps its reception and transmission (in case of the grandmaster and a bridge). The grandmaster and each bridge will then communicate the transmission and, respectively, forwarding delay of the `Sync` message in a second message, the `Follow_up` message. As the `Follow_up` message propagates along the synchronization spanning tree from the grandmaster to the final receivers, each component adds the forwarding delay, that is, the difference between transmission time and reception time of the previous `Sync` message, into the payload of the `Follow_up` message (using the `correctionField` field).

In addition to the forwarding delay, the network periodically also measures the communication delay of the communication links. This measurement is called the *peer delay mechanism* and is done individually on each communication link in the network, for example, on the communication link connecting bridge A to bridge C. We continue to assume that bridge A is the grandmaster clock in the network. Hence, bridge C needs to measure the communication link delay to bridge A. This is done by the exchange of three messages between bridge C and bridge A:

- Bridge C sends a `Pdelay_Req` message to bridge A and locally stores the transmission point in time as  $t_1$ .
- Bridge A timestamps the reception point in time of the `Pdelay_Req` message and locally stores the value as  $t_2$ .
- At a point in time  $t_3$ , bridge A responds to bridge C with a `Pdelay_Resp` message, which contains  $t_2$ .

- Bridge C records the point in time ( $t_4$ ), when it receives the Pdelay\_Resp message from bridge A.
- To accurately inform bridge C of time  $t_3$ , bridge A sends another message, the Pdelay\_Resp\_Follow\_Up message, after the Pdelay\_Resp message, which contains  $t_3$ .

Bridge C can then approximate the communication link delay to bridge A, as  $[(t_4 - t_1) - (t_3 - t_2)]/2$ .

The Pdelay\_Resp message serves also a second purpose—to measure the relative difference of the clock rates in the components connected by the communication link (e.g., in the example earlier the differences in clock rates between bridge A and bridge C). However, the IEEE 802.1AS standard does not describe a particular mechanism for rate ratio measurement but only requires that the measurement can be done within  $\pm 0.1$  ppm.

While the resulting synchronization quality of IEEE 802.1AS is quite remarkable and certainly sufficient for a wide range of, for example, automotive and industrial applications, the TSN task group is currently developing reliability enhancements. Some proposed mechanisms discuss the use of redundant grandmasters that operate in hot or warm standby; that is, instead of exactly one grandmaster in the system, at least two are configured to run concurrently, a primary and a secondary grandmaster. In the absence of failures, all components (inclusively the secondary grandmaster) synchronize to the primary grandmaster. Once the primary grandmaster fails, the system continues to use the synchronization information provided from the secondary. The simplicity of a fault tolerance scheme like the hot/warm standby one is certainly attractive and a sufficient reliability increment to broaden the application domain of TSN/AVB significantly. However, there also exist a lot of safety-critical applications that demand more sophisticated fault-tolerant clock synchronization approaches. Hence, to enable TSN/AVB also in these domains, the standardization of interfaces to highly dependable clock synchronization protocols is desirable.

### 20.3.3 Traffic Shaping

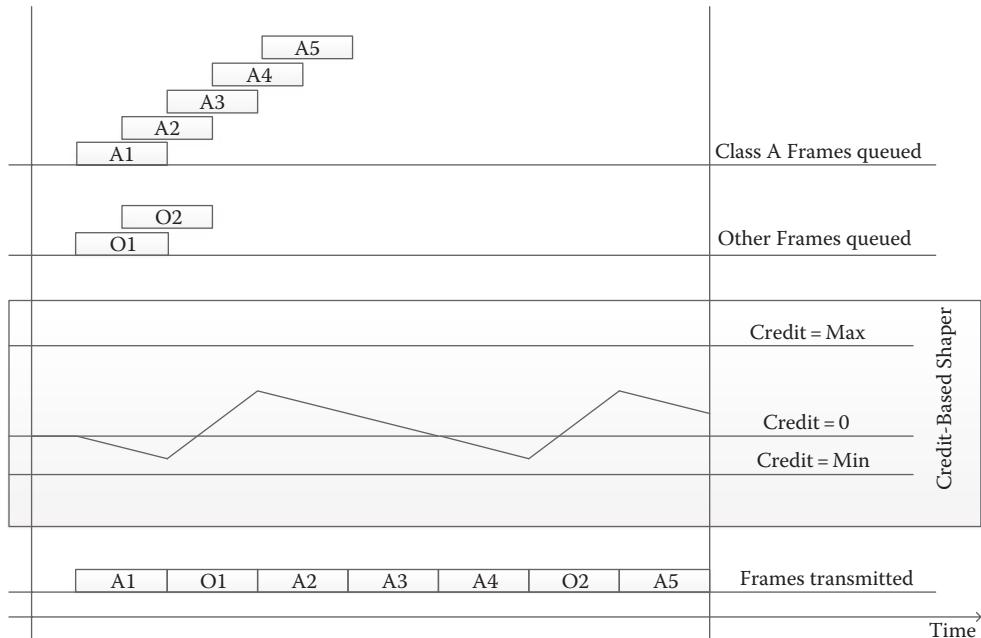

Typically, several applications need to share a single network, and frequently, the messages from several applications will be ready to forward inside a particular bridge to the same communication link, which has then to decide which message should be transmitted next. Furthermore, in several industries, we can observe a trend toward *converged* networks in which more and more applications that used to be physically separated are now being integrated onto the same network. Hence, the question of which message to transmit next becomes more and more complex, as systems become more and more integrated. When the network in addition also has to guarantee end-to-end delays of some critical messages, the serialization problem of the messages in the bridges becomes severely complex.

We have already discussed the simple solution to use a strict priority scheme, but it has several shortcomings: First, high-priority frames only get a significant better service if their number is limited; otherwise, high-priority frames compete regularly for transmission, thereby downgrading the priority effect. Second, if high-priority messages always become precedence over lower-priority messages, then the applications using these lower-priority messages face a starvation problem—they may not be able to continue their execution as an insufficient number of their messages are being serviced by the network.

Hence, more advanced traffic-shaping mechanisms have been developed: AVB standardized the *credit-based shaper*; the TSN task group is currently developing the *time-aware shaper*.

#### 20.3.3.1 Credit-Based Shaper

The credit-based shaper defines two traffic classes, class A and class B, and the classification of Ethernet frames is done based on their PCP in the VLAN tag. Furthermore, the credit-based shaper specifies the CMI. Within each CMI, each AVB talker will only send up to a defined bandwidth as granted by the SRP. In praxis, this means that an AVB talker will typically send one Ethernet frame of configurable size per CMI. For class A messages, the CMI is standardized to 125  $\mu$ s; for class B messages, to 250  $\mu$ s.

**FIGURE 20.7** Example execution trace of traffic shaped according to the credit-based shaper.

The execution of the CMIs is not synchronized between the AVB talkers and the bridges. Hence, class A frames from different AVB talkers can still queue up in the outgoing port of a bridge. An example scenario of a bridge-shaping AVB class A traffic is depicted in Figure 20.7.

Figure 20.7 shows the operation at a single outgoing port of a bridge. In particular, it depicts two outgoing queues of the one outgoing port: a first queue serving AVB class A frames (A1–A5) and a second queue serving other traffic (O1–O2). Class A frames have higher priority than the other frames. Thus, a bridge implementing a strict priority-driven traffic-shaping policy would simply send the AVB frames first followed by the other traffic, thereby causing potential exhaustive delay to the other frames. Hence, in the presented scenario, the credit-based shaper is depicted to show a bridge that will only select an AVB class A frame if the current *credit* of AVB class A frames is nonnegative. Credit is a local variable that changes state with progress in time using the following rules:

- When no AVB class A frame is queued, then credit is set to zero.
- When AVB class A frame is transmitted, then credit is decreased over time with a configurable rate *sendSlope*.
- When at least one AVB class A frame is queued, but not transmitted (because either the credit is negative or another frame is currently in transit), then credit is increased over time with a configurable rate *idleSlope*.

The scenario in Figure 20.7 starts with an initial credit of zero, and AVB class A and other frames become ready for transmit back-to-back. As depicted, the first frame transmitted is A1, rendering the credit negative. Hence, the next frame selected for transmission is O1. As the *sendSlope* is typically set lower than the *idleSlope*, several AVB class A frames are transmitted next (A2–A4) until, again, credit becomes negative. Hence, again, a non-AVB class A frame will be transmitted (O2), and the scenario finally concludes with AVB class A frame A5.

The credit-based shaper operates on AVB class B frames analogously as for class A frames but maintains a separated local variable to keep track of the AVB class B credit.

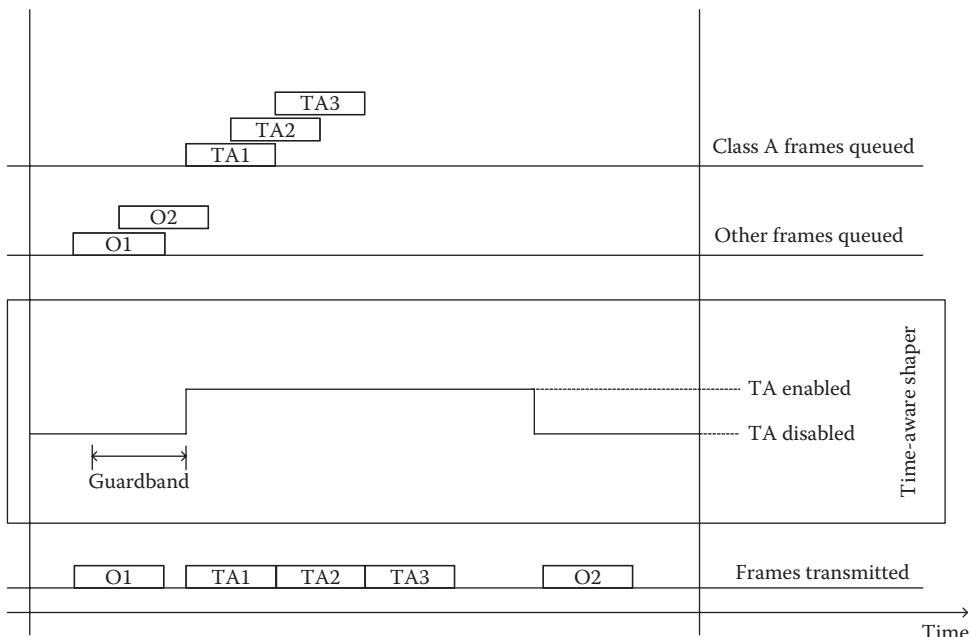

The original goal of the credit-based shaper was to achieve a latency for highly time-critical messages of 2 ms over network paths consisting of a maximum of six bridges. Although it has been demonstrated that this design goal may not always be satisfied in arbitrary network topologies, the credit-based shaper remains valuable to several industries.

Currently, the static configuration of the CMI of 125 and 250  $\mu$ s for class A and class B traffic, respectively, is under debate, and it is likely that in future revisions of the standard, other configurations for the CMI will be allowed.

### 20.3.3.2 Time-Aware Shaper

In order to minimize communication latency and communication jitter, the TSN task group is currently defining another shaper, called the time-aware shaper, which at the time of this writing is currently under standardization as IEEE 802.1Qbv *Enhancements for Scheduled Traffic*. It aims to translate the time-triggered communication paradigm toward the IEEE 802.1 queue-based traffic-shaping model. As in time-triggered communication, the time-aware shaper needs to address two aspects: first, components that use the time-aware shaper require access to a synchronized timebase, and second, the components need to define a communication schedule. The access to the synchronized timebase is inherently present in an AVB/TSN network through the IEEE 802.1AS clock synchronization standard. Hence, all TSN needs to define is how to link this synchronized time to the execution of the communication schedule. The second aspect, how to generate the communication schedule and how to distribute this information in the system, is still in an early phase of technical discussion. However, it is likely that the distribution of the communication schedule will require modifications of the SRP and/or the use of the IS-IS (Intermediate system to Intermediate system) protocol. An example execution trace of what the time-aware shaper is likely to look like is depicted in Figure 20.8.

Again, the scenario depicts two outgoing queues at an outgoing port in a bridge. The higher-priority queue serves time-aware frames (TA1–TA3) while the lower-priority queue serves other nontime-aware frames (O1 and O2). The functionality of the time-aware shaper is shown in the shaded box simply by a TA-enabled/disabled signal: when TA is enabled, the time-aware frames are transmitted; when TA is

**FIGURE 20.8** Example execution trace of traffic shaped according to the time-aware shaper.

disabled, the bridge may forward frames from other queues. As depicted in the scenario, the first frame delivered is O1 followed by the time-aware frames TA1-TA3.

The figure further shows an interval called the *guardband* immediately before the time-aware frames are transmitted. The purpose of this guardband is to ensure that no nontime-aware frame causes a conflict with the time-aware frames once the TA is enabled. Hence, all nontime-aware frames need to finish transmission before the TA is set to be enabled. For example, in the aforementioned scenario, O2 would be ready for transmit before the time-aware frames. However, as the transmission of O2 would not conclude before the TA is enabled, frame O2 cannot be forwarded.

As bandwidth is in general a precious commodity, but even more so in the IEEE 802 community, several ideas have been presented on how to make efficient use of the guardband to avoid idle times. The straightforward solution is to start the transmission of frames during the guardband, but only when it can be guaranteed that the frame transmission will be completed once TA is enabled. However, this means that the closer time advances to the point in time when TA is enabled, the shorter the frames must be that can be selected for transmission. In the IEEE 802.1, it is, furthermore, uncommon, and to a certain degree also prohibited by the standard, to search an outgoing queue for a frame with matching length to transmit next as the order of frames needs to be preserved within certain bounds. Therefore, this straightforward solution does not increase bandwidth efficiency to an optimum. A more sophisticated approach is frame preemption.

IEEE 802.1Qbu investigates a mechanism that allows a bridge to preempt a current frame in transmission and to intersperse another frame. Thereby, the goal is to achieve lower latency for the interspersed frame and to preempt in a way such that the preempted frame can be continued after the communication of the interspersed frame. Preemption as a response to the IEEE 802.1AS time reaching a configured point in time allows the guardband to be used more efficiently than the simple approach discussed earlier as a frame can now be selected for transmission irrespective of its length.

### 20.3.4 Redundancy Management

Each network may lose frames because of the imperfection of the environment it operates in. For example, electromagnetic emission may cause bit flips on the communication links, rendering the frame check sequence of an Ethernet frame, that is, its cyclic redundancy check (CRC), invalid. A typical office network handles frame losses like this one by implementing higher-layer retransmission protocols, for example, by using TCP/IP. However, in real-time networks, the temporal penalty of retransmissions is often not acceptable, and alternative approaches are required.

In safety-related networks, it is common to install redundant communication paths on which redundant copies of the frames are transmitted in parallel. Hence, this *parallel* form of redundancy increases the reliability of frame transmission in a network as it is more likely that at least one of the redundant copies reaches its destination than in a network without parallel redundancy. At the destination, or at selected bridges in the network, the redundant copies of a frame need to be eliminated such that the information transported in the redundant copies of a frame will be used only once.

In the TSN task group, this form of parallel redundancy is incorporated into the IEEE 802.1 standards. In particular, the setup of redundant communication paths in the network is developed in the 802.1Qca project and is looking into using the IS-IS protocol for this purpose. The 802.1CB project explores how to eliminate the redundant copies at the receiver (or at selected bridges in the network). The current proposals for the elimination use the well-known sequence number mechanism: redundant copies of the same frame are tagged with the same sequence number. This sequence number is then incremented with each new frame of a stream transmitted by a talker. From the sequence number, a listener can distinguish redundant copies of the same frame, which have the same sequence number, from different frames in the stream, which should have sufficiently different sequence numbers.

**TABLE 20.1** AVB Maximum Transit Time

### 20.3.5 IEEE 1722 and IEEE 1722.1 (AVBTP)

IEEE 1722 and IEEE 1722.1, also referred as the AVB Transmission Protocol (AVBTP), are layer 2 protocols that operate on top of the AVB protocols and mechanisms described earlier. IEEE 1722 handles the actual transmission of media data, reusing established protocols (e.g., IEEE 1394). Currently, it is possible to transmit the following formats as can be found in the specification [1]:

- IEC 61883-2:2004: SD-DVCR data transmission
- IEC 61883-4:2004: MPEG2-TS data transmission
- IEC 61883-6:2005: Audio and music data transmission protocol
- IEC 61883-7:2003: Transmission of ITU-R BO.1294 System B
- IEC 61883-8:2008: Transmission of ITU-R BT.601 style Digital Video Data
- IIDC 1394-based Digital Camera Specification [B8]

In addition to standardized frame formats, AVBTP also defines the *presentation time* a timestamp, expressed in nanoseconds referring to the IEEE 802.1AS time when a received data unit of the AVBTP has to be presented by the listener. It represents the time when the sample is sent from the talker plus a constant, the maximum transit time to take the maximum network latency into account. AVBTP defines maximum transit times (i.e., the maximum network latency) per traffic class as shown in Table 20.1.

Therefore, for professional applications, a maximum transit time of 2 ms should not be exceeded. The maximum transit time depends on the number of hops and network speed and can vary. The requirement is not to exceed this limit for a network of seven hops using full-duplex Ethernet for class A, or two wireless plus six Ethernet hops using traffic class B. The talker defines the presentation time *in the future* by adding the maximum network latency to the actual IEEE 802.1AS time, and it is also in the responsibility of the talker to make sure the AVBTP data unit is handled over to the MAC no later than *presentationtime*—*max.traveltimes* to ensure timely delivery. Eventually, the talker needs to further add some time due to the talker's internal implementation, but this is not covered in IEEE 1722 and is up to the application. Any other required timing delays due to format conversion or video compression are also not handled by AVBTP and must be taken into account on an application level. The synchronization of audio and video (also called *lip sync*) has to be done at the application level but can take advantage of the global timebase already established.

## 20.4 Target Domains and Components

The target market for AVB has been, as the name suggests, audio and video applications. In particular, the AVB technology targets at in-car entertainment, professional audio/video equipment like studio equipment, consumer electronics, and large-scale audio/video installations like in theaters or amusement parks. Large IT networking and semiconductor companies implement AVB in their solutions and have their products operational in the field.

The TSN task group further develops the AVB technology toward more time-sensitive and potentially also time-critical networked applications. Examples of domains targeted by TSN are factory automation and industrial control and automotive driver assistance systems. Indeed, recent academic studies analyze AVB for driver assistance systems [2] and present simulation results. It will be interesting to

study the performance improvements taking the TSN-developed mechanisms into account. As the standardization process in IEEE 802.1 usually takes several years, it is common that IT companies and silicon vendors implement prestandard versions of the technology under standardization. Out of the current activities of the TSN task group, the time-aware shaper (IEEE 802.1Qbv) is probably the most stable piece of technology, and it is likely that upcoming products will support this basic form of time-triggered communication.

In general, the benefit of technology becoming part of the IEEE 802.1 family of standards is in its usual broad market acceptance and deployment. Hence, it is fair to expect a constant growth of devices and components that implement the AVB and TSN technologies. The interoperability of these devices is thus a major requirement. Hence, well-known experts like the University of New Hampshire InterOperability Laboratory help to ensure the interoperability of Ethernet devices from different vendors. For AVB (and in the future most likely also for TSN) AVnu Alliance ([www.avnu.org](http://www.avnu.org)) forms the bridge between the IEEE standardization activities and the commercial markets. While TSN/AVB standardizes a baseline technology, particular products will typically implement additional, probably not standardized or prestandard, functionality. For example, bridges typically implement *metering* functions that implement input policing. The significance of the IEEE 802.1 TSN/AVB standardization activities has also influenced other real-time Ethernet products for industrial communication, for example, upcoming TTEthernet products will be compatible with TSN/AVB.

### 21.1 Introduction

---

The measurement of time and time intervals has been subject to investigation since the dawn of mankind. With the rise of spatially distributed computers connected by a data network, the need to establish a network-wide timebase has sparked the interest in clock synchronization. One of the first works covering the ordering of events in a distributed network was published by Lamport in 1978 [1]. In the following, a plethora of algorithms and protocols have been designed, not only to enable the ordering of events but also to provide a common notion of time. This degree of synchronization additionally enables to coordinate and schedule actions between multiple computers connected to a common network. Nowadays, clock synchronization is often considered as a basic service of a network technology.

The widespread success of Ethernet and the use of the Internet Protocol (IP) enabled to connect billions of nodes using a universal and flexible communication scheme. Yet, neither Ethernet nor IP have been designed to support real-time capabilities required for numerous applications, such as industrial control, test and measurements networks, or audio and video applications. Common to these applications is that they demand clock synchronization, for example, to synchronize audio to video streams, to fuse sensor data originating from different sensor entities, or to coordinate the access to a shared medium. Fortunately, clock synchronization can be retrofitted to any kind of network even if it has not been designed for it.

This chapter addresses clock synchronization in distributed systems in general and gives particular insight into two state-of-the-art synchronization protocols, namely, the Network Time Protocol (NTP) and the Precision Time Protocol (PTP).

## 21.2 Clock Synchronization in a Nutshell

---

This section provides an overview of clocks and their synchronization and briefly describes the most common approaches for synchronizing clocks.

### 21.2.1 Clocks

A clock can be considered an instrument to measure, keep, and indicate time. Practically, all clocks are built as a two-part device: An oscillating device for defining a reference time interval (e.g., a second or fraction thereof) and a counter device, which accumulates the number of time intervals and provides a time indication. Mechanical oscillators, such as a pendulum or balance wheel, have been widely used for timekeeping until the invention of electronic oscillators. Quartz-crystal oscillators are today the most widely used oscillators, thanks to their low price, ruggedness, and low power consumption. Atomic clocks provide a much better stability than Quartz oscillators or any mechanical oscillator. They exploit the quantum effect, where the transition between two energy levels in an atom requires exactly a certain amount of energy to emit a photon. As the frequency of the emitted photon and its energy are connected by the Planck's constant, the atomic resonance can be exploited to create a well-defined frequency. Due to the stability of the quantum transition, the SI unit second was defined in 1967 as the duration of 9,192,631,770 periods of the radiation of the two hyperfine levels of the ground state of the cesium-133 atom [2].

The second part of a clock is a counter or accumulator, which sums up the oscillations. These oscillators are then divided by a certain number to generate seconds, minutes, hours, and so on. In wrist-watches, for example, the 32,768 Hz oscillation of a Quartz is divided by a 15 bit counter ( $2^{15} = 32,768$ ) to generate a 1 s tick signal. Naturally, a clock must be set up initially to have an offset-free time indication with respect to a given reference clock. An ideal clock, consisting of an oscillator with known and constant frequency and a counter with an unbiased initial offset, would maintain the reference time  $t$  infinitely. However, neither the initial offset can be set without error, nor do real oscillators keep a constant and stable oscillation frequency for an infinite amount of time. In particular, the immunity of the oscillation frequency on environmental changes (e.g., temperature, mechanical stress) is critical for the stability of a clock. Due to inevitable offset initialization error and the limited stability of clocks, periodic clock synchronization is required to maintain a time indication with low offset with respect to the reference clock for an extended amount of time. A simple approach to describe the time  $t_j$  at clock  $j$  by only two parameters  $a_j$  and  $b_j$  is

$$t_j(t) = a_j t + b_j, \quad (21.1)$$

with  $a_j$  being the rate of the clock  $j$  and  $b_j$  the offset, both with respect to the reference clock  $t$ .  $a_j$  is commonly termed clock skew as it describes the clock speed ratio with respect to the reference. Synchronization aims for minimizing the clock offset error

$$e = t_j(t) - t \quad (21.2)$$

between the clock under investigation and the reference by an exchange of time information. This information can be shared by various means: It can be transmitted encapsulated as data in the form of a timestamp over a packet network, or implicitly in the form of a pulse signal, which allows the slave clock to synchronize to the reference clock.

### 21.2.2 Basic Synchronization Principle

Independent of how the time information is shared, the packet-based synchronization of state-of-the-art protocols is either based on a one-way or two-way message exchange. The one-way message exchange mechanism transmits timing information from the time source to the sink. Two-way synchronization extends the one-way exchange by sending packets from the sink back to the source. This allows for measuring the round-trip time and thus compensating for the path delay. Examples for such protocols are the NTP [3], which is commonly used to synchronize PCs over the Internet, and the IEEE 1588 standard defining the PTP [4], which is used in a variety of fields, such as test and measurement, or in industrial applications.

To demonstrate the basic synchronization principle, consider a synchronization scenario with two clocks  $i$  and  $j$ . Without loss of generality, we assume that clock  $i$  is identical to the reference clock, and therefore  $t_i = t$  and clock  $j$  synchronizes to clock  $i$ . We assume the skew  $a_j = 1$ , which means the clocks differ by a time-invariant constant offset  $b_j$  as indicated in Figure 21.1 by the arrow pointing from the time  $t_i = 0$  to  $t_j = 0$ .

The synchronization procedure is initiated by device  $i$  at time  $t_1$  by transmitting its current time  $t_1$  in the form of a timestamp to clock  $j$ . After an unknown propagation delay  $T_{ij}$ , the clock  $j$  receives the notification at  $t_2$ . The process is reversed by  $j$  sending a timestamp at  $t_3$  to  $i$ , which receives it after  $T_{ji}$  at  $t_4$ . The propagation times  $T_{ij}$  and  $T_{ji}$  can therefore be expressed by

$$T_{ij} = (t_2 + b_j) - t_1, \quad (21.3)$$

$$T_{ji} = t_4 - (t_3 + b_j). \quad (21.4)$$

If (21.3) is substituted into (21.4), the delay  $b_j$  can be expressed by

$$b_j = \frac{(t_1 - t_2) - (t_3 - t_4)}{2} + \frac{T_{ij} - T_{ji}}{2}, \quad (21.5)$$

where  $(T_{ij} - T_{ji})/2$  represents the asymmetry of the communication channel. If the skew  $a_j \neq 1$ , the rate of clock  $j$  is different than the one of  $i$ , and the timestamps between  $i$  and  $j$  cannot be converted by simply adding the offsets, as the skews scale the time spans,

$$t_j = \frac{a_j}{a_i} (t_i - b_i) + b_j. \quad (21.6)$$

When converting times with respect to the reference clock  $t$  with  $a = 1$  and  $b = 0$  to clock  $j$ , (21.6) can be simplified to  $t_j = a_j t_i + b_j$ . If we stack (21.3) and (21.4) into matrix notation using (21.6), the clock skew

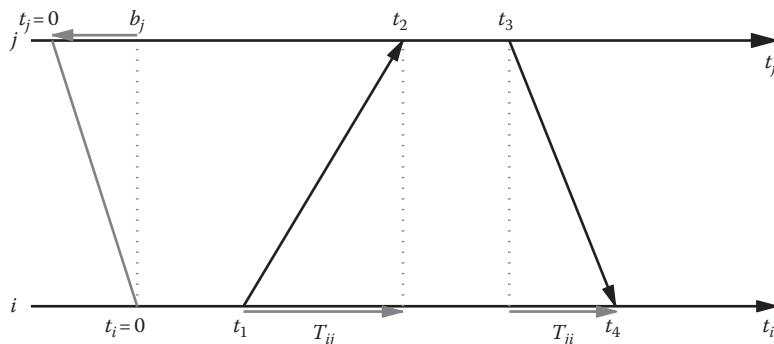

FIGURE 21.1 Generic clock synchronization message flow.

and offsets with respect to the reference clock can be found by solving the equation system using a least-squares solution. The parameter  $N$  corresponds to the number of rounds of two-way message exchanges.

$$\begin{bmatrix} t_1^{(1)} \\ \vdots \\ t_1^{(N)} \\ -t_4^{(1)} \\ \vdots \\ -t_4^{(N)} \end{bmatrix} + \begin{bmatrix} T_{ij} \\ \vdots \\ T_{ij} \\ T_{ji} \\ \vdots \\ T_{ji} \end{bmatrix} = \begin{bmatrix} t_2^{(1)} & 1 \\ \vdots & \vdots \\ t_2^{(N)} & 1 \\ -t_3^{(1)} & 1 \\ \vdots & \vdots \\ -t_3^{(N)} & 1 \end{bmatrix} \begin{bmatrix} a_j \\ b_j \end{bmatrix} \quad (21.7)$$

As visible from (21.5), it is impossible to perform pairwise synchronization on the basis of the timestamps  $t_1$  to  $t_4$ . As a result, (21.7) has a rank deficit of one and therefore one degree of freedom, the asymmetry. Even an infinite number of timestamp sets are not sufficient to synchronize two clocks, when  $T_{ij}$  and  $T_{ji}$  are considered unknown but constant. Yet, even in this general case, the clock skew  $a_j$  and round-trip delay  $T_{ij} + T_{ji}$  can be calculated just by the timestamps. A common assumption to enable synchronization is to assume constant (or even zero) asymmetry, which renders the last term in (21.5) to a known constant. Hence, the asymmetry needs to be provided by, for example, a previous measurement or calibration. This approach is, for instance, taken by PTP [4].

### 21.2.3 Taxonomy of Clock Synchronization Approaches

Given the limited stability of real clocks, the aim of clock synchronization is to establish a common notion of time, compensating for offset and rate errors. Clock synchronization approaches can be classified by several criteria as listed in the following. Within each class, the main ideas are only outlined in a representative way and should not be considered comprehensive.

#### Degrees of synchronization

1. Ordering of events: The protocol ensures that events are ordered in the correct chronological sequence, for instance, by Lamport timestamps [1]. Yet, the exact time of an instant is not estimated. The ordering of events is just a weak notion but might be sufficient for databases or simple monitoring.
2. Relative synchronization: Relative synchronization aims for synchronizing all nodes within a network to a common timebase; it is also referred to as internal synchronization. Relative synchronization is sufficient for many applications such as delay measurements, coordinated actions, or distributed measurements.
3. Absolute synchronization: This type of synchronization aims at synchronizing devices to an absolute (external) reference and is therefore also called external synchronization. It demands access to an absolute time source (e.g., a receiver locked to a global navigation satellite system [GNSS]). It is the strongest notion.

#### Which devices are synchronized?

1. Sender/receiver (SR) synchronization: A sender submits its time indication in the form of a timestamp message to one (or multiple) receivers. The receivers take a timestamp at the arrival of this message and use the difference between the sender's and their local timestamp, corrected by the offset, to synchronize to the sender. In a steady-state condition, the sender and all receivers are synchronized.
2. Receiver/receiver (RR) synchronization: A sender broadcasts an arbitrary message to multiple receivers. The receivers timestamp the message upon reception and exchange the timestamp information with other receivers that have captured the same message. The difference between

the foreign receivers' timestamps and the own timestamp is used to steer the local clock. Thus, only the group of receivers are synchronized, while the sender remains unsynchronized. RR synchronization does not require any timestamping capabilities in the sender; thus, any device that delivers a sufficient stream of packets to the receivers can be used.

#### Propagation time correction

1. No offset correction: Clock offsets are not corrected for the propagation time of the message. Thus, in an SR synchronization scheme, the receivers lag behind the sender; in an RR synchronization scheme, the clock offset of two receivers depends on the propagation time difference of the sender with respect to the receivers.
2. Round-trip time-based correction: Clock offsets are corrected by round-trip measurements with the assumption that the individual path delays are exactly half the round-trip time, i.e., no asymmetry. Given this condition is fulfilled, SR synchronization achieves unbiased synchronization.
3. Individual path delay correction: Round-trip time-based offset correction creates synchronization offsets for asymmetric propagation paths. In this case, the individual propagation delays in each direction (up and down link) need to be measured. Note that general purpose synchronization protocols based on timestamps are unable to perform asymmetry measurements. Thus, asymmetry cannot be resolved unless the physical layer provides support for such measurements (e.g., reflectometric cable length measurements).

#### Timestamping method

1. Software-based timestamping: Timestamps are taken within the device driver or within the application upon the reception of a packet. As the packet processing delay in software depends on the current system and bus load, timestamps are superimposed by nondeterministic jitter.
2. Hardware-based timestamping: Timestamps are taken by dedicated timestamping hardware that removes all jitter impairments from the software. Yet, as hardware timestamps cannot be taken with arbitrary resolution, a small timestamping jitter still remains. Hardware timestamping is used for applications aiming at high synchronization accuracy.

### 21.2.4 Synchronization Approaches for Packet-Based Networks

Clock synchronization based on the exchange of time information encapsulated in data packets is one of the widely used synchronization techniques due to its seamless integration into existing network and communication techniques. It should be remarked that legacy synchronization technologies exist as well, for example, based on pulses coupling of multiple nodes [5]. Yet, pulse-based synchronization and similar schemes are rather used for niche applications where packet-based message exchange is not available or unsuitable. Messages containing timestamps can be transmitted from the reference clock to the clock to be synchronized, the so-called slave clock, by various means: as wireless signal, for example, from a terrestrial transmitter, satellite, or access point, or using wired communication media, such as Ethernet or an Internet connection. In the following, a number of state-of-the-art synchronization technologies outlining the strengths and limitations of each approach are briefly introduced, yet without providing a comprehensive comparison. Subsequently, the NTP and the PTP are covered in more detail in Sections 21.3 and 21.4.

#### 21.2.4.1 DCF77

Among the first examples of time distribution systems, the DCF77 [6] system should definitely be mentioned. DCF77 sends the time information using long waves with a standard radio station. The primary DCF77 transmitter is located in Mainflingen, Germany, and started radio transmission on January 1, 1959.

The carrier signal at 77.5 kHz is generated from local atomic clocks that are linked with German master clocks. The time provided by the radio transmission is Universal Time Coordinated plus 1 h (UTC + 1), Central Europe Time. The DCF77 signal is modulated using amplitude-shift keying by reducing the carrier amplitude for 0.1 or 0.2 s at the beginning of every second. Every full minute is marked by no carrier power reduction. The same signal is also modulated using phase modulation combined with direct-sequence spread spectrum (DSSS) using a 512 bit long pseudorandom sequence. The synchronization accuracy that can be obtained using the DCF77 signal is limited by wireless propagation conditions and by the technology adopted in the implementation of the receiver. Normal low-cost DCF77 receivers, which typically use only the amplitude-modulated time signal, have a synchronization uncertainty on the order of 0.1 s, enough for radio-controlled low-cost clocks. For more demanding devices, which require an accurate time information, a DCF77 receiver based on the cross-correlation of the phase-modulated time signal can be used to obtain an accurate estimation of the beginning of the second markers. Using this solution, a synchronization accuracy on the order of tens of microseconds can be achieved [7]. Similar radio time signal stations with slightly different modulations and encodings are deployed all over the world, such as the WWVB in Fort Collins, the United States, or the TDF in Allouis, France.

#### **21.2.4.2 Global Positioning System**

One of the most commonly used GNSSs is the Navigation Satellite Timing and Ranging System (NAVSTAR GPS). The concept of global positioning system (GPS) was developed for the US Department of Defense (DoD) starting in the 1970s, and the system became fully operational in 1994. Each GPS satellite is equipped with four atomic clocks (two rubidium and two cesium clocks) with a fundamental frequency slightly below 10.23 MHz. This slight frequency skew ( $-0.4467 \text{ ppb}$ ) is required to compensate for relativistic effects so that the clock appears as 10.23 MHz for a GPS receiver on the ground [8]. The legacy GPS navigation signals are transmitted on two frequencies, the L1 and L2 band. The L1 band operates with a center frequency of 1575.42 MHz, 154 times the fundamental frequency, and broadcasts the course/acquisition code (C/A code) and the precision code. As the precision code is encrypted, forming the so-called Y-code, it is abbreviated with P(Y). The L2 band at 1227.60 MHz carrier frequency, 120 times the fundamental frequency, transmits the P(Y) code only. The C/A code is free for civilian use, while the encrypted P(Y) code is only accessible for military or special organizations.

The ephemerides of the satellites as well as the clocks are constantly monitored by multiple ground stations. The measurements taken by the ground stations are communicated back to the satellites, which embed this information into the navigation messages sent to the GPS receivers. A GPS receiver tracks the signals of at least four GPS satellites and calculates its four unknown quantities, the three coordinates, and the clock offset to the satellite system. Thus, a GPS receiver can provide an accurate time indication with respect to the synchronized GPS. According to [9], a C/A receiver can provide a median clock offset of below 19 ns with respect to the reference clock network. The versatility and high accuracy of GPS makes clock synchronization using GPS a good choice for synchronization over larger distances. Nevertheless, it should be pointed out that GPS is under the control of the DoD and that deteriorations, such as selective availability, might be reenabled in crisis or wartimes. In addition, the low transmission power of GPS (and in general any GNSS) allows for jamming and spoofing of the signals. Thus, for a safety-critical systems, a synchronization backup solution should be available.

#### **21.2.4.3 Inter-Range Instrumentation Group**

The Inter-Range Instrumentation Group (IRIG) standard [10] defines a set of timecodes, each of them characterized by its own specific attributes. The IRIG signal consists of a carrier that is modulated to transfer the timecode. The type of the carrier and its frequency depend on the type of IRIG encoding adopted. The different timecodes are identified by alphabetic designations: A, B, D, E, G, and H. A three-digit

numerical suffix defines the type and the frequency of the carrier. The three modulations supported are direct current level shift (DCLS), sine wave carrier (amplitude modulation), and Manchester modulation. The main difference between the codes is the data rate, which ranges between 1 and 10,000 pulses/s. The time information provided by the IRIG signal includes the binary coded decimal (BCD) representation of the day of year, hours, minutes, seconds, and fractions. Additional time information (such as year) can be optionally provided. One of the most common IRIG codes is IRIG-B. This code provides a bit rate of 100 Hz and a frame transmission rate, in BCD coding, of every second. The IRIG code is adopted for transferring time information recovered by a primary time source, like a GPS receiver or an atomic clock, using dedicated network infrastructures. A typical application of an IRIG-B encoded signal is the time distribution to measurement and control devices in substation automation systems (SASSs) [11]. Nevertheless, an accurate distribution of the IRIG-B signal requires a dedicated network infrastructure and a periodic calibration of the entire system. Thus, this solution is becoming less and less adopted for the implementation of new systems, for the benefit of network-based synchronization solutions.

## 21.3 Network Time Protocol

---

The NTP is defined in RFC 5905 [12]. NTP systems can operate as a primary server, secondary server, or client. The primary server derives its time directly from a UTC reference clock like GPS or Galileo receiver. On the contrary, the client NTP system can be synchronized to one or more upstream servers, but it is not able to synchronize other clients. The last type, the secondary server, lies in between primary servers and clients; for this reason, in large NTP networks, the implementation of secondary servers is critical since they pass synchronization from high layers to end user clients. The NTP protocol can be implemented in three variants: client/server, symmetric, and broadcast:

1. Client/server variant: The client sends request packets to the server that answers, providing synchronization. Generally, a server can deal with several clients, while it does not accept synchronization from any client. Clearly, the server may be directly connected to a UTC standard source (e.g., GPS receiver). Note that in this variant, clients ask for synchronization to the servers.
2. Symmetric variant: The NTP implementation is at the same time a server and client. Two possibilities are allowed: symmetric active association or symmetric passive association. The symmetric active association is persistent (i.e., it is created and never destroyed) and operates by sending packets to the correspondent symmetric active peer association. The symmetric passive association is ephemeral (i.e., it is created on packet arrival, and it is destroyed if an error or timeout occurs). Note that in this variant, each peer bidirectionally requests and sends synchronization information. Thus, the peer is also a client.
3. Broadcast variant: The broadcast server associations are both persistent and ephemeral. The broadcast server is persistent and periodically transmits packets that are received by multiple clients. On the contrary, the broadcast client association is ephemeral since it is created when a packet from a broadcast server is received and it remains active until error or timeout occurs. Sometimes, the client starts with the client/server variant and after an initial synchronization (for delay calibration and security setup) becomes a broadcast client. Note that in this variant, the server sends synchronization information to clients or other servers.

NTP is organized as a hierarchical structure of servers to which the clients are connected. The servers' level in the hierarchy is given by the stratum number. Stratum one is the level of the primary servers; all the secondary servers have stratum numbers higher than one: specifically, one greater than the preceding level. The highest stratum number for the current NTP version is 15. Usually, the server accuracy decreases as the stratum number increases, since the network path becomes longer and the cascade of multiple clocks decreases the clock stability. Generally speaking, in NTP networks, the synchronization mean errors are proportional to the server stratum number. For this reason, the NTP topology should

minimize the synchronization distance between servers and between servers and clients, although loops should be avoided. A variant of the Bellman-Ford distributed routing algorithm is used to determine the shortest-path spanning tree that originates from the primary servers. A network topology can be rearranged to overcome the results of failures (both physical faults and timing-related errors).

### 21.3.1 NTP Time Scale, Time Format, and Other Definitions

For NTP implementations, two timescales are considered: UTC time for dating events and the running time, which is the output of the NTP synchronization function. Depending on the context, the timestamp  $T(t)$  may represent either the UTC date of an event or the time offset from UTC at a given running time  $t$ . If  $T(t)$  is the time offset,  $R(t)$  is the frequency offset (expressed in seconds-per-second (s/s) or ppm), and  $D(t)$  is the aging rate (first derivative of  $R(t)$  with respect to  $t$ ). If  $T(t_0)$  is the UTC time offset determined at  $t = t_0$ , the UTC time offset at time  $t$  can be expressed by

$$T(t) = T(t_0) + R(t_0)(t - t_0) + \frac{1}{2}D(t_0)(t - t_0)^2 + e. \quad (21.8)$$

The term  $e$  in (21.8) refers to the stochastic error term. The performance of the NTP timekeeping function is computed each time a time information exchange takes place using four statistics. As defined in the standard, these statistics are as follows:

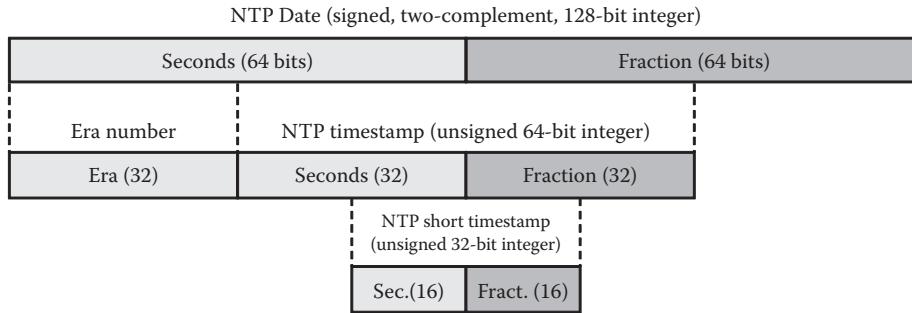

1. The offset  $\theta$  represents the maximum-likelihood time offset of the server clock relative to the system clock.
2. The delay  $\delta$  represents the round-trip delay between the client and server.
3. The dispersion  $\epsilon$  represents the maximum error inherent in the measurement. It increases at a rate equal to the maximum disciplined (hardware) system clock frequency tolerance  $\Phi$ . Note that  $\Phi$  is system-dependent, involving an assumption about the system worst-case behavior in case the time source (e.g., the NTP server) has become unreachable.
4. The jitter  $\psi$  is defined as the root-mean-square (RMS) average of the most recent offset differences. It represents the nominal error in estimating the offset.

There is a separate group of the four statistics ( $\theta$ ,  $\delta$ ,  $\epsilon$ , and  $\psi$ ) for each server the system clock is connected to. However, the strength of the NTP protocol is the way it combines the statistics of many servers in order to increase the overall system clock accuracy. For this reason, the standard also defines the system statistics:

1. The system offset  $\Theta$  represents the maximum-likelihood offset estimate for the server population.
2. The delta statistic is accumulated at each stratum level from the reference clock to produce the root delay statistic  $\Delta$ .
3. The epsilon statistic is accumulated at each stratum level from the reference clock to produce the root dispersion statistic  $E$ .
4. The system jitter  $\Psi$  represents the nominal error in estimating the system offset.
5. The synchronization distance  $\Lambda$  equal to  $E + \frac{\Delta}{2}$  represents the maximum error due to all causes.

In the NTP system, there are three time formats, shown in Figure 21.2:

1. The 128 bit date format can be used if sufficient memory space is available in the system. This format has the highest resolution and range, since the 64 bit wide seconds field may reach  $584 \times 10^9$  years and the 64 bit fraction may resolve  $0.5 \times 10^{-18}$  s. In order to be compatible with other formats, the seconds field is divided into a 32 bit era number field and a 32 bit era offset field. Usually, era numbers are out of the scope of normal NTP implementations.

**FIGURE 21.2** The three time formats of NTP.

2. The 64 bit time format is commonly used for packet headers and in systems with limited memory space. It is composed of 32 bit unsigned seconds (range of 136 years) and 32 bit fraction (resolution of 232 ps).
3. The 32 bit short format is used only if the range/resolution of the other formats is not required (e.g., for delay and dispersion header fields). It is composed of a 16 bit unsigned seconds field and a 16 bit fraction field.

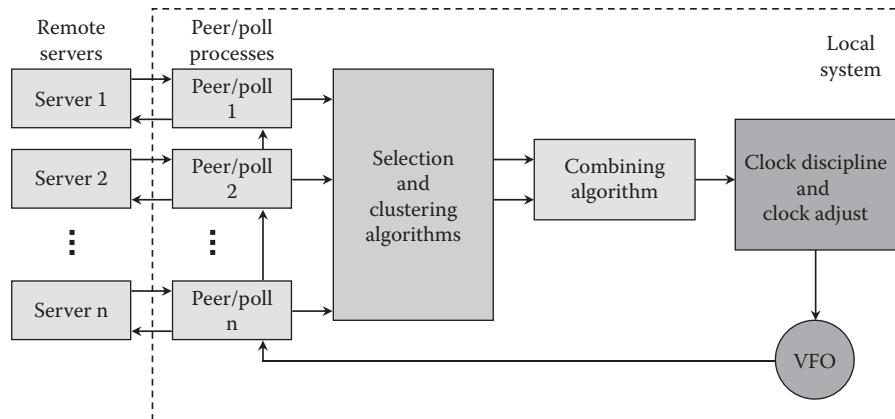

Every time the 32 bit wide seconds field wraps around, a new era is started; the prime epoch, or base date of era 0, is at 0:00, January 1, 1900, UTC, which corresponds to all bits set to zero. A date value greater than zero represents the time after the prime epoch; conversely, a time value less than zero means a time before the prime epoch. Note that dates are signed values while the timestamps are unsigned values; however, only the subtraction is permitted on dates and timestamps, so both of them can be processed with two's complement arithmetic without problems if the timestamp difference is less than 68 years (which is the half of the 32 bit s field range).

The clock resolution depends on the number of significant bits  $p$  in the second fraction field, that is  $2^{-p}$ . Obviously,  $p$  can be lower than 32, meaning that some fractional bits are nonsignificant. Note that for minimal bias, the nonsignificant bits should be randomized to unbiased values. In the NTP standard, the clock precision  $\rho$  is the larger between the clock resolution and the running time needed for reading the system clock. In other words, the very high resolution cannot be exploited if the access time to the system clock is large.

### 21.3.2 NTP Implementation Model

The NTP is usually implemented with a multithread structure, since its basic particularity is the ability to exchange time information with several servers at the same time. For each server, two processes exist, one for receiving messages from servers (the peer process) and one for sending requests to servers (the poll process). For each server, a data structure called association is maintained with all statistics described in the previous section, the network addresses, and the protocol ports used by the partner peer. Every time NTP packets are received, the statistics  $\theta$ ,  $\delta$ ,  $\epsilon$ , and  $\psi$  are updated. The time retrieved by each association is fed to the system process, which includes three algorithms (selection, cluster, and combine) to harmonize/mitigate the various servers, determining which are the most accurate and reliable. A block diagram of the NTP system process is shown in Figure 21.3 to illustrate the interactions between the modules.

1. The *selection algorithm* is used to detect Byzantine faults, that is, discarding the apparently incorrect servers (*falsetickers*) and retaining the good servers (*truechimers*). By standard definition, “a truechimer is a clock that maintains timekeeping accuracy to a previously published and trusted standard, while a falseticker is a clock that shows misleading or inconsistent time.”

**FIGURE 21.3** The block diagram of NTP system process.

2. The *cluster algorithm* is used to classify the truechimers by means of statistical principles, and to identify the most accurate set for further processing.
3. The *combine algorithm* is the last one, and it is used to statistically average the selected truechimers creating the final clock offset.

The obtained offset is passed to the clock discipline process controlling both time and frequency of the system clock, which can be generally represented as a variable frequency oscillator (VFO). The clock discipline process triggers the clock-adjust process every second in order to act on the VFO for time offset and frequency compensation. Note that VFO parameters and drivers depend on both the operating system (OS) and the hardware implementation. The VFO is also the clock source from which all the timestamps are taken, closing the feedback loop of the NTP implementation model.

Note that a client uses the poll process to send messages to the corresponding server using the variable  $\tau$  for the calculation of the poll interval ( $2^\tau$  s). In NTP,  $\tau$  can range from 4 (16 s) to 17 (36 h), and it may vary depending on the clock discipline algorithm that tries to match the *loop-time* constant  $T_c = 2^\tau$ . NTP provides negotiation means for the peers so that they can agree on a common  $\tau$  (which is the minimum of both of them).

### 21.3.3 On-Wire Protocol

The time exchange between peers (servers and/or clients) is the core mechanism of NTP. The on-wire protocol describes how time quantities are exchanged. It is based on four timestamps ( $t_1, t_2, t_3, t_4$ ) and three state variables (origin timestamp “org,” receiving timestamp “rec,” and transmitting timestamp “xmt”), as depicted in the most general case in Figure 21.4. The figure shows two peers, A and B, that autonomously compute the offset and delay with respect to each other. Note that if NTP has direct control over the physical layer, the timestamps refer to the beginning of the first symbol just after the start of frame (SOF). If no physical layer control is available, NTP implementations should attempt to associate the timestamp to the earliest accessible point in the receiving stack. The procedure is the following:

1. The first packet is transmitted by A and contains only the origin timestamp  $t_1$ . After sending,  $t_1$  is copied to the “xmt” state variable of A as  $T_1$ .
2. B receives the packet at  $t_2$  (the receive timestamp) and copies it to the “rec” state variable of B as  $T_2$ . The  $t_1$  inside the packet is copied to the “org” state variable of B as  $T_1$ .

3. Immediately, or some time later than  $t_2$ , B sends a packet to A at  $t_3$ ; the packet contains  $t_1$  and  $t_2$  and the transmit timestamp  $t_3$ . The timestamp  $t_3$  is copied to the “xmt” state variable of B as  $T_3$ .
4. When A receives the packet at the destination timestamp  $t_4$ , it copies  $t_3$  to the “org” state variable of A as  $T_3$  and  $t_4$  to the “rec” state variable of A as  $T_4$ .

The algorithm implements two sanity checks: In order to discover duplicated or replayed packets, the transmit timestamp  $t_3$  is compared with the “org” state variable  $T_3$ . If they match, the packet is duplicated and should be discarded. In order to discover bogus packets, the origin timestamp  $t_1$  is compared with “xmt” state variable  $T_1$ . If they match, the packet is correct (and the “xmt” state variable is set to zero). In case of corruption, the packet is discarded. With the described sanity checks, the protocol can resist the replay of server response packets, but it is still vulnerable to the replay of client packets. In this case, the server replays again with new values of  $T_2$  and  $T_3$ . This vulnerability is eliminated, if the “xmt” state variable is set to zero after the offset and delay computation as described in the following. For each peer, the four most recent timestamps ( $T_1$ ,  $T_2$ ,  $T_3$ ,  $T_4$ ) are used to compute the offset and the round-trip delay of B relative to A as described in the standard:

$$\theta = T_B - T_B = \frac{(T_2 - T_1) + (T_3 - T_4)}{2}, \quad (21.9)$$

$$\delta = T_{ABA} = (T_4 - T_1) - (T_3 - T_2). \quad (21.10)$$

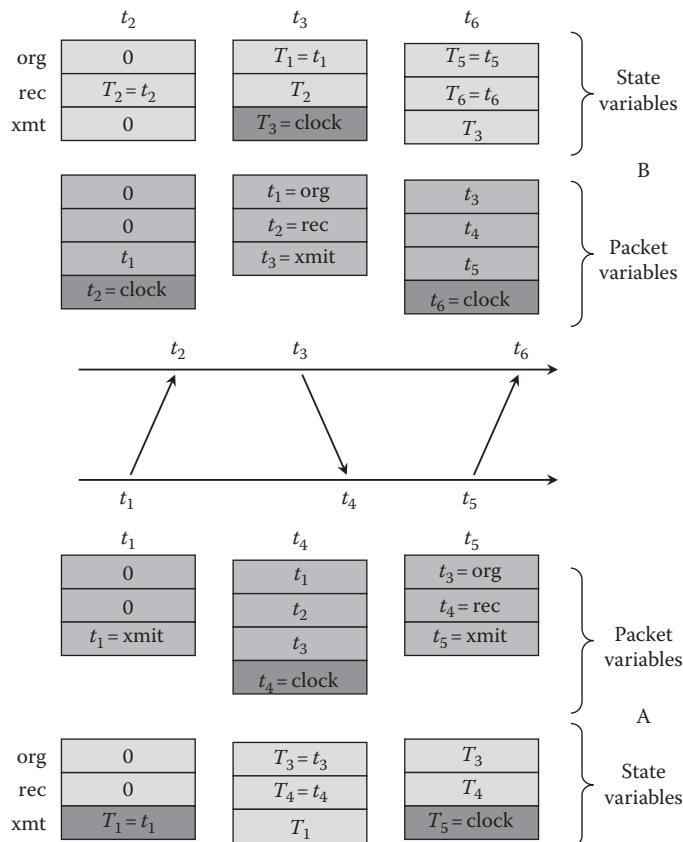

FIGURE 21.4 The NTP time exchange between peers.

These equations match the basic equations of the two-way message exchanges described by (21.3 through 21.5). In addition, the peers need to estimate the dispersion statistic  $\epsilon(t)$ , which represents the maximum error due to the frequency tolerance and time since the last packet was sent. The initial value of  $\epsilon$  at  $t_0$  is

$$\epsilon(t_0) = \rho_p + \rho_s + \Phi \cdot (T_4 - T_1), \quad (21.11)$$

where

$\rho_p$  is the precision of the timestamps in the received packet

$\rho_s$  is the system precision

The two terms take into account the uncertainty in reading the system clock for the server and the client, respectively. As a result, the dispersion grows linearly at rate  $\Phi$  (which is constant, the default value of  $\Phi$  is 15 ppm or about 1.3 s/day). Note that special care must be taken when these calculations are executed on a real platform in order not to lose resolution. Moreover, known problems may arise if the server and client time has a starting time difference greater than 34 years, or if the initial frequency offset is large and the propagation delay is small. In order to fix these problems, a set of parameters (value clamping and saturation) is provided by the software implementation. Generally speaking (Figure 21.4), the synchronization mechanism is bidirectional: the peer  $B$  can also estimate the offset of  $A$  relative to  $B$ , the next time a packet is exchanged (using timestamps  $T_3, T_4, T_5, T_6$ ). In case the NTP server  $B$  is not required to estimate the offset to the client  $A$ , the server only appends the timestamp  $T_3$  to the timestamps  $T_1$  and  $T_2$  of the client packet, without implementing the “org,” “rec,” and “xmt” state variables.

In conclusion, the on-wire protocol can be considered resistant to dropped or duplicated packets, without requiring any flow control or retransmission mechanism. Nevertheless, the implementation must pay attention to the fact that the timestamps should be as accurate as possible, meaning that they have to be recalculated in case of retransmission at the link level or in case of security computations during transmission.

### 21.3.4 Network Data Packet for NTP

The NTP packet is transported inside a UDP datagram. The specific UDP port 123 has been assigned by Internet Assigned Numbers Authority (IANA) for use with NTP. In case of broadcast servers, the IPv4 multicast group address 224.0.1.1 and the IPv6 multicast address ending: 101 are also reserved by IANA for NTP. The NTP packet is composed of three parts: the header, the extension fields, and the message authentication code. Only the header is mandatory since it includes the most relevant variables. The header consists of an integral number of 32 bit words. The optional fields are used for authentication and security mechanisms, like the Autokey public key cryptographic algorithms [13] or the native symmetric key cryptographic authentication algorithm (128 bit MD5) defined in the NTP standard. Authentication and security fields are computed at transmission time, implying additional delays. Such a situation must be properly taken into account when writing the transmission timestamps to the packet header. The packet also includes a 32 bit Reference ID (refid), which is used to identify the time server or reference clock. This 32 bit field can carry a four-character ASCII string defined by IANA in case of servers belonging to stratum 1; otherwise, it encodes the IPv4 address (or the MD5 hash of the IPv6 address) of the server. The primary purpose of the Reference ID is to avoid timing loops across large NTP networks. The header includes four timestamps in the NTP timestamp format: the Reference Timestamp, which is the time when the system clock was set or corrected for the last time; the Origin Timestamp, which corresponds to the “org” state variable (departure time of the client request); the Receive Timestamp, which corresponds to the “rec” state variable (arrival time at the server of the client request); and the Transmit Timestamp, which corresponds to the “xmt” state variable (departure time of the server response). Note that the Destination Timestamp (i.e., the arrival time at the client of the server response) is not transported in the packet, but it is made available in the client receive buffer by the NTP implementation.

### 21.3.5 NTP Managing Process

The NTP core is focused on filtering and analyzing the time information coming from several servers. In the following, the most important of these processes are described.

#### 21.3.5.1 Clock Filter Algorithm

The clock filter algorithm is used to produce, for each peer, the following variables: offset  $\theta$ , delay  $\delta$ , dispersion  $\epsilon$ , jitter  $\psi$ , and time of arrival  $t$ . The output of the filter algorithm is fed to the mitigation algorithms, which determines the best control strategy for disciplining the system clock. The clock filter algorithm uses the eight most recent sample tuples  $(\theta, \delta, \epsilon, t)$  in the order of packet arrival. When a new packet is received, the least recent tuple is discarded. If a request is not answered by the server, a dummy tuple  $(0, "maximum\_dispersion," "maximum\_dispersion," 0)$  is inserted in the filter stages; suitable controls are implemented to release associations when too many requests are dropped by the server. The operation of the filter algorithm is outlined in the following:

1. The eight tuples in the filter are sorted by increasing  $\delta$ . Only the valid tuple relative to received packets are considered.
2. The filtered  $\epsilon$  (i.e. dispersion of the considered peer) is calculated as

$$\epsilon = \sum_{i=0}^{n-1} \frac{\epsilon_i}{2^{(i+1)}},$$

where

$i$  is the list order

$\epsilon_i$  is the epsilon variable of the tuple

$n$  is the number of valid tuples in the filter ( $n > 1$ )

Given this formula, the filter produces a dispersion less than 1 s if at least four valid packets were received in the last eight polls.

3. The  $\theta$  of the first tuple of the ordered list is used as  $\theta_0$  for the calculation of the filtered jitter (which is the RMS average of all the valid tuples)

$$\psi = \sqrt{\frac{1}{(n-1)} \sum_{j=1}^{n-1} (\theta_0 - \theta_j)^2}.$$

Note that  $\psi$  is low-saturated to the system precision for avoiding inconsistency. The jitter is used as indicator of the timekeeping performance.

4. The synchronization distance between server and client is obtained from

$$\lambda = \epsilon + \left( \frac{\delta}{2} \right).$$

Note that  $\lambda$  is recalculated every time if needed, starting from the current  $\delta$  and  $\epsilon$ . It is used by the mitigation algorithms to determine the root synchronization distance of servers and to classify their time quality.

#### 21.3.5.2 Mitigation Algorithm

As already introduced, the mitigation algorithm consists of the selection algorithm, the cluster algorithm, the combine algorithm, and the clock discipline algorithms. The mitigation algorithm is run

each time a new tuple  $(\theta, \delta, \epsilon, \psi, t)$  is produced by the clock filter algorithm described before. Note that all associations (server-client relationships) are scanned by the mitigation algorithms. The selection algorithm is used to discard the falsetickers and keep the truechimers. With an iterative procedure, the cluster algorithm reduces the number of associations to the specified minimum, discarding the peers that are statistically away from the centroid. The combine algorithm is used to weight the statistics producing the final estimate, which is then passed to the system clock discipline algorithm. Note that the time-related system variables, which are used for propagating the time to other servers and clients and passed to the applications running on the same machine as NTP, are an output of the cluster algorithm; the cluster algorithm selects one of the surviving truechimers as the system peer, and the system inherits its variables  $(\theta, \delta, \epsilon, \psi, t)$ .

#### 21.3.5.2.1 Selection Algorithm

The selection algorithm tries to find out an intersection interval that contains the majority set of the truechimers. It is focused on the exclusion of Byzantine faults, and it is based on an improved Marzullo algorithm. The selection algorithm is applied only to peers that are usable according to the protocol rules, while others are immediately discarded. For the scope of the algorithm, each server is identified by its midpoint (the offset  $\theta$ ), its upper endpoint  $\theta + \lambda$ , and its lower endpoint  $\theta - \lambda$ , where  $\lambda$  is the root synchronization distance. The algorithm assumes initially that there are no falsetickers and tries to find the nonempty intersection interval that contains midpoints of all the truechimers. It may happen that the nonempty interval cannot be found; in this case, the number of falsetickers is increased by one, and the algorithm tries to find the nonempty intersection that contains midpoints of *all minus one* truechimers, and so on. Two possible outcomes are expected: a nonempty interval is found and the number of truechimers is greater than the number of falsetickers; that is, the majority clique has been found. If there are more falsetickers than truechimers, or the number of truechimers is lower than the minimum number of true servers required by the system, no majority clique can be found. In the first (positive) case, the midpoint of each truechimer ( $\theta$ ) represents the candidate for the cluster algorithm. Note that in most NTP implementations, the minimum number of servers required to be truechimers for running the discipline algorithm is just one. Increasing this lower bound results in a more robust system.

#### 21.3.5.2.2 Cluster Algorithm

The following variables are considered by the cluster algorithm for each candidate  $p$  belonging to the majority clique: the current offset  $\theta_p$ , the current jitter  $\psi_p$ , and the  $QF_p = \text{stratum}_p \cdot \text{MAXDIST} + \lambda$  where  $\text{stratum}_p$  is the stratum of the considered candidate, MAXDIST is the maximum allowed distance, usually set to 1 s, and  $\lambda$  is the root synchronization distance.

$QF_p$  must be considered a merit factor of candidate  $p$ , and it is used to sort the candidates in ascending order. In turn, each candidate is used as the reference, and the selection jitter (RMS average with respect to its  $\theta$ ) is calculated by

$$\psi_s = \sqrt{\frac{1}{(n-1)} \sum_{j=1}^{n-1} (\theta_s - \theta_j)^2}. \quad (21.12)$$

The algorithm is iterated, and in each round, the candidate with the maximum selection jitter  $\psi_s$  is discarded. Two conditions terminate the clustering algorithm: if the  $\psi_s$  is less than the minimum peer jitter  $\psi_p$  (which means that no improvement is possible by discarding candidates), or the number of survivors is less than a given threshold. The *system peer*, whose time variable will be used to update the system time variable, is the candidate with the minimum  $\psi_s$ . On the other hand, the maximum  $\psi_s$  value of the survivors is saved as indicator of the system selection jitter  $\Psi_s$ .

### 21.3.5.3 Combine Algorithm

The combine algorithm receives as input the peer offset and jitter statistics of the remaining survivors after the clustering algorithm. Then, the combine algorithm outputs the combined system offset  $\Theta$  and system peer jitter  $\Psi_p$ . The standard recommends weighting the statistics coming from each server  $j$  using the weighted average as

$$\Theta = \frac{\sum_{j=0}^{n-1} \frac{\theta_j}{\lambda_j}}{\sum_{j=0}^{n-1} \frac{1}{\lambda_j}}, \quad (21.13)$$

$$\Psi_p = \sqrt{\frac{\sum_{j=0}^{n-1} \frac{(\theta_j - \theta_0)^2}{\lambda_j}}{\sum_{j=0}^{n-1} \frac{1}{\lambda_j}}}, \quad (21.14)$$

where

$\theta_0$  is the offset of the system peer selected by the cluster algorithm

$\theta_j$  is the offset of  $j$

$\lambda_j$  is the root synchronization distance of  $j$

Note that in some implementations, the weighted average can be bypassed, and the variable of a preferred peer (among the survivors) is directly used. Note that  $\Theta$  is fed to the clock discipline algorithm, while  $\Psi_p$  is processed together with the selection jitter  $\Psi_s$  in order to obtain the system jitter

$$\Psi = \sqrt{\Psi_s^2 + \Psi_p^2}. \quad (21.15)$$

After this calculation, all the system variables are ready to be used by any applications or program in the local system, so the clock update routine can be called. Resuming, the final system variable set is composed by the system offset  $\Theta$  (the clock offset relative to the considered synchronization sources), the system jitter  $\Psi$  (the estimate of the error in determining the offset), the root delay  $\Delta$  (the total round-trip delay referred to the primary server), the root dispersion  $E$  (the dispersion accumulated from the primary server due to network effect), and finally  $\Lambda$  (the maximum error due to all causes  $\Lambda = E + \Delta/2$ ).

### 21.3.5.4 Clock Discipline Algorithm

In NTP, the strategy adopted by the clock discipline algorithm is rather complex since it is the combination of two feedback controllers. Basically, there is a phase-locked loop (PLL) controller that periodically corrects the time error with update intervals of microseconds. Besides, a frequency-locked loop (FLL) periodically acts on the frequency error with the update interval  $\mu$ . The twin approach is used since usually the PLL is better if the network jitter dominates, while the FLL is better if the local oscillator frequency instability is greater than other contributions. The decision on which control action is taken is based on a state machine, meaning that, actually, the control is nonlinear. Such approach allows very fast recovery from unsynchronized situations at the expense of a more complex algorithm. An in-depth description of the controller is available in the standard. The clock adjustment process is executed every second (interrupt-driven) and passes the control values to the OS, usually relying on the OS's functions. The clock adjust process interrupt is also used by the poll process to trigger the transmission of requests to servers.

### 21.3.6 Simple Network Time Protocol

Servers and clients may comply with a subset of NTP, implementing the RFC4330 Simple Network Time Protocol (SNTP) [14]. The basic difference to NTP is that SNTP does not implement the mitigation algorithms. Generally, the SNTP is used in primary servers that have a single reference clock, or in clients with a single upstream server. Note that NTP and SNTP servers and clients are fully interoperable. The behavior of an SNTP server is indistinguishable from an NTP server from the on-wire protocol point of view. The NTP server has the mitigation algorithms so it is able to manage several upstream time sources, while the SNTP server has a single time reference. When a client request is received, the SNTP server constructs and sends the reply packet only adding the transmit timestamp (no peer state machine is implemented). The SNTP client just implements the on-wire protocol since it has only a single server. The implementation complexity can be scaled, and an arbitrary subset of the on-wire protocol can be implemented. The simplest implementation of the SNTP client just makes use of the transmit timestamp of the server contained in the server response packet; the SNTP client simply updates its system clock to this value.

## 21.4 IEEE 1588 Precision Time Protocol

---

The IEEE 1588 standard specifies the PTP enabling highly accurate clock synchronization in packet-based networks. The initial version of PTP, IEEE 1588 version 1, was approved in 2002. In 2008, the second release of IEEE 1588, version 2 or 2008, was published. Apart from the change of the data format, many new features have been introduced and refinements have been made to improve various aspects, such as the synchronization accuracy, fail-over to alternate masters, and management support. As of 2013, a refinement of IEEE 1588 version 2 is considered by the IEEE 1588 committee, which is intended to be backward compatible to version 2. PTP has been designed as a general-purpose synchronization protocol, which can be used over any kind of network and topology. The roots of PTP originate from the test and measurement field where PTP should synchronize multiple distributed measurement instruments. Since the rise of IEEE 1588, the fields of application have extended to power engineering, factory automation systems, real-time communication, telecommunications, and audio-video broadcasting.

PTP is a master-slave synchronization protocol defining mechanisms to find the best master in the network, and to synchronize all slave devices to the master. In the PTP nomenclature, all devices that participate in synchronization are termed *clocks*. Clocks can be categorized into *ordinary clocks*, *boundary clocks*, *end-to-end transparent clocks*, and *peer-to-peer transparent clocks*. The class of ordinary clocks consists of *master clocks*, which provide the time reference to other nodes, and *slave clocks*, which synchronize to a master clock. Figure 21.5 depicts the model of an ordinary clock. It consists of the local clock, the PTP control engine, the data and port data sets, timestamping functions for event messages, and application-specific functions. The latter are used, for instance, to generate timing signals, to trigger external actions, or to timestamp external signals. The core of an ordinary clock is the local clock, which contains a time indication device, depicted as watch, and a control servo, which performs adjustments in offset and skew as requested by the PTP protocol engine.

A dedicated master clock synchronizes a group of slaves. This master clock can be either a boundary clock, a clock synchronizing itself to another PTP clock, or a PTP *grandmaster*, which is ideally the best synchronized node in a whole system, such as a node connected to a GPS receiver or an atomic clock. The protocol has two phases, the start phase and the synchronization phase. In the start phase, the best master clock (BMC) algorithm is elected by the so-called BMC algorithm, which finds the device with the best accuracy. After the BMC algorithm has decided which node to promote as master clock, the synchronization phase is started where the slave clocks synchronize to the master clock by an exchange of synchronization messages.

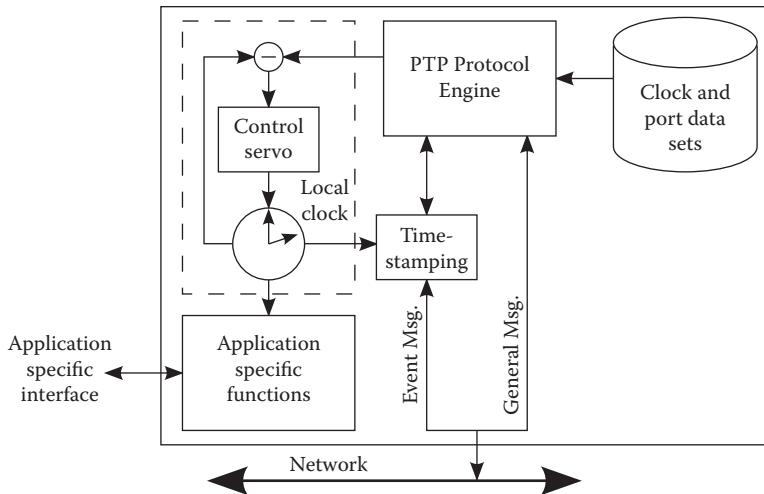

FIGURE 21.5 Model of an ordinary PTP clock.

#### 21.4.1 Master Election

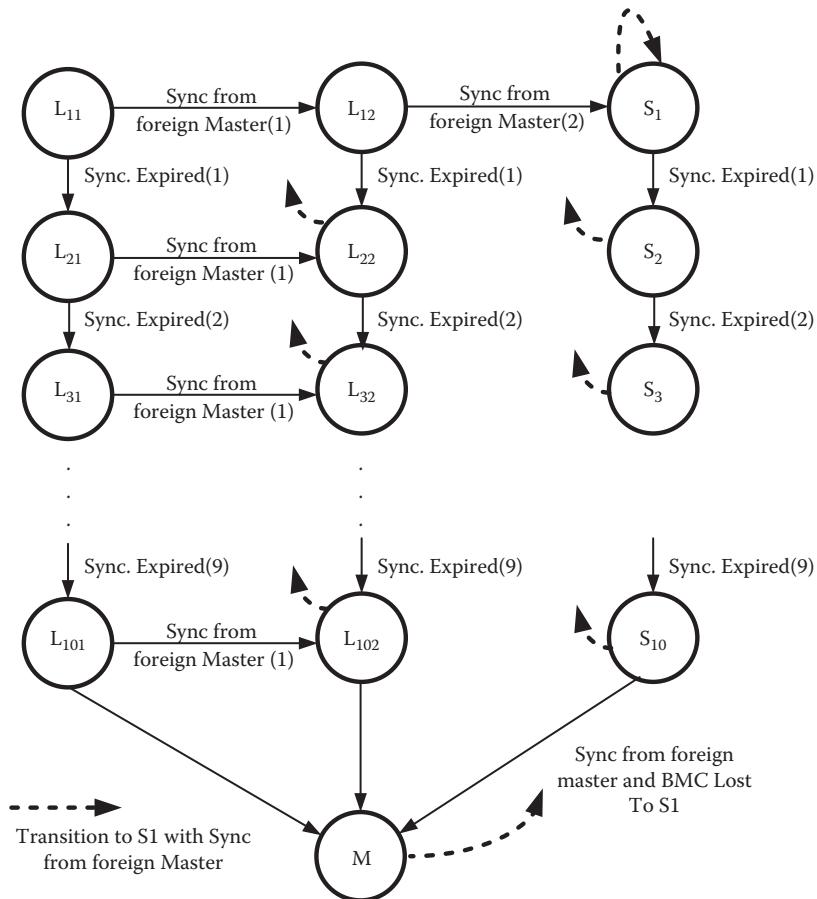

PTP permits two forms of BMC algorithm: the BMC specified in the IEEE 1588 standard and an alternative algorithm specified in a PTP profile. The BMC specifies a way to determine which clock among all contenders is the *best*. The BMC is executed independently on each clock, and every clock makes the master decision on its own; that is, no negotiations between the clocks are done. The BMC is structured into two parts:

1. The data comparison algorithm ranks the clocks and determines which clock is the *best*.
2. An algorithm that computes the recommended state of the synchronization state machine.

A prerequisite for the master election is that each node has knowledge about its data set used for the comparison. This data set includes the priority, clock class, clock accuracy, clock stability, second priority, and clock identity. The data set comparison algorithm first compares the clock identity. If another device has the same identity, the data comparison exits with an error. In Ethernet, the identity corresponds to the MAC address. Thus, this error corresponds to the situation when source and destination address of an announce message are identical, for example, a duplicate MAC address or illegal MAC address modification. If the identity does not match, subsequently the priority, clock class, clock accuracy, clock stability, second priority, and clock identity are compared; and a ranking between the clocks can be made.

Each node in the network starts in the status **INITIALIZED**. The only valid transition from this state is to the state **LISTENING** as denoted by  $L_{ij}$  in Figure 21.6. In the **LISTENING** state, the node waits for incoming messages. The nodes broadcast Announce messages to inform other nodes about their data set to compete for the master role. If a node receives two messages indicating better clock values than its own clock, it changes into the **SLAVE** state. If no synchronization message is received for 10 synchronization intervals, the node considers itself the master and switches to the **MASTER** state.

In the **MASTER** state, illustrated as **M** in Figure 21.6, a PTP node starts multicasting synchronization messages to all other nodes in the PTP domain. The **MASTER** state can only be left if a synchronization message from another node is received and the analysis shows that the node's clock is less accurate than the clock from which the synchronization message was received. In this case, the master node changes to the **SLAVE** state. A node that is in the slave state (**S<sub>j</sub>**) may change to the **MASTER** state if it has not received a synchronization event for 10 subsequent synchronization periods. This case occurs, for instance, if the data connection to the master is temporarily not available or in case of a master failure.

**FIGURE 21.6** State transition diagram of the master clock election.

For the latter case, PTP offers the option of alternate master, which allows a fast handover to an alternate master clock. The BMC algorithm also offers the option to prohibit the devices transiting into the SLAVE state by setting the clock class to a value between 1 and 127. One application for this option are grandmaster clocks that are connected to GPS or an atomic clock.

### 21.4.2 Synchronization in PTP

The synchronization process in PTP is based on timestamps that are taken at the ingress and egress of event messages. IEEE 1588 defines four types of event messages: Sync, Delay\_Req, Pdelay\_Sync, and Pdelay\_Resp. The first two are used for the delay request-response mechanism; the second two are used for the peer delay mechanism. In addition to event messages, general messages are used to transport nontiming critical data between the devices, such as Announce or Follow\_Up messages.

#### 21.4.2.1 Offset and Skew Correction

The synchronization in PTP uses the two-way synchronization principle; thus, it compensates for the path delay by round-trip measurements. In the delay request-response mechanism, the master transmits periodic Sync messages to the slaves at time  $t_1$  as shown in Figure 21.7 (cf. [4], p. 34). The slave takes the timestamp  $t_2$  at the arrival of the Sync message. The master may have either included its own egress timestamp  $t_1$  already in the Sync message or it may use the Follow\_Up message to transport

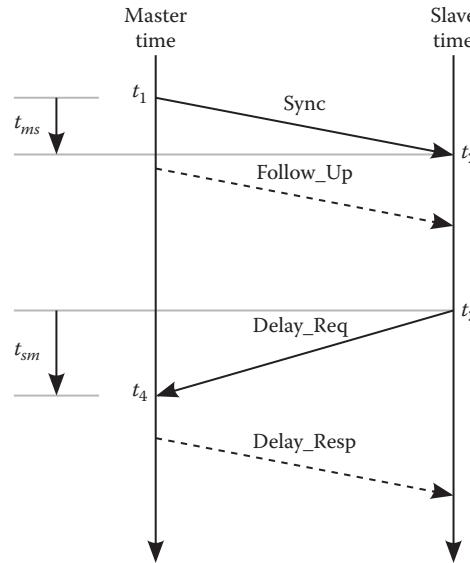

FIGURE 21.7 Synchronization principle of IEEE 1588.

the timestamp to the slave. Devices that are capable of providing the timing information directly within the event message are called one-step clocks. A clock that requires the combination of an event message (e.g., Sync message) and a subsequent general message (e.g., Follow\_Up message) is termed two-step clock.

Similarly, the slave transmits a Delay\_Req message and takes the egress timestamp  $t_3$ . The master receives this message at  $t_4$  and submits  $t_4$  within the Delay\_Resp message back to the slave. When the slave has received at least two Sync messages, it can estimate the clock skew by dividing the timespans elapsed in the master and the slave, and in consequence, it can adjust its rate to the master. When the master and slave clocks have approximately the same clock rate, then only the initial clock offset  $t_{off}$  exists due to different bootstrapping times. The offset  $t_{off}$  can be exactly determined by the timestamps  $t_1$  to  $t_4$  and the link delays  $t_{ms}$  and  $t_{sm}$  by

$$t_{off} = \frac{(t_2 - t_1) - (t_4 - t_3)}{2} - \frac{t_{ms} - t_{sm}}{2}. \quad (21.16)$$

#### 21.4.2.2 Asymmetry Correction

The last term in (21.16) is referred to as  $\text{delayAsymmetry} = (t_{ms} - t_{sm})/2$ . Commonly used media, such as switched Ethernet, wireless networks, or wide-area networks, impose different delays for the receive and transmit path and thus create asymmetry. Although asymmetry fields in the protocol have been introduced in PTP version 2, asymmetry is not detectable by PTP. This limitation is not only applicable to PTP but applies to all packet-based time transfer protocols as only round-trip measurements can be performed. Thus, only known asymmetries can be compensated. The delays  $t_{ms}$  and  $t_{sm}$  are composed of the  $\text{meanPathDelay} = (t_{ms} + t_{sm})/2$  and the  $\text{delayAsymmetry}$  as follows:

$$t_{ms} = \text{meanPathDelay} + \text{delayAsymmetry}, \quad (21.17)$$

$$t_{sm} = \text{meanPathDelay} - \text{delayAsymmetry}. \quad (21.18)$$

If the asymmetry is unknown, IEEE 1588 suggests configuring or selecting components that minimize the effects of asymmetry. The accuracy and precision of clock synchronization using PTP therefore depends on three factors: the quality of the timestamps taken by the master and slaves, the stability of the oscillators providing the reference for the clocks to be synchronized, and the knowledge of asymmetry.

#### **21.4.2.3 End-to-End and Peer-to-Peer Synchronization**

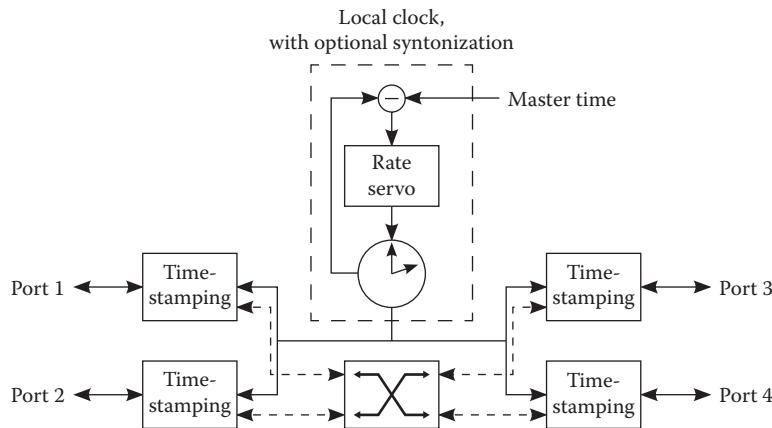

The delay request-response synchronization mechanism outlined earlier is applicable for ordinary or boundary clocks that are connected by any kind of network topology. Ordinary clocks have a single clock port and may either be master or slave. Boundary clocks are in principle ordinary clocks with multiple ports, where the clock data sets and the local clock are shared to all ports but each port runs its individual protocol state machine. Thus, a boundary clock may serve as slave clock on one port and as master clock on the other port. Boundary clocks are therefore one possible network element to connect multiple timing networks. In addition to the delay request-response synchronization end-to-end mechanism, PTP version 2 introduced the peer-to-peer clock synchronization. The peer-to-peer mechanism is used to measure the link delay between two clock ports. With the gathered information, ordinary and boundary clocks can synchronize using the peer delay information and the information contained in the `Sync` and `Follow_Up` messages.

#### **21.4.3 Transparent Clocks**

The accuracy and precision of PTP relies on the timely delivery of event messages; that is, event messages should have constant transmission latency and the latencies in both directions should be identical or known. Real-world equipment often does not offer a constant latency for a number of reasons. For instance, in an Ethernet store-and-forward switch, the entire frame is received, checked, and then forwarded to the destination port queue. Depending on the processing speed of the switching fabric, the queue allocation before the current frame, and medium access delay, the residence time in the switch may vary. This variable delay leads to timestamp jitter and in consequence degrades the synchronization accuracy.

PTP solves this issue by transparent clocks. A transparent clock is a network device (e.g., a switch, router, or gateway) that measures the residence time of PTP event messages within the device and provides this information to clocks receiving these event messages. As a result, the slave clocks still receive event messages with a variable delay, but the magnitude of the variable delay is measured and sent to the slave clocks in order to compensate for the packet delay variation. Figure 21.8 shows the block diagram of a transparent clock with four ports. Each port is connected to a timestamping unit that takes a timestamp for egress and ingress event messages. The timestamping units are supplied by the time indication from the local clock as depicted in the center of Figure 21.8. Messages that have passed the timestamping unit are put into the switch, router, or gateway connecting the ports as indicated with dashed arrows.

In IEEE 1588, two types of transparent clocks are defined: end-to-end transparent clocks and peer-to-peer transparent clocks. An end-to-end transparent clock supports the use of the end-to-end delay measurement mechanism between ordinary and boundary clocks. It timestamps all ingress event messages and forwards them through the switching element to the egress port. The egress port takes another timestamp. The difference between these timestamps is the residence time within the transparent clock. In a one-step, end-to-end transparent clock, the PTP correction field within the event message is directly updated, while a two-step transparent clock measures the residence time of the event message first and then updates the corresponding `Follow_Up` message. One-step transparent clocks have the advantage that the slave clock receives the correct timestamp (the message timestamp plus the correction field) within the event message without any additional latency. Yet, such a transparent clock must be capable of inserting the correction field on the fly. A two-step transparent clock, on the other hand, needs to find the `Follow_Up` frame matching to the event message and modify the correction field. This processing may lead to larger delays and thus reduced synchronization performance as the slave clock cannot adjust its clock before the `Follow_Up` has been received.

**FIGURE 21.8** Block diagram of a PTP transparent clock.

When using end-to-end transparent clocks, the propagation time compensation is done from the master to the slave device without characterizing the intermediate delays. A change in the routing between master and slave changes the path delay between master and slave and therefore temporarily degrades the synchronization until the synchronization has resettled. Thus, end-to-end transparent clocks are particularly suitable for networks with nonvariable routing. Note that end-to-end transparent clocks violate (strictly speaking) most network standards (e.g., IEEE 802.3 for Ethernet) as it is commonly not allowed to modify the contents of a frame without updating the source address to the modifying device. By keeping the source address from the PTP master, transparent clocks appear to be totally transparent to master and slave clocks.

Peer-to-peer transparent clocks additionally provide corrections for the propagation delay of a link that receives PTP event messages. When using the peer-to-peer delay measurement mechanism, propagation delays are corrected on a link basis instead of end-to-end. Thus, any change in the routing immediately changes the path delay correction, and therefore, the synchronization does not degrade in case of dynamic packet routing.

The residence time measurement in transparent clocks is calculated by the difference of the egress and ingress timestamps generated from the local clock. As any clock offset to the master cancels out in this calculation, transparent clocks do not need to be synchronized to the master. Yet, if the clock rates of the transparent clock and the master clock differ, then the residence times are scaled incorrectly, and an error is created. Depending on the residence time, the rate difference, and the desired synchronization accuracy, the error magnitude may be anything from negligible to unacceptably large (e.g., for large rate differences and/or long residence times). Two solutions for this issue are possible: Master and transparent clocks can be equipped with oscillators that have a very low frequency offset with respect to each other, such as oven controlled oscillators. If standard crystal oscillators are used, frequency offsets of about 50 ppm are typical. The transparent clock may also adjust its local clock frequency to the received upstream synchronization packets from the master clock. If the transparent clock uses a free-running local clock, numerical rate estimates can be used for the rate correction as well. The optional rate synchronization is also depicted in Figure 21.8. To differentiate offset synchronization from rate synchronization, the latter is termed syntonization.

#### 21.4.4 Timestamp Generation

The quality of the timestamps generated for all ingress and egress messages is of paramount importance for PTP. All ingress and egress PTP event messages should be timestamped at a common timestamping point. According to Section 7.3.4.1 of IEEE 1588 [4], the timestamping point is the beginning of the first

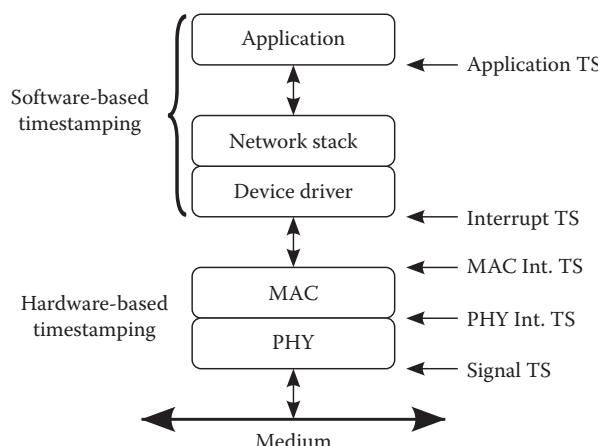

symbol after the SOF delimiter has passed the reference plane (i.e., the network connector or antenna). Nevertheless, note 1 in Section 7.3.4.2 of [4] also allows for other timestamping points given that the timestamps are appropriately corrected by the delay between detection and reference plane.

Figure 21.9 illustrates the possible locations where timestamps can be taken. Commonly, timestamping is classified into hardware- and software-based approaches. Hardware-based timestamping generates the receive and transmit timestamps with the aid of dedicated logic. These approaches may either estimate the timestamp based on the received and transmitted signal (Signal TS in Figure 21.9), the interface between the physical (PHY) layer and the medium access control (MAC) layer, or the interface between the MAC and the software. Alternatively, software timestamps can be taken within the device driver, when processing interrupt requests, or within the synchronization application. With the increasing number of network layers, the jitter increases due to nondeterministic processing delays, and therefore, the timestamping should be as close as possible to the medium.

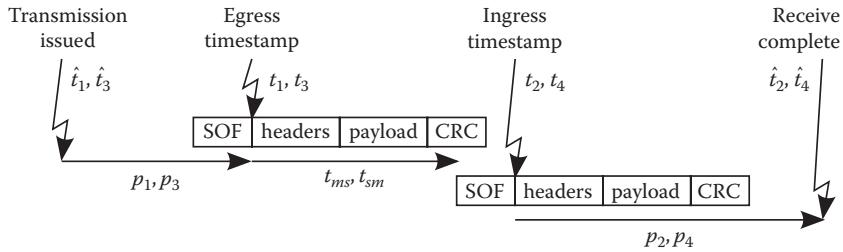

The majority of clock synchronization implementations using IEEE 1588 aiming at high accuracy have been based on Ethernet. As Ethernet offers standardized media-independent interfaces between PHY and MAC (e.g., MII, GMII), universal hardware timestamping methods have been developed in the last years able to minimize the timestamp jitter. These Ethernet-based solutions reach accuracies in the nanosecond range or even below [15].

Particular care for the correction to the timestamp reference plane needs to be taken when using software timestamping as illustrated in Figure 21.10. When using the PTP numbering for egress timestamps,  $t_1$  and  $t_3$  (cf. Figure 21.7), let the transmission at master or slave be issued in software at time  $\hat{t}_1$  or  $\hat{t}_3$ . After a certain latency ( $p_1, p_3$ ), the first bit of the message is put on the line. After the propagation delay ( $t_{ms}, t_{sm}$ ), the first bit of the message arrives at the receiver. Finally, when the entire frame is received, the frame is passed through the network stack, and the payload is presented to the synchronization application (receive complete).

In software timestamping systems, a timestamp at the transmitter is taken when handing a packet over to the network stack of the OS, and at the receiver when retrieving the packet from the OS. This is shown by the egress timestamps  $\hat{t}_1$  and  $\hat{t}_3$ , and the ingress timestamps  $\hat{t}_2$  and  $\hat{t}_4$  in Figure 21.10. Thus,  $p_1$  and  $p_3$  are dependent on the implementation of the network stack in the master or slave. As the ingress timestamps  $\hat{t}_2$  and  $\hat{t}_4$  are usually generated after the entire frame is received,  $p_2$  and  $p_4$  contain the transmission delay as well. When the link speed is asymmetric, the transmission delays and therefore the processing delays are different ( $p_2 \neq p_4$ ), leading to a clock offset. Thus, in any case, it is important to correct all timestamps to the reference plane; that is, for software-based timestamping, the frame length, link

**FIGURE 21.9** Locations for timestamping in a clock.

**FIGURE 21.10** Software timestamping latencies from master to slave.

speed, and other parameters need to be taken into account. In fact, the issue of correcting timestamps to the reference plane also applies to hardware timestamping. For instance, the DP83848 Ethernet PHY from Texas Instruments [16] has a receive latency of 255 ns and a transmit latency of 50 ns. Thus, a synchronization bias is induced when using PHYs with different latencies ( $p_2 - p_3 \neq p_4 - p_1$ ), for example, different PHY devices.

### 21.4.5 Implementation and Application Issues

The performance of clock synchronization can be quantified by the statistics of the offset  $e = t_s - t_m$  between the slave clock  $t_s$  and the master clock  $t_m$ . To assess the offset between master and slave, it is common practice to use a one-pulse per second (PPS) signal generated at the master and slave. The PPS signal is asserted every full second, and therefore, the time difference between the rising edges of the PPS signals from the master and slave can be used to determine the clock offset at every full second. Commonly used statistics are the mean clock offset  $\mu$  and the standard deviation  $\sigma$ , also termed jitter.  $\mu$  reflects any bias and asymmetry in the synchronization path, while  $\sigma$  is influenced by the quality of the timestamps, the synchronization interval, the stability of the local clocks, as well as the control servos.

It has to be outlined that the clock error measured by the slave, that is the difference between the slave clock and the received timestamp from the master, is not an appropriate measure for the synchronization performance. The clock error is used to steer the slave clock and is filtered by the slave servo to generate the PPS signal. In addition, as the slave is unaware of any asymmetry or bias in the system, it cannot detect clock offsets. Thus, an external unbiased measurement instrument, such as a time interval measurement instrument or an oscilloscope, is required to determine the synchronization performance. For purely software-based synchronization systems, nevertheless, PPS signals might not be available, and the clock error needs to be used for a performance assessment.

#### 21.4.5.1 Synchronous Ethernet and PTP

IEEE 802.3 Ethernet [17] can be considered as the state-of-the-art communication technology for home, office, and even industrial networks. It is used to build local area networks using either fiber or copper cabling with transmission rates of up to 100 Gbit/s. Copper-based Ethernet is widely used and allows for cheap copper cabling and simple rewiring using patch panels. The two most common implementations are 100Base-TX and 1000Base-T. Both 100Base-TX and 1000Base-T transmit the information with a symbol rate of 125 MS/s. 100Base-TX uses a single cable pair in each direction and encodes one bit per symbol using the Multilevel Transmission Encoding-3 levels (MLT-3). In contrast, 1000Base-T uses all four wire pairs of an Ethernet cable simultaneously in both directions and transmits its information using pulse-amplitude modulation (PAM) with five levels.

Besides the modulation-specific differences, 100Base-TX and 1000Base-T differ in the interface to the physical layer transceiver (PHY) and thus require different hardware timestamping logic. For 100Base-TX, the most common interfaces are the media-independent interface (MII) and the reduced media-independent interface (RMII). A particular advantage of MII is that the receive clock of the PHY is

simply the recovered clock from the line, and therefore, the receive clock is synchronous to the transmitter on the other end of the line. This enables the construction of synchronous networks by propagating one clock through the entire network, that is, similar to a shared clock line. The concept of exploiting the embedded carrier in Ethernet is in fact not new. The trend in the 2000s to replace traditional circuit switching technologies, such as Synchronous Digital Hierarchy/Synchronous Optical Networking (SDH/SONET), with packet-based networks created the demand for synchronous packet-switched networks.

*Synchronous Ethernet* (SyncE) was created to fill this gap with the ITU-T recommendation G.8262 [18]. The idea behind SyncE is to provide high frequency stability through syntonization with a clock distribution concept that resembles a cascade of PLLs. The master node, which is connected to an external reference clock signal, embeds the clock into the Ethernet transmit signal. Switches recover the clock, clean it using PLLs, and use it to embed the clock in the transmit signal until it reaches the final destination [19]. Synchronization, if required, can be achieved by protocols on top of SyncE like PTP. The SyncE concept was well accepted by telecom carriers as the core network required no major changes for the introduction of SyncE [20]. When using SyncE or any other form of frequency distributing Ethernet network, the syntonization is maintained through PLLs, and therefore, the clock variance is mainly dependent on the PLLs' phase noise. Nevertheless, the clock bias is unaltered by the introduction of a synchronous network.

A particular issue in both 100Base-TX and 1000Base-T is the asymmetry of the PHY devices and the cabling. The propagation delays of the wire pairs of a category 5E Unshielded Twisted Pair (UTP) cable are permitted to differ by up to 50 ns according to the ANSI/TIA/EIA 568-B specification. This results in an unresolvable synchronization offset of up to 25 ns per link. The asymmetry of real cables is often much lower, such as about  $\pm 2$  ns for a 60 m cable as measured in [21]. Still, the asymmetry-induced synchronization offset can be considered as one of the main reasons why PTP with hardware timestamping can hardly reach accuracies below 1 ns over copper-based Ethernet. Commercial off-the-shelf PTP equipment using hardware timestamping synchronizes with residual offsets in the range of 10–100 ns depending on the number of transparent clocks, timestamping resolution, synchronization rate, and lastly the asymmetry, which is not detectable by PTP [22]. When using asymmetry determination approaches, such as line swapping [21], or asymmetry calibration, for instance, by the fiber-based WhiteRabbit system [23], the residual clock offsets can be reduced to below 0.5 ns.

PTP can also be used with software timestamping and standard switches instead of PTP transparent or boundary clocks. For synchronization solutions based on software timestamps, the clock offset induced by asymmetric propagation delays may not be relevant due to the large jitter of the software timestamps. Software-based synchronization approaches may reach synchronization accuracies of about 10  $\mu$ s [24].

#### 21.4.5.2 PTP in Substation Automation Systems

Modern SASs are the core of the smart grid deployment. SASs are based on networked equipment providing the needed protection, remote monitoring, and measurement functions for correct grid operation. The primary and secondary substations are generally structured following the IEC 61850 standard, which describes the communication inside the SAS and sets the base for new interoperating devices in an Ethernet network infrastructure. More recently, the need for clock synchronization among the SAS components for timestamping of critical events (faults and related protection actions) or synchrophasor measurement [25] generated a very high interest in the IEC 61850 community for distributed synchronization protocols like NTP or PTP. Among the two standards, PTP is preferred, since the IEEE C37.238 synchronization profile [26] for power applications requires a synchronization accuracy of end devices below 1  $\mu$ s. The reason of such constraints is the object-oriented architecture of IEC 61850, where different functions can be separated in different devices inside the substation: the execution of measurement functions like the estimation of synchrophasors is done by acquiring voltage and current signals by means of distributed devices (called Merging Unit—MU); hence, the synchronization performance of

the MU became a very critical aspect. Today, new SAs already offer PTP support by means of dedicated hardware, while integration of PTP over existing IEC 61850 SAs (which use NTP, SNTP, or IRIG-B) is basically a trade-off between installation costs and performance, since it may require the replacement of already installed Ethernet infrastructure.

## 21.5 Conclusion

---

Distributed systems need clock synchronization as a basic network feature. In packet-based networks, which are the most commonly used network concepts in IT and automation environments, this always boils down to determining the message delays over the network and taking them into account when adjusting the local clock. Historically, NTP and PTP emerged in different application contexts, but their basic operation is very similar as they both essentially rely on the two-way synchronization principle using round-trip delay measurements. Yet, there are many differences in the details, which make the two suitable for different domains. NTP, with its strictly distributed and fault-tolerant approach of finding a good agreement between several time servers, is ideally suited for large-scale networks such as the Internet with unclear and changing topologies. In such environments, resynchronization does not occur often. Evidently, the attainable synchronization accuracy is not comparable with that of PTP, but it is sufficient for most typical IT applications.

PTP, on the other hand, using a simpler master-slave approach, is better suited for smaller-scale networks with clear, well-maintained topology where synchronicity is more essential than in IT environments and thus resynchronization takes place much more frequently. Provisions to achieve a high accuracy are significantly more elaborated such as transparent clocks to measure the residence time of packets in network elements like switches. The extensions included in the recent version of PTP, in particular the boundary clock concept, in principle allow taking PTP beyond network borders and thus widen the spatial extension of network synchronization. Nevertheless, it is to be expected the PTP will remain the synchronization protocol for automation applications and not make NTP obsolete. The two will coexist also in the future, possibly complementing each other in more complex applications.

### 22.1 Introduction and Historical Background

---

One of the key issues in automation is the exchange of information, and substantial efforts were devoted in the past to introduce communication systems at all levels of the automation hierarchy. The original goal was geared toward *vertical* data transfer between the levels. Nevertheless, as appropriate networking concepts were still in their infancy or entirely missing at that time, academic and industrial activities focused on the development of dedicated automation networks and thus primarily on *horizontal* integration aspects. Many different networks emerged: fieldbus systems of all kinds, Ethernet-based networks, and wireless concepts tailored to automation purposes [1]. Even though early publications did foresee the use of gateways between the individual networks for protocol conversion [2], true integration was not a primary goal for system developers, and so the lower automation levels remained largely separated from the upper, office-oriented levels in terms of data exchange and application integration [3].

Today, interconnection essentially boils down to a linkage between arbitrary automation systems—which may involve also dedicated automation networks—and networks based on the Internet Protocol (IP). For the sake of simplicity, we will stick with the familiar terms fieldbus and Internet, however keeping in mind that the fieldbus is not a must and that the Internet can as well be an intranet or any other network governed by IP and the protocol suite on top of it. The benefits of such an interconnection are two major, nonetheless interwoven aspects: remote access to automation systems and the promise of easy integration of automation data in a user-friendly environment. In other words, there are two reasons why a fieldbus/Internet connection can be beneficial:

**FIGURE 22.1** CIM pyramid and network types used in the various automation levels.

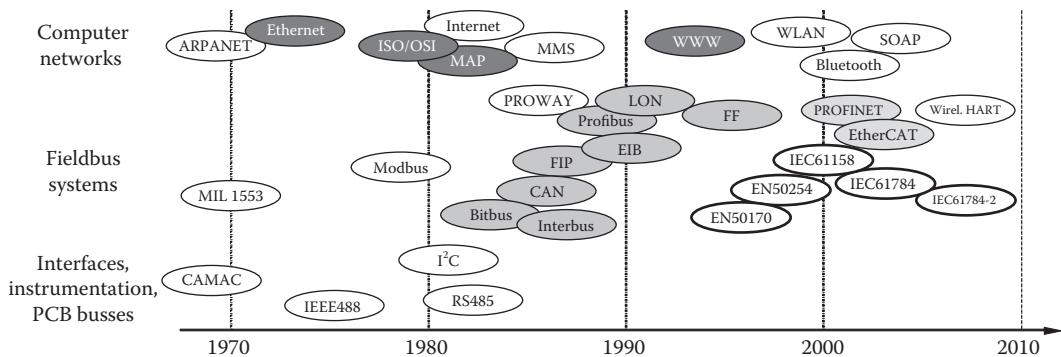

- To extend the physical dimensions of an automation system. Mostly for historical reasons, the extension of a typical automation network is rather limited due to length restrictions in fieldbus segments and the lack of routing capabilities. If an Internet infrastructure is available, it can be used as a kind of backbone to connect distant segments of the installation.
- To provide vertical integration. In the automation domain, this widely used term essentially means bringing information from an automation system into a framework used in the office domain, where it can be used not only for data acquisition but also for strategic operations such as system management or resource planning.

Especially, the second aspect is currently also connected to the growing use of Ethernet in industrial automation. However, it must be stated that the idea of vertical integration is nothing entirely new. The roots date back to the 1970s when the computer-integrated manufacturing (CIM) concept was developed. The hierarchical model was an early attempt to structure the information flow within a company. There are many ways to draw this pyramid, and the names of the individual levels differ according to the application area (Figure 22.1). But the ultimate goal has always been the same: to provide transparent data exchange between the various levels.

The first attempts to implement the CIM concept were more or less futile, for a number of mostly technological reasons. On the one hand, the protocols designed for the communication inside the automation system—essentially the Manufacturing Automation Protocol (MAP) as a full-fledged implementation of the ISO/OSI model—were too complex for implementation. On the other hand, the progress of microelectronics as a technological backbone had not yet been far enough to provide sufficient computing resources at a reasonable price. Therefore, integration of CIM on the field level turned out to be nearly impossible. In addition, fieldbus systems as low-level automation networks were only at a very early stage of their evolution; hence, there was, from a networking point of view, a missing link between the actual source of the process data and the already existing company networks.

Figure 22.2 shows a few milestones in the evolution of both IT and automation networks and demonstrates how the situation changed over the years. Partly driven by the insight that MAP was too clumsy to use (but still following its basic ideas), partly driven by application-specific needs, fieldbus systems as dedicated automation networks emerged. They filled the networking gap at the lowest levels of the automation pyramid, providing an anchor point for subsequent integration efforts. The great leap forward for integration itself came with the success of the Internet and, more precisely, with the invention of the World Wide Web. While in the fieldbus domain, a large variety of approaches still exists even after a lengthy and cumbersome standardization process [1], the office world is dominated by the IP suite and a small number of well-known, widely used applications.

The reason why the old idea of vertical integration was revived in recent years was merely a psychological one. As the timeline in Figure 22.2 shows, the Internet and its basic technologies have been available (and used) for a long time. However, it took the sheer simplicity of the web browser as a ubiquitous tool to boost the acceptance of the Internet and to secure the dominant role of the IP suite in the office

**FIGURE 22.2** Evolution of networks in automation and information technology.

world. From the user's point of view, a web browser allows access to distant data in a nearly trivial manner. Hence, it is no wonder that the easy navigating through hypertext documents was soon adopted as a model also for the remote access to automation data. Consequently, many solutions of fieldbus/Internet connectivity rely on web technology and a web browser interface. The great success of IP-based networks also significantly simplified the automation pyramid. Figure 22.1 shows that actually only two network technologies are left in today's automation scenarios: dedicated field-level networks to cope with the special demands of automation and IP-based networks on the upper levels to allow for data transfer over large distances and easy integration into office automation. Still, the impression that *the Internet* naturally entails a uniform way of remote access to automation networks is deceptive. The user interface is only one aspect; the underlying mechanisms and data structures are another. In fact, when it comes to implementing an interconnection between IP-based networks and an automation system fieldbus, there is a surprising variety of possibilities even in the so much *standardized* Internet environment. In particular, the web-based approach is by no means the only one.

## 22.2 Interconnection Approaches

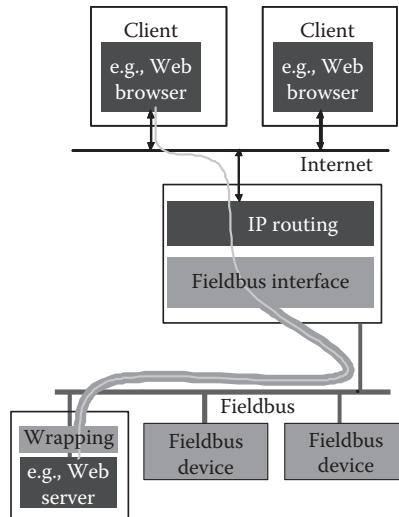

From an architectural point of view, there are two main possibilities to achieve a fieldbus/Internet interconnection, both of which are being used in practice [11]:

- Tunneling of one protocol over the other
- Providing protocol and service translation via a gateway

As far as the network topology is concerned, both approaches are very similar. In both cases, a central access point between the networks is either required or at least reasonable. What differs is the way the information is processed by this link or, more accurately, how the processing is distributed between the devices involved in the communication.

### 22.2.1 Protocol Tunneling

In communication networks, tunneling essentially means that data frames of one protocol are simply wrapped into the payload data of another protocol without any modification or translation. The tunneling approach in the automation context falls into two categories. The currently more common solution is to encapsulate IP packets in fieldbus messages, which also opens a channel for the upper layer protocols required for, for example, direct web access to the field devices [12–14], while in most cases not foreseen in the beginning, this possibility has recently been included in several fieldbus systems—a move that has to be seen mainly in connection with the discussion about Ethernet in automation. At first glance, IP tunneling does provide an easy way to achieve vertical integration, as Figure 22.3 shows. The

**FIGURE 22.3** Structure of IP tunneling over a fieldbus.

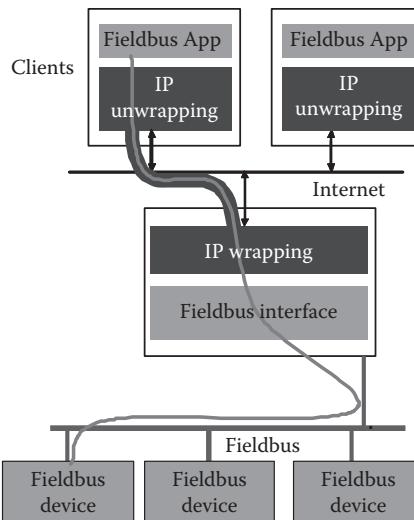

field devices run an IP-based service such as a web server providing data for a respective application in the Internet, which can directly access the device or process data.

A second look, however, reveals that the integration is not at all that easy. There are a few critical points to be considered to properly design such a system.

*Computing resources at the field device.* First of all, it is evident that the field device as the endpoint of a tunnel must be able to run the complete IP stack with all additional protocols required for the particular application. In addition, memory space is required for the actual application program handling the data that are to be accessed via IP. With today's embedded systems, all this may not be overly problematic, as there are very lightweight protocol implementations available (typically at the expense of detailed error handling). At any rate, this often requires additional hardware at the device and might be a cost factor especially for simple devices like sensors or actuators.

*Traffic handling at the access point.* The node that connects the IP-based network and the fieldbus has to encapsulate the IP packets and forward them to the appropriate fieldbus node, where they are unwrapped and handed over to the IP stack. To this end, the access point has to act as an IP router. More than that, it has to map the IP connections to the respective fieldbus communication channels. This requires an address translation on the fieldbus side of the access point. On the Internet side of the node, an additional translation can become necessary if the IP addresses in the fieldbus are not public ones, but taken from a private address range, which is the usual network configuration. The access point, thus, acts as a simple masquerading firewall with network address translation (NAT). Unlike the case where the IP addresses in the fieldbus are public, the fieldbus as a whole is accessible only via one single IP address, and the distinction between the individual devices (e.g., web servers) hidden behind the firewall can only be done via port forwarding. This means that the services are not reachable through their well-known standard ports, but via dedicated ones that have, of course, to be configured appropriately at the client side in the Internet.

*Performance issues.* IP packets tend to be rather large, whereas fieldbus data frames are usually optimized for the transmission of only small pieces of data at a time. Squeezing IP packets in the small payload data fields of a fieldbus message, therefore, requires segmentation, which in turn increases the transmission time. An extreme example is Interbus, where IP traffic can

**FIGURE 22.4** Structure of a fieldbus tunnel over the Internet.

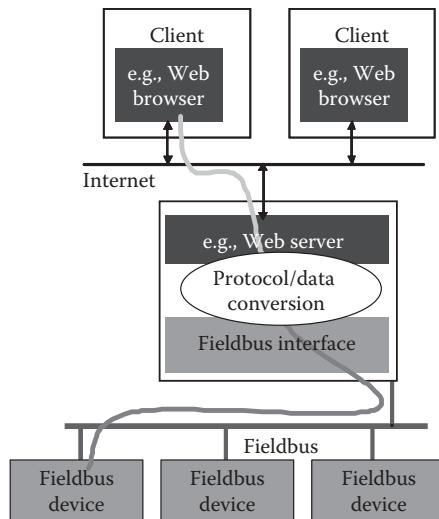

be transported in the parameter channel [15]. This channel has only a small capacity of, say, 8 bytes per cycle in order not to interfere with the real-time process data, and 1 byte is needed for control purposes. Depending on the size of the network and the selected baud rate, one cycle may take a few milliseconds. As an IP packet usually is of the size of several hundred bytes, it is clear that the performance is rather limited. In other fieldbus systems, the data frames are large enough to avoid excessive segmentation. At any rate, the efficiency of IP over fieldbus tunneling depends strongly on the fieldbus.

The alternative way of tunneling works the other way around. Fieldbus messages are wrapped into IP packets (or those of other protocols such as Transmission Control Protocol [TCP], depending on how the tunnel is set up) and sent to a distant network node (Figure 22.4). From the viewpoint of vertical integration, the disadvantage of this approach is immediately visible. The fieldbus data must be interpreted at the client side, which requires a fieldbus-specific application or at least an experienced user with detailed knowledge about the particular automation system.

This approach does not fulfill the requirements of user-friendliness posed by the idea of vertical integration. In fact, fieldbus tunnels over the Internet are rather used to conveniently connect remote segments of an installation [16]. A wide field of application for this concept are network-based control systems, for instance, in building automation [17,18]. It has to be noted, though, that the interconnection of two fieldbus segments over an Internet tunnel is not fully transparent but has to cope with timing problems introduced by the processing of the data packets and the transmission delays, which has an impact on the design of network-based control systems [19–21]. Therefore, this concept is useful only if the fieldbus protocol provides some routing functionality, where timing requirements can be relaxed.

## 22.2.2 Gateways

The alternative approach to achieve fieldbus/Internet connectivity is to design the central access point as a gateway. Like with the tunneling approach, the gateway is a full member of the fieldbus on the one side and can be accessed through IP-based mechanisms via the Internet (Figure 22.5). What is different, though, is the way the information exchange is handled. In the IP tunneling approach, the client connects directly to the server running on the field device. The access point just forwards the IP traffic but is not further involved in the data transfer. In the gateway approach, the access point takes the role

**FIGURE 22.5** Network topology for a gateway-based interconnection.

of a proxy representing the fieldbus and its data to the outside world. It fetches the data from the field devices using the usual fieldbus communication methods and is the communication partner addressed by the client.

Unlike the tunneling approach, where each field device has to provide and maintain its data on an individual basis, information processing for the client in the Internet is centralized here. This enables the gateway to set up a comprehensive and consistent view of the automation system, which is undoubtedly a benefit. In addition, the field devices need no special equipment to process IP-based data and services.

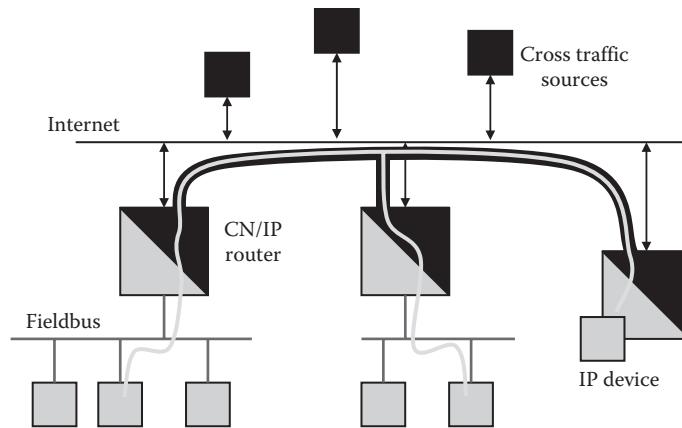

For the sake of completeness, it should be noted that a gateway would in principle also allow for the reversal of the communication direction. Therefore, field devices could as well access resources in the Internet, for example, different fieldbus systems connected to the LAN via compatible gateways. Although there have been efforts to foresee this possibility by providing harmonized interfaces (as in the Network Oriented Application Harmonization (NOAH) project [22]), it is irrelevant in practice.

## 22.3 Control Data Tunneling

A special case of protocol tunneling is the interconnection of two remote fieldbus segments over an IP-based backbone. As stated before, this has become popular in recent years in control engineering. In this type of application, the performance of the backbone is essential. Specifically, the way the *IP channel* connecting the control nodes or networks is set up has a direct influence on the system behavior, and modeling of the network is not a simple task [23].

To implement the tunnel and exchange data between the end points requires a special protocol. Apart from proprietary solutions and those designed in the context of industrial Ethernet, one standard that has been designed for this purpose and enjoys a growing user base is CEA-852 [24]. It describes the system components, the communication protocol, and management requirements to establish an IP channel with control devices and routers. A typical CEA-852 topology is depicted in Figure 22.6. The devices in a CEA-852 system can either be purely IP-based or regular control network (CN) devices connected to the IP network through CN/IP tunneling routers.

CEA-852 control devices communicate directly in a peer-to-peer fashion using a native CN protocol without the need of gateways. The native protocol data units are encapsulated in User Datagram Protocol (UDP) frames and routed to the respective recipients on the IP channel. The choice of UDP transport over TCP has several advantages: First, because of the connection-less nature of CN communication, it

**FIGURE 22.6** EIA-852 system configuration.

would incur unnecessary overhead to manage connection setup in TCP. Second, TCP ensures delivery through retransmissions. Because of the (soft) real-time requirements of control applications, however, retransmissions will most likely miss the deadline, which makes them useless. Third, CN protocols typically implement their own retransmission scheme where necessary. So, on top of the actual IP-based network, this tunneling protocol is a viable solution.

### 22.3.1 Network Parameters for Control Data Tunneling

On the lower layers of the tunnel, that is, regarding the IP-based network, quality of service (QoS) parameters can be used to describe requirements imposed on the network behavior. The origin of QoS definitions was the usage of the Internet to transport multimedia services, specifically the difficulty of using a packet-switched, statistical multiplexing network to transmit stream-based data that normally require directly switched connections. In automation systems, and especially in network-based control, the situation is comparable: Formerly direct connections are being replaced by packet-oriented networks that influence the quality of control (QoC) of the implemented application. QoS parameters are a reasonable means to quantify this influence [25]. In principle, QoS refers to the capability to provide resource assurance and service differentiation in a network. In a narrower sense, timeliness and reliability properties are often referred to as network QoS. Some typical QoS parameters relevant for the interconnection of distributed control systems by IP-based tunnels are discussed in the following.

#### 22.3.1.1 End-to-End Delay

This is an absolute measure for the total delay packets suffer from the emission by the sender until the reception over the network. It is also known as transit delay. A requirement on the end-to-end delay  $D_i$  of each packet  $i$  can be defined such that the delay  $D_i$  of each packet  $i$  must not exceed a maximum end-to-end delay  $D_{\max}$  with a probability greater than or equal to  $Z_{\min}$ ,

$$P(D_i \leq D_{\max}) \geq Z_{\min} \quad (22.1)$$

This statistical bound on the end-to-end delay can be easily converted into a deterministic bound by defining  $Z_{\min} = 1$ .

#### 22.3.1.2 Delay Jitter

The delay jitter  $J_k$  is the variance of the end-to-end delay  $D_k$  and is a measure for the stochastic part of the delay. It is often defined as

$$D_k = D_{\min} + J_k \quad (22.2)$$

where the deterministic part from (22.1) is subsidized by  $D_{\min}$  and the stochastic part by  $J_k$ . Delay jitter is a function of different processing times in intermediate nodes, different queue lengths, and typically a result of network congestion, which in turn depends on the various types of data traffic like parallel and cross traffic running over the same network [23]. As a result, a packet stream transmitted in equidistant instants in time will be distorted while it traverses the network. Applications may want to bound the delay jitter  $J_i$  to a maximum value  $J_{\max}$  with a probability equal to or greater than  $U_{\min}$ ,

$$P(J_i \leq J_{\max}) \geq U_{\min}. \quad (22.3)$$

### 22.3.1.3 Throughput

The throughput defines how many bits per time unit can be transferred over a given network path. In an end-to-end view, the delay can be seen as a direct function of the instantaneous throughput. The practical notion of throughput, however, implicitly includes a certain time interval. If  $A(t)$  denotes the aggregate amount of transferred data up to a time  $t$ , the throughput can be defined as

$$\Theta = \frac{A(t + \Delta t) - A(t)}{\Delta t} \quad (22.4)$$

Throughput is especially important for applications transmitting constant data streams. A requirement for the throughput can be written as

$$P(\Theta \geq \Theta_{\min}) \geq \zeta_{\min} \quad (22.5)$$

Since CN applications usually deal with small data transfers only, this requirement will not be as important as for multimedia applications. However, throughput might become an issue over dial-up or other low-speed links.

### 22.3.1.4 Loss Rate

The drop probabilities for different packets on the individual hops can be subsidized by a global *loss probability* or average *loss rate*. The most common reason for high loss rates is again network congestion. The probability of complement can be defined as the reliability of the network path. The reliability defines how reliable packet transmission should be on the network. A requirement can define at which minimum probability  $W_{\min}$  a packet should be received, thus

$$P(\text{packet received}) \geq W_{\min} \quad (22.6)$$

### 22.3.1.5 Packet Ordering

Some services rely on order preservation of a sequence of packets. Let  $\langle p_k \rangle$  be the sequence of transmitted packets and  $\langle p'_k \rangle$  be the sequence of received packets, then the network is order-preserving if and only if

$$\langle p_k \rangle = \langle p'_k \rangle, \forall k \quad (22.7)$$

Typically, order preservation is a property depending on delay jitter and network topology. If the network provides multiple possible paths connecting any two nodes, control packets may traverse the network

in any of those paths. Given that packets suffer different delays in the paths, they may be reordered even if the intermediate nodes obey a strict first-in, first-out (FIFO) policy. More complex queuing policies (e.g., priority queues) implemented in QoS-enabled routers may even lead to reordering on a single path, due to changing packet priorities.

### 22.3.2 Performance and Application Classes

Another possibility to assess the performance of an IP-based tunnel is from the application point of view. Depending on the application's needs, the network must satisfy certain requirements [17]. With respect to the packet delay as the most important parameter, we can distinguish several *performance classes* and derive characteristic features for the delay density  $f(D)$ .

*Hard real-time.* If an application has hard real-time requirements, any given deadline must be met under all circumstances. Missing a deadline will inevitably result in a catastrophic failure of the system. Although the definition of what actually constitutes a catastrophic failure is not always clear, we can at least find a concise requirement for the delay, which must be upper-bounded, that is,

$$f(D) \equiv 0 \text{ for } D \geq D_{\max} \quad (22.8)$$

*Soft real-time.* If missing of a deadline does not lead to a catastrophic failure, the application imposes only soft real-time requirements. For our purpose, this definition is too loose and therefore not useful. In fact, either of the following two classes is a subset of soft real-time.

*Guaranteed delivery.* For this requirement, the actual delay of a packet is irrelevant. What counts is that the packet is definitely received by the addressed node. There are no particular constraints for the delay density; it may not even be bounded (if it was, we had effectively a hard real-time situation).

*Best effort.* This scenario is the weakest one. Here, the network only attempts to deliver the packets as fast as possible, without making guarantees concerning deadlines or successful delivery at all. Formally, this comes down to treating the delay density  $f(D)$  as conditional distribution,

$$f(D|X) = f(D) p(X), \quad (22.9)$$

where  $X$  denotes the successful delivery of the packet, which is independent of the delay distribution. For the simulation model, the conditional distribution has the convenient property:

$$\int_{-\infty}^{\infty} f(D|X)dD = p(X = \text{true}) < 1 \quad (22.10)$$

so that the residual probability that a packet is lost in the best effort scenario is implicitly included.

Distributed applications implemented on automation networks typically cope with process data acquisition, processing, and signaling. They can be categorized into several *application classes*, which can be mapped onto the performance classes introduced before (Figure 22.7).

*Monitoring/logging.* This application class allows to view or record data within a control application. Typically, selected process parameters are sent to a monitoring station where they can be tracked or logged. The QoS requirements can range from hard real-time to no requirements at all (meaning an entirely unreliable network is acceptable as well). Examples are remote power meters, weather sensors, or occupancy detectors.

Application class	RT	GD	BE
Monitoring	+	+	±
Open-loop control	±	++	+
Closed-loop control	+	-	+
File transfer	±	++	-

**FIGURE 22.7** Application classes and possible requirements (RT, hard real-time; GD, guaranteed delivery; BE, best effort) imposed on the network.

*Open-loop control.* Open-loop control appears where the process characteristics and disturbances are well-known so that feedback paths are not required. The network should provide at least reliable data transfer, but the timing requirements can range from nonreal-time to hard real-time. Multidimensional open-loop controls can pose additional timing requirements originating from the time dependencies of the output values. Control data are typically sent periodically, in which case, the overhead for providing guaranteed delivery, for example, by packet retransmission, can be avoided. Examples are light switches, intelligent power outlets, or dot matrix displays.

*Closed-loop control.* Closed-loop control applications are commonly found in automation tasks where control quality and error compensation are required. The controller does not need to be part of the application; it can be an external system such as a human operator. Timing variations influence the stability and performance of a closed-loop control, so this application class has at least a demand for soft real-time behavior. Again, multidimensional control is possible and can enforce more strict timing requirements. Examples are heating, industrial control, and power management.

*File transfer.* All distributed automation systems need in one form or the other the transmission of files or at least larger data blocks instead of process data. The typical application is to configure or parameterize field devices either at system start-up or later during runtime. Sometimes, even executable code is transferred, for example, to update programs running on controllers. The minimum requirement for the data transmission is reliable and guaranteed data transfer. In rare cases, when the upload of a device configuration is time-critical, also hard real-time requirements may apply.

## 22.4 Design Considerations for a Gateway

There are no general guidelines on how to implement a gateway between a fieldbus and the Internet. From the user's perspective, however, there exists a clear-cut requirement for the integration: as the automation data are brought into the office world, the ways and means employed must comply with the standards used there. In particular, this requires some sort of abstraction for both data and functionality. There is a good reason for this. Within the scope of vertical integration, the automation data are accessed from a *strategic* level (rather than control level), so the user wants to have a clear picture of the most relevant data. Too many fieldbus-specific details can obscure this picture and be distractive. After all, the user is typically not a fieldbus expert, let alone the one who set up the automation system.

Another argument speaking in favor of an abstract view to the automation system is the desired user-friendliness of the interface. Typically, the user wants to retrieve data from different systems with only one tool. Therefore, the user interface should be as independent of the underlying system as possible.

It is important to notice that the way data and functionality abstraction can actually be achieved also depends on the protocols and mechanisms used on the Internet side of the gateway. In the sequel, we list and discuss a few design issues. They may vary with the concrete target application. The model for the present discussion is a simple and cost-effective residential gateway for linking a home network to the Internet [26].

### 22.4.1 Services

The basic function of a gateway evidently is to provide read and write access to process and device data on the fieldbus for monitoring and control operations, but also for network management purposes. However, as the gateway has to accomplish protocol (and maybe data) conversion and therefore needs a certain amount of computational intelligence anyway, additional services can be included. With the gateway acting as a proxy server for the automation data, there are a number of autonomous functions it can (or should) provide [27,28]. Some of these add-on services can in an abstract way be described as *events*. Events are triggered by predefined criteria: if a criterion is fulfilled, an action is taken. Criteria can be the expiration of timers (time-based events) or the crossing of thresholds by the value of a data point (value-based events). The actions to be performed upon the occurrence of an event can be manifold.

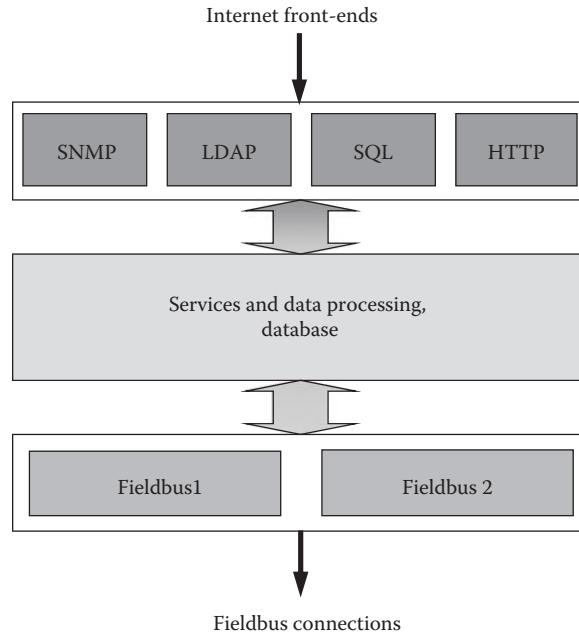

*Data logging.* The storage of data point values based on either time or the recognition of certain trigger conditions enables the gateway to perform stand-alone operation independently of the availability of an online connection to the high-level network. Especially in remote access via unreliable channels (e.g., wireless or heavily congested service providers), the possibility of creating log files (and retrieving them at a later time) may be an essential requirement of the application. A management station can then retrieve logs (fully or incrementally) to perform subsequent analysis or feed specialized software with control system data.

*Asynchronous notifications.* Contrary to the predominant client/server communication model in the Internet, where the client has to continuously poll the server (the gateway) to get information, the gateway should become active as a response to certain events. The availability of such a mechanism is an important criterion for the choice of a suitable protocol on the Internet side of the gateway. In practical implementations, the lack of native asynchronous notification mechanisms is usually circumvented by the use of services based on some sort of e-mail.

Two other types of services are independent of the fieldbus data and cannot be modeled as events.

*Security.* Fieldbus systems are traditionally security-unaware [3,29]. When a connection to the Internet is provided, however, the security of protocols that are able to communicate with the gateway is vital for both the field area networks that the gateway is connected to and the gateway itself [11,30]. The gateway has to take care of access control, the minimum level of security being authentication.

*Network structure updates.* A last point that might be relevant for the gateway depending on the desired application area is some sort of plug-and-play functionality. By this, we understand that the gateway is capable of recognizing changes in the network structure autonomously and adapting its internal data point structure. This does not necessarily eliminate the need for preconfiguration, but it may help to keep the gateway operational. A typical application for this feature are residential gateways that—once installed—have to be as autonomous as possible and must cope on their own with devices joining or leaving the field area network. In this case, the underlying fieldbus must, of course, also support basic plug-and-play features. A key issue here is the ability of the high-level protocol on the Internet side to reflect structural changes in the field area network: nodes in a field area network can be removed, added, or replaced.

**FIGURE 22.8** Modular three-level gateway structure.

This can influence the mapping between protocol addresses and fieldbus addresses. It has to be taken into account how a protocol deals with such changes in the network structure and how objects that existed before a change can be consistently addressed after a change.

#### 22.4.2 Gateway Structure

There is no best architecture for a gateway. Its primary function is to act as an abstract interface to an automation system, independent of both the fieldbus protocol (because it operates on application level) and the fieldbus-specific coding of the data. Therefore, the gateway provides unified access to, maybe, more than one fieldbus simultaneously. The software structure of the gateway implementation can reflect this demand for versatility and exhibit a modular structure [26,31]. Alternatively, the architecture can as well be monolithic and tailored to one specific case. A modular approach will have to provide abstraction as a matter of course; the three-level approach shown in Figure 22.8 is just one possibility.

What has to be considered separately is the low-level access to the fieldbus. One degree of freedom is the strategy used to fetch the data. This can be based on a caching mechanism, where the gateway autonomously retrieves the data with a predefined refresh rate. Upon request from the client, the response is taken from the cache and returned without further delay. This approach provides immediate answers and can reduce the fieldbus traffic, especially in situations where multiple access from different clients needs to be handled. For proper operation, a timestamping should be foreseen so that the client can keep track of the age of the data values.

The alternative is to get the data from the fieldbus only when requested to do so by the client. This avoids cyclic updates as well as timestamps, but the gateway may have to cope with substantial delays of the response from the field device. The connection to the client has to be kept alive in the meantime.

Which strategy can be used depends on both the properties of the fieldbus and the capabilities of the interface used. To avoid excessive bus load in the caching scheme, the gateway can passively listen to the network traffic. Provided the fieldbus interface supports such a monitoring mode, this approach is convenient to track cyclic (in systems like Interbus or Profibus-DP) or event-driven data transfer (in fieldbuses

based on the producer/consumer model like Controller Area Network (CAN) and European Installation Bus (EIB)). Unfortunately, many of today's integrated fieldbus controllers perform a low-level data filtering, inhibiting straightforward monitoring. In these cases, the gateway must actively retrieve the data from the bus. The same applies to data that are not normally transferred on a regular basis, such as diagnostic data (e.g., in Profibus-DP). Even worse, the transmission of such specialized information often requires the execution of dedicated commands that cannot be mapped to simple read/write commands. Such fieldbus-specific communication sequences (but also other peculiarities like remote program invocation or special network management functions) must be handled differently. As the high-level access via the Internet most likely will not provide methods for direct command execution, such special functions can be triggered by an ordinary read/write access to specially assigned data points.

Another important restriction may be the medium access control scheme employed by the fieldbus. There are no problems with multimaster systems; here, any node can host the gateway. Single-master systems, on the other hand, imply that the gateway must either be the fieldbus master or cooperate with it, in the sense that there is a dedicated and typically nonstandard communication channel through which the gateway can tell the bus master which data values are to be read or written. Otherwise, writing data points will inevitably lead to inconsistencies, when the gateway sets a value and the bus master overwrites it during a regular update cycle.

### 22.4.3 Data Representation

A crucial point in the design of a gateway is the way the fieldbus data are represented. A *data point* is the smallest information unit available via the gateway. To achieve fieldbus independence, the data points have to be arranged in a rather general, high-level way. The question how to find a unified view and coding for the sometimes extremely heterogeneous fieldbus objects is an interesting topic on its own and will be left aside here. More relevant for our purpose is the way the complete set of data points is structured inside the gateway. Basically, there are two different possibilities to do so [32]. The first is a function-oriented approach. In this case, emphasis is put on the content of the individual data point, and the underlying network structure is completely irrelevant. The gateway thus offers a simple flat list of data points.

The second approach is a structure-oriented one. Here, the data points are arranged according to the structure of the field area network. The gateway offers a list of nodes, and each node can contain one or several data points. In addition to the simple form of a data point, a data point can also contain a set of values instead of only a single value. This type of data point is referred to as an *aggregate* data point. Data points can also contain multiple values of different types (structures). The advantage of the structure-oriented solution is that properties of nodes (and not only properties of data points) can also be modeled on the gateway. These properties are, for example, a self-identification of the node or a location information that describes the position of a node in a field area network.

Which of the two possibilities is actually used is a matter of taste and also depends on the target application. Furthermore, the choice might be limited by the high-level access protocol and its capabilities of describing and managing data. Every object that is available to a client needs an address that uniquely identifies the object. Protocols typically define their own addressing scheme; the gateway, on the other hand, also defines an addressing scheme that may be similar to or completely abstract from the fieldbus network addressing. These two schemes need to be mapped onto each other to make data points available.

Another point to be observed is how the information of a data point is encoded. This again might be limited by the capabilities of the way the data are transferred from the gateway to the client. Not every protocol may support special data types or encodings used in a particular fieldbus, so there must be some form of data translation and, necessarily, abstraction. This might not be too problematic for scalar data points like temperatures (although there are obviously many possibilities to encode a temperature value), but it will get increasingly difficult for such common things as date and time, not to speak

of aggregate data points available only as a structure on the fieldbus level. For all these more complex data points, no one-to-one mapping is possible, and there are basically only two options to cope with the situation: One is to find a compromise in the form of abstract data representations that omit excess information; the other is to collapse the complete data point into a flexible and unspecific data format such as a string—with the disadvantage that the client needs to take the string apart and to interpret it, which again requires fieldbus-specific knowledge.

In addition to the actual value, a data point also may need some attributes to facilitate interaction with the client. Such attributes can be a description of the data point type and encoding (to tell the client how the data are to be handled) and maybe a string providing a textual description of the data point. In some fieldbus systems, such a self-description is foreseen for data objects anyway. Application and device profiles defining functional models for devices are another way to deal with the complexity problem [33,34]. Last not least, there can be a specification of the access mode, that is, what the client is allowed to do with the data point. It should be noted that although the restrictions concerning data representation have been discussed for the gateway approach, they also apply to the IP tunneling solution. In this case, the list of data points has to be maintained by every field device on its own. Typically, the implementation is up to the vendor, and unless there are very stringent rules, this may lead to a substantial inhomogeneity stemming from the many degrees of freedom mentioned before.

## 22.5 Gateway Access from the Internet

---

The primary goal of vertical integration is to bring automation data into an IT context, and consequently, there are many ways to incorporate data provided by a gateway into office-level applications. To this end, it is not necessary to employ full-fledged application-level protocols on top of IP/UDP/TCP. A very common approach used in contemporary supervisory control and data acquisition (SCADA) systems is OLE (Object Linking and Embedding) for Process Control (OPC). A more unconventional idea is to treat the gateway as a database and use, for example, SQL to retrieve the data [35].

The protocols discussed in the sequel have been evaluated with respect to their feasibility for home network access, specifically for remote meter reading [32]. The criteria for the evaluation were described in the previous section: a reasonable way of structuring and handling data, a possibility to send asynchronous notifications, and of course security provisions. In addition, the protocol (together with its data representation) should be able to cope with changes in the network structure. This requirement is a direct consequence of the target application in an intended mass-market with a high number of installations, where updates calling for specially trained personnel are not affordable. Likewise, the overall costs of such a gateway should be low, which typically means limited computing power and memory space. Compact implementations on possibly embedded devices are therefore a must. The results of the survey are presented in Table 22.1.

### 22.5.1 Simple Network Management Protocol

Simple Network Management Protocol (SNMP) is a comparatively old protocol and has been designed for remote administration of networked devices. Data are represented in a tree structure called *management information base* (MIB) where each branch and each leaf have a unique identifier, called *object identifier* (OID). SNMP *managers* (i.e., the client that connects to an SNMP-enabled device) use this MIB to get extended information about the managed *agent* (i.e., the device that allows SNMP access, in the present case the gateway). The MIB is a static representation of all the objects available at the managed agent. As SNMP does not provide mechanisms to download the MIB from the agent, the information which OID stands for which data point needs to be transferred to the manager over mechanisms that are out of scope of SNMP (usually this is done by the administrator of the system during setup). SNMP is based on the connectionless UDP running on top of IP. This is rather efficient because of the low overhead, but unlike TCP, UDP does not guarantee delivery of packets, so packets can be lost on the network without being noticed by the sender.

**TABLE 22.1** Features of Several Protocols Applicable for an IP/Fieldbus Application Gateway

Criterion	SNMP	LDAP	SQL	Web Technologies	OPC UA
Transport protocol	UDP	TCP	TCP	HTTP over TCP	TCP; optionally, SOAP/HTTP or UA-specific protocol on top
Data organization and namespace	Tree structure (MIB)	Tree structure (DIT)	Tables	No limitations	Objects organized into a hierarchical or meshed address space
Fieldbus data point mapping	Mapped to OIDs in the MIB	Mapped to attributes of DIT entries	Used as primary keys	Used as identifiers inside HTML/XML pages	Objects
Flexibility of data organization (per installation)	Limited (tables as workaround), MIB must be known by the client	Unproblematic	Unproblematic	Unproblematic	Unproblematic
Dynamic updates of data structure (during runtime)	Can result in corrupted data (nonatomic access to tables)	Possible (atomic data access)	Possible (atomic data access)	Must be handled by the server (consistent access to data within one doc.)	Can be supported by both server and client
Data type support	Available, but unusable inside tables. Limited (e.g., no structural data types)	Data are packed into strings	Available, though limited. Data are packed into ASCII strings. Not usable inside tables	No data types, data are packed into strings	Protocol defines standard data types and allows for manufacturer-specific types
Overhead per request	Low	Low if clients use specific filters in search queries	Low if clients use specific filters in select queries	High, reload of complete page required	High for SOAP/HTTP with XML/text, low for UA TCP with UA Binary
Asynchronous notifications	TRAP and INFORM	Not available	Not available	Not available	Via subscription service
Security	Authentication and encryption in version 3	Kerberos authentication in version 3, can also use TLS	Uses TLS	HTTP over TLS	Integrated encryption, integrity and authentication services
Client support	Good	Weak (mostly <i>address book</i> applications)	Programming interfaces and generic applications (like office suites)	Very good (HTML), programming interfaces (SOAP/XML)	Very good, many applications

The major commands provided by SNMP are GET and GETNEXT for reading data (GETNEXT allows the manager to traverse an unknown MIB tree and to retrieve the OIDs) and SET for writing to data points. In contrast to the standard manager-driven communication (in typical client/server fashion), SNMP also defines the unacknowledged TRAP command (from version 2 on also the acknowledged INFORM command), which can be sent by an agent to asynchronously inform a manager about special conditions in the agent. This possibility to reverse the client/server communication is a rare exception among the investigated protocols and together with the good protocol efficiency is a strong argument in favor of SNMP.

One of the big problems of SNMP is the static structure of the MIB together with the lack of native transfer mechanisms between agent and manager, which does not allow dynamic updates of the network (or data point) structure [36]. Therefore, the list of nodes and data points needs to be stored in an SNMP table rather than as a set of separate objects in the MIB. To access individual objects, the manager needs the OID of the table, which is fixed once and for all, and the number of the row containing the object. If the structure of the field area network is changed, the table can be updated by adding or removing the rows that represent the according nodes. This is a critical issue in that SNMP requires the rows in an SNMP table to be numbered continuously; therefore, the insertion or removal of a row changes the numbering of all subsequent rows.

The workaround of using tables to add a somehow dynamic behavior also raises problems if the gateway is accessed by more than one client simultaneously. It is possible that data in a table are modified by one client (e.g., rows are deleted or added) while another client is in the process of reading the table. This results in an inconsistent set of data. A possible solution used in the case study was to introduce a sequence number for every table. This sequence number changes every time data in the table change. The workaround for achieving data consistency is to read the sequence number, read the table, and afterward read the sequence number again to check if it changed [35]. In case it remained unchanged, the table data are consistent; otherwise, the whole process has to be repeated. To this end, for write access, the protocol had to be slightly changed in a way that every SNMP SET command contains a sequence number that uniquely identifies the version of the table to which a data point is written.

Another problem of SNMP is security. The commonly used version of SNMP is version 1, which does not contain any considerable security features. In the most recent version 3, security mechanisms have been introduced that are sufficient (though not widely used at present). Still, difficulties arise from the connectionless UDP used as transport protocol. UDP traffic is usually not permitted to pass through a typical firewall. But even if communication is possible, the underlying UDP does not guarantee packet delivery. This means that an SNMP manager communicating with an agent cannot rely on the last action he has taken on an agent to be successfully finished. Neither can an agent be sure about the status of a communication with a manager. Hence, error monitoring must be implemented within the manager application.

## 22.5.2 LDAP

The Lightweight Directory Access Protocol (LDAP) is the lightweight counterpart to X.500 directory services. It is oriented toward directories that are organized in a tree, the *directory information tree* (DIT). The DIT is a hierarchically structured organization of data items, the directory entries. Every entry consists of a collection of attributes. Every attribute has an attribute name, an attribute type, and a value associated with it. One special attribute that is mandatory for every tree entry determines the position of the entry in the tree—the *distinguished name* (DN), which is used as a unique *address* for the entry. It specifies the path by listing all parent entries up to the root entry. The directories contain mostly (but not necessarily) small pieces of data, which are mainly read and searched for. Writing of data is intended to occur only rarely, as well as changes in the tree structure.

LDAP offers a set of data querying and manipulating commands for accessing the directory service. The SEARCH command is very powerful and allows specifying search filters that are applied to each

entry. It is possible to request just a subset of the available attributes, and in order to narrow a search even more, the scope can be limited to a certain level of the directory tree (search only the current level, one level deeper, or the whole subtree). With the commands ADD, DELETE, and MODIFY, single entries can be added, deleted, or modified, respectively. The COMPARE command is used for comparison of two entries.

Since LDAP uses TCP as transport protocol, there are no problems with firewalls. Also, all security extensions designed for TCP-based protocols such as the *Transport Layer Security* (TLS) can be used. LDAP version 3 also provides appropriate authentication mechanisms in combination with those already defined in TLS.

Dynamic update of the directory information tree is also not particularly problematic, although the changes are not automatically taken over by the client. The DIT as such is not confined to a static structure like the SNMP MIB, which facilitates the adding and deleting of entries even at runtime. Consequently, there is also no problem with the consistency of data, because the address of a data point can be added as an attribute to the directory entries to unambiguously identify the data points. As operations on a DIT entry are always atomic, simultaneous and consistent access to one single data point from multiple clients is inherently handled by the built-in mechanisms of the protocol.

A general difficulty of LDAP is that its original application idea does not exactly fit the purpose of fieldbus gateway access. The main application of LDAP is the access to data that are related to humans, for example, telephone numbers, employee data, or classical white pages services. The client support reflects this field of application, and although clients exist, they are not widely used and very different in their performance with respect to network load. A second point is that the access to white pages directories is typically read-only. Therefore, the powerful search command can provide a convenient means to retrieve fieldbus data [37]. Writing, on the other hand, is more difficult and likely becomes a bottleneck. Hence, LDAP is not so well suited for control tasks where intensive write access is required. Another problem is the lack of an asynchronous notification mechanism, so workarounds (like e-mails or the like) have to be used.

### 22.5.3 Structured Query Language

To consider SQL as a protocol for remote gateway access may seem a bit exotic, but there are examples for its use as middleware concept in sensor networks [38]. As SQL is the standard language for relational database management systems, it is widely used also in Manufacturing Execution System (MES) and Enterprise Resource Planning (ERP) systems, which are the intended end points for the vertical integration of field-level data. On the other hand, the fieldbus data on the gateway are handled by a database-like mechanism, anyway, so it is natural to investigate the usability of SQL. It should be noted that SQL is no protocol; it only defines the syntax and semantics of a database query. The transmission mechanism depends on the driver (like Open Database Connectivity [ODBC] or Java Database Connectivity [JDBC]); implementations based on TCP are available, which seems to be best from the viewpoint of additional security mechanisms and handling of multiple connections.

The most essential command is SELECT, which allows searching the database by defining a search query. Compared with LDAP, the SELECT statement in SQL provides much more complexity. Write operations on tables are performed with the UPDATE and the INSERT statements, where INSERT creates new rows in a table, while the UPDATE completely or partly overwrites existing rows. The CREATE and DROP statements are used for creating and removing database objects (primarily, tables). The gateway logic must comprise appropriate modules to parse and handle the SQL statements in order to perform the operations on the database.

The way the data are organized in tables is extremely flexible; hence, suitable ways can be found to allow for dynamic updates of the data point structure. In the case study, four tables for the nodes, data points, events, and logs were used according to the services provided by the gateway. The relation between the tables and the physical fieldbus addresses is achieved by using the fieldbus addresses as primary keys in the node and data point tables. Because these addresses are unique and are not changed

over the lifetime of a node (or data point), it is not possible to confuse one object with another one. If objects are added between two queries, the response of an SQL query will of course differ before and after the change; however, every query response by itself provides a consistent view of the structure of objects at that time. It is up to the client how it will handle such structural changes; the protocol does not impose any additional constraints here.

A weak point of SQL is client support, and there is no standard *SQL client*. Instead, an additional ODBC driver (C/C++) or JDBC driver (JAVA) needs to be provided for the development of client-side applications. Like LDAP, SQL has no built-in possibility to send notifications from the gateway to the client, and alternative means must be found. Furthermore, due to the organization of data in tables, the use of different data types is limited. A typical but not very convenient way to circumvent this problem is to convert all data to strings and use the native SQL VARCHAR type for all fieldbus values.

#### 22.5.4 Web-Based Approaches

For many solution providers in the area of fieldbus/Internet connectivity, web-based approaches seem to be the only conceivable solution; at least they are strongly favored. However, unlike the protocols described so far, methods based on the WWW are very heterogeneous. They include communication and data representation using web browsers as clients. The common transport protocol is HTTP, which is typically used to transmit HTML documents. HTML documents can contain embedded objects and script languages (e.g. JavaScript) and can be created by multiple technologies on the server side (such as CGI, ASP, JSP). They all have in common that the client receives a predefined view of a set of data. This view can be modified by the user (e.g., by selecting specific objects in a page and filtering out the others), which requires the creation of a new document on the server side. This process is usually not very responsive because of the necessary communication and computation overhead.

The two main commands HTTP supports are GET (for sending requests to a server to retrieve data) and POST (to send data to the server). This, however, does not cover the whole spectrum of possibilities that are based on top of this mechanism. In many cases, however, the user is presented with a view based on a template, which is filled with data by some server mechanism.

A definite strength of web technologies is the availability of many different clients. A lot of Internet browsers for multiple platforms exist, leaving hardly any white space on the map of supported systems. The main problem of pure HTML is the response behavior that is imposed by the necessity to refresh (i.e., completely reload) a page in order to receive current data (this can be circumvented by advanced mechanisms, which only retrieve, for example, the data point value). There is also another performance problem with this approach: As the view on the data depends on HTML documents, typically several data points will be collected on one page to have a better overview. Therefore, even for very small amounts of data (e.g., the value of just one data point), a complete document needs to be created and transmitted. This causes a considerable amount of both computational overhead and network traffic. Likewise, it is not possible to collect data from multiple servers in a single document, which considerably limits the use of this approach. In an IP tunneling scheme, for example, every device providing data needs to maintain a set of HTML pages, and the client needs an instance of the browser for each device. An integrative view of the entire installation, let alone an automatic data acquisition, is not feasible and has to be done manually.

A positive point about the web approach is the comparatively unproblematic security issue. As HTTP is based on TCP, TLS can be used. Furthermore, HTTP is conveniently routable through firewalls [39], which is an important point in an environment becoming increasingly aware of security—although it has to be noted that the simple routing possibility actually opens a way to circumvent security. A drawback is that there is no way for the server to send data to the client without request. Like with all other protocols except for SNMP, other ways have to be found to accomplish such notifications (e.g., special applets or e-mail-based services). Very poor is also the support of different data types. In fact, the data have to be sent as strings and processed appropriately by the client. This lack of ample data type support

ideally supports (and also demands) pragmatic, proprietary solutions but is a severe obstacle to standardized, interoperable implementations. A possible way out of this dilemma is the increasing use of XML. If the data are based on (standardized) XML descriptions, they are not only readable for a human operator (a severe drawback of HTML), but also machine parsable, which makes gateway access based on web technologies finally also suited for automatic data acquisition.

A further step in this direction could be the XML-based Simple Object Access Protocol (SOAP), which defines methods for data exchange typically used over HTTP, and on top of it web services allowing for flexible, easy-to-integrate solutions [40–45]. A tremendous benefit is an utmost platform independence as both HTTP and XML are available everywhere. However, as SOAP is a protocol on its own, client applications are still needed, a web browser today is not sufficient. A potential weak point is, as with the somehow related technology Common Object Request Broker Architecture (CORBA), the relatively complex structure that does not lend itself to a lightweight implementation on those resource-limited devices that today make up a significant portion of a typical automation system.

### 22.5.5 OPC

OPC (originally OLE for Process Control, nowadays the abbreviation no longer has an official meaning) has become a de facto standard for interconnecting fieldbus systems and local area networks. Although the basic intention of OPC is to provide a comprehensive middleware, it is commonly used *only* for direct access to fieldbus data. This also fits the discussion of remote access possibilities to fieldbus gateways: the OPC server itself is the gateway; various OPC modules already implement most of the functionalities desired from a gateway and listed in Section 22.1. Like with all middleware approaches, there are no stand-alone client applications available. The objective of an OPC client is to provide communication and data exchange functionalities to other applications like SCADA or configuration tools [46]. From the viewpoint of vertical integration, it is important to notice that OPC has become a building block for many MES products [47]. In all these applications, OPC serves as a kind of driver to the fieldbus integrated in the application software. Alternatively, there can be an additional layer in the architecture, and OPC can be the fieldbus driver for a gateway, which in turn connects to the actual application via any other protocol, such as HTTP [39].

With regard to the data representation, data in OPC are organized in an arbitrary tree-like namespace consisting of nodes and items (the leaves of the tree) with respective sets of properties like in most other protocols discussed before. Unlike all previous examples, however, the structure relevant for the application is not defined by the OPC server. Rather, the client is free to define its private view on the data. According to the original OPC specification, server presents a flat list of items to the client and lets client organize these items into groups. The newer version OPC XML-DA depreciated the notion of groups and, instead, allowed server to arrange items into a hierarchical *browse space* (somewhat similar to data representation of SNMP and LDAP). Basically, OPC-XML allows the access to process variables only. All specific functions (like fieldbus startup, access to special resources or protocol objects) have to be implemented by the server logic, and access to these functions must be mapped to generic data points on the server.

A major drawback of the original OPC version based on Distributed Component Object Model (DCOM) was a lack of security features, which limited the applicability to closed environments. The technological reason was that DCOM requires a large and a priori unknown number of UDP ports to handle the connections between the distributed objects. For the implementation and administration of a security policy, for example, by means of a firewall, such a situation is highly undesirable and should be avoided. The recent extensions based on XML and SOAP mitigate the problem and permit the use of OPC also over corporate intranets, even over the Internet. Compared with plain web-based approaches, OPC-XML pursues a much more rigorous way of structuring data, which improves interoperability while at the same time exploiting the benefits of web technology.

The most recent OPC UA (Unified Architecture) specification provides further extensions: It drops the reliance on a single communication protocol, or even a single wire format for transmitting messages,

and introduces a set of core services that can be made available by a server (gateway) to its clients via a particular *transport* (protocol) in a certain *encoding* (message serialization format). Transport possibilities are UA TCP (UA-specific framing on top of TCP with its own session handling, fragmentation, and reassembly capabilities) and SOAP/HTTP (web services, like in the case of XML-DA). The possible encodings are XML/text and UA Binary. The XML encoding is human readable but not very efficient because it requires decent communication bandwidth and sufficient computing resources for XML parsing. With binary encoding, transmitted data are serialized into binary structures for improved efficiency also on resource-limited embedded systems. The standard also leaves room for other protocols and encodings in the future, while maintaining the core set of services [48].

The information model in UA was changed to a new object-oriented concept. Gateway and CN resources are defined in terms of objects that can encapsulate both data variables and methods, that is, gateway-side functions that a client may invoke. Objects are arranged as nodes in the *address space* without any prescribed structure like in earlier versions. Finally, the UA standard addresses issues related to representing CNs and their services. While XML-DA only described data acquisition, UA also describes Alarms and Conditions (asynchronous notifications), Historical Access (logs), and Programs (complex gateway- or fieldbus-side functions that cannot be represented as a single object method). All this makes OPC UA the most suitable protocol out of all considered standards [49].

## 22.6 Role of Industrial Ethernet

---

A discussion of fieldbus/Internet connectivity is incomplete without consideration of the growing use of Ethernet in automation. After all, Industrial Ethernet is often praised as *the* solution to vertical integration overcoming all problems encountered in the design of heterogeneous network interconnections. Beyond all well-sounding marketing slogans, it is a matter of fact that the dominant use of Ethernet in local area networks has renewed efforts to employ Ethernet also in the automation domain. These efforts date back to the early days of Ethernet development, but only recent technological advances in the development of full duplex and switching techniques made high data rates possible without the old drawbacks of the Carrier Sense Multiple Access with Collision Detection (CSMA/CA) medium access control. The main benefit is clear: If Ethernet was used as a replacement for the fieldbus, and if IP plus the common transport protocols were used on top of it (which is not necessarily the case in all industrial Ethernet approaches), Internet technologies would be the natural way of accessing automation data. It is thus not astonishing that many contemporary concepts of vertical integration rely strongly on Ethernet as an automation network. For the old CIM pyramid, the penetration of LAN technologies into the classical fieldbus domain has the ultimate consequence that intermediate levels become obsolete. The hierarchy thus gradually turns into a flatter structure with only two, maybe three levels.

How do the facts of Industrial Ethernet compare with the characteristics of vertical integration discussed so far? It is of course shortsighted to postulate that the use of Ethernet alone entails an interoperability with *the office world*. In fact, Ethernet is but a transport medium. Using Ethernet for both office and automation applications may allow for a coexistence on a shared medium (within certain limits posed by, e.g., bandwidth and security considerations) but does not mean integration. What is much more important to this end is the protocol stack employed on top of Ethernet. Some solutions rely on TCP/UDP/IP as a transport layer, and many, especially real-time Ethernet approaches, provide some possibility for a parallel nonreal-time channel that can carry also IP traffic [50,51]. In many cases, however, the higher protocol layers are in fact *fieldbus* application-layer protocols that were retained for compatibility reasons and that are sort of tunneled using TCP/UDP encapsulation methods.

Of course, industrial Ethernet approaches have the benefit of a—thanks to the possibility of using the same medium for office and automation tasks—tight integration from a pure networking point of view. Unless a traffic separation seems reasonable for performance or security reasons, no dedicated connection node is necessary. On the application level, however, integration is by no means so tight. Even though the inclusion of automation data into office applications is simplified by, for example,

object-oriented techniques borrowed from the IT world, there is still a substantial amount of fieldbus-specific information to be handled. Consequently, an abstract view on the automation data—one of the requirements for vertical integration—is not a matter of course. Nor is an *automatic* inclusion of industrial Ethernet into the office world easy to achieve. In fact, the effort that needs to be spent on a gateway design has in this case to be put into the development of appropriate nonstandard application-level tools. The only exception where Ethernet together with standard protocols definitely brings an advantage is a web-based human machine interface used, for example, for configuration purposes. But this is only one small aspect of automation.

## 22.7 Summary

---

The classical fieldbus systems have been devised as highly specialized communication systems for the factory floor. Their development, though innovative at that time, was aimed at conventional self-contained automation applications. Today's automation tasks, however, are usually no longer stand-alone systems. At least SCADA is required in many cases, with the respective SCADA software running in a typical office environment as regards hardware and software platform or network environment. More advanced demands are remote data access for monitoring or maintenance, or the inclusion of automation data into company-wide management systems. All these functions are in fact not part of the factory floor or the process control level; they belong to a higher, more strategic level of information processing, which is governed by office networks. This circumstance calls for an interconnection between automation and office networks.

As different as the goals of interconnection are the possible realizations. Although the systems on either side are standardized, the link is not—not even in a coarse architectural sense. One reason is the still existing plethora of fieldbus systems. But also on the Internet side, the IP suite is just a least common multiple of an equally large set of possible applications serving as targets for the interconnection. The preceding sections have highlighted the basic system architectures and the many design options to be considered. Evidently, the properties of the networks together with the applications have an important influence on these options and in fact limit the designer's flexibility with respect to the implementation.

Contrary to an initial guess, the architectural approach (i.e., gateway or tunneling) does not seem to affect the overall system complexity very much. As the discussion showed, it rather influences the distribution of the implementation efforts among the involved entities: field devices, clients on the Internet side, and a possible central access node. The particular choice must largely depend on the intended application; there is no golden rule for it. In fact, all approaches have their own strengths and shortcomings. Even though the major part of the article discussed the subject from the viewpoint of a gateway solution, this does not imply that the tunneling approach is inferior. It is simply suited for slightly different types of application, and most of the points described for a gateway are equally valid.

The overall complexity of the interconnection is—according to practical experience—chiefly determined by the desired level of data and functionality abstraction and the degree of vertical integration to be achieved. A direct forwarding of fieldbus data packets *as is*, with the interpretation left up to the client (and, ultimately, the user), is easier to achieve than a reasonable data and protocol translation with the aim of a smooth integration into a nonfieldbus-specific application. Not always is true vertical integration and abstraction really an issue. But if it is, the price to be paid is necessarily a loss of precision, mostly from a functional point of view. The higher the abstraction level, the fewer functions and specific pieces of information can be mapped to the *other side* without problems. Timing precision or real-time behavior should not be a requirement at all because timing relations are typically lost in the node linking the two different networks. Timestamps can help, but only to a certain extent.

The great flexibility of fieldbus/Internet connections sketched in this chapter is a bit deceptive. In practical implementations, one has to live with a number of inconveniences. Timing is just one. Especially if one goes for vertical integration, the high-level target application and the underlying protocol may not support services provided by the automation system. This frequent lack of a one-to-one relation

between the two networks requires some creativity from the designer, especially on the Internet side. Good examples are the basic gateway services discussed in Section 22.3. Vital mechanisms such as asynchronous notifications rarely exist as native protocol features and have to be replaced by workarounds outside the actual application. In this respect, the large number of different interconnection approaches is not astonishing but only reflects the fact that the one ideal solution for all occasions does not exist.

### 23.1 Classic N2 Problem in Discrete Manufacturing

---

The huge networking problem with manufacturing was that each machine tool spoke a different proprietary protocol. The problem is depicted in Figure 23.1. As the text in the drawing states, it is a connectivity and integration nightmare.

In Figure 23.2, you will notice that the number of connections is the classic  $n$ -squared problem of connectivity. This was a huge nightmare for software application developers. Prior to MTConnect, the onus was on software developers to have to write an adapter for each and every piece of manufacturing equipment on the shop floor that the customer was trying to collect data from. MTConnect takes the burden from the application developer and moves it where it should be—closer to the device itself.

#### 23.1.1 Discrete Manufacturing after MTConnect

Figure 23.3 shows how MTConnect addresses this issue. From a developer standpoint, the problem of converting the proprietary formats has been moved from the client side much closer to the actual

---

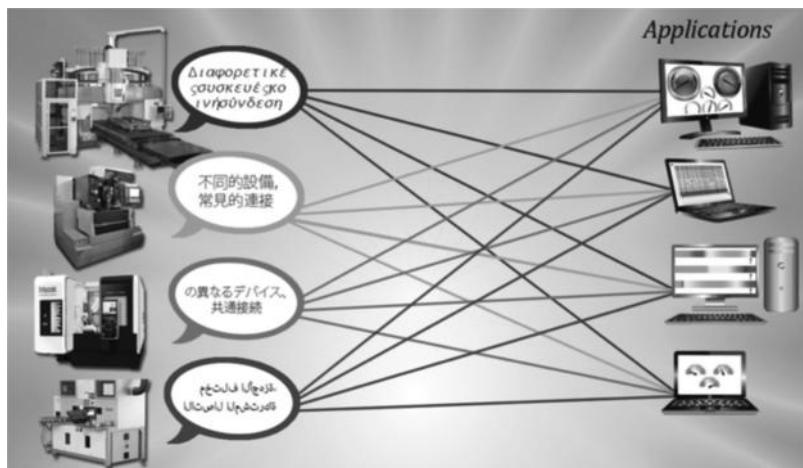

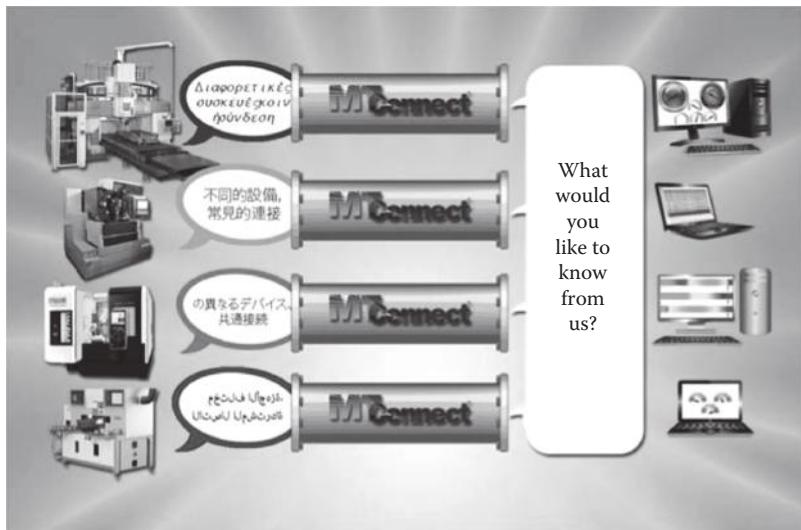

FIGURE 23.2 A version of the classic  $N^2$  problem.

piece of manufacturing equipment. The advantage of this to the application developer is that now with MTConnect, each client application only needs to concern itself with speaking MTConnect.

## 23.2 MTConnect: An Overview

### 23.2.1 What MTConnect Is

MTConnect is an open and royalty-free standard for manufacturing that is used for connecting manufacturing equipment with applications by using proven Internet protocols. Think of MTConnect as the Bluetooth for manufacturing. With Bluetooth, both devices must *speak* Bluetooth for anything useful to happen. Just as simply having an OBD-II port on your car does not provide you with any more

**FIGURE 23.3** MTConnect is the Bluetooth for connecting the manufacturing equipment to applications.

data unless you have an OBD-II scanner, the same *pairing* principle applies to MTConnect and software applications. You can have an MTConnect-enabled machine tool or piece of manufacturing equipment, but without the software to read and analyze the data, you do not have both sides of the equation. The OBD-II scanner is really the application or the tool that you use to help you understand what is happening with your engine. In manufacturing, it is software applications, such as shop floor monitoring programs that are the applications, that speak to an MTConnect-enabled piece of manufacturing equipment on the shop floor.

### 23.2.2 What MTConnect Is Not

MTConnect is not an application. Let me say that again, MTConnect is not an application. MTConnect is not a product. The MTConnect Institute does not sell MTConnect. MTConnect is a standard based on open and royalty-free protocols. This is a common point of confusion with nonsoftware developers. Paul Warndorf likes to tell the story of the individual at IMTS 2010 who pulled out their credit card and wanted to buy MTConnect. It was analogous to a shopper in Best Buy pulling out their credit card and wanting to buy Bluetooth. It is natural to understand where the confusion comes in because MTConnect in and of itself is simply the plug-n-play for making it easy to get data from manufacturing equipment. However, it is what you *do* with that data that turn the MTConnect data into actionable intelligence.

## 23.3 MTConnect Standard

The MTConnect standard is broken down into four parts. What follows are the four standard sections of MTConnect and its major subsections. Before a developer is able to develop anything more than a very simple application, it will be necessary to read and understand Parts 1, 2, and 3 of the standard. Part 4 is for assets, and this becomes important for developers who are using those typically *mobile* assets of the manufacturing equipment. Mobile assets are those items that are not always connected to a piece of manufacturing equipment. A cutting tool or a part would be good examples. The purpose of listing the sections of each of the four parts is to let the reader know where to go for more specifics on the standard—which is at [MTConnect.org](http://MTConnect.org)

## **23.4 Types of MTConnect-Enabled Devices**

---

From a manufacturing equipment or device perspective, there are three types of MTConnect-enabled devices:

- Native
- Translation dependent
- Connection dependent

A native device simply means that this device comes with an MTConnect agent already included in the device, and an MTConnect-enabled application could immediately speak to this device with no additional software or hardware that is needed. Native MTConnect devices would be newer devices as MTConnect was first released to the outside world at the end of 2008.

A translation-dependent device is a device, which could be hardware and/or software, that acts as a translator between whatever proprietary hardware and/or software interface that the manufacturing equipment speaks and MTConnect applications.

An example of this might be a small black box that runs Linux and has both an adapter and an agent running. The black box might also have a number of ports on it to speak to a wide variety of protocols as well as have one or more Ethernet ports on it. The adapter speaks to the manufacturing equipment using the physical port and protocol that the manufacturing equipment understands and then that adapter sends information to the agent using the SHDR protocol, which is a simple flat, fast, and low-latency human-readable protocol delimited by pipes (|) that is in ISO 8601 date-time format with optional decimal places. The agent then takes that information and makes it available in an MTConnect-compliant format. A specific example of this might be a black box that has a FANUC FOCAS adapter that is speaking to a FANUC CNC controller as well as the MTConnect agent on the same box that is accepting SHDR from the adapter and then making it available to MTConnect-enabled applications.

The key part of an MTConnect translation-dependent device is that the adapter is typically speaking to an Application Programming Interface (API) to send queries to that device, translating that information into SHDR, and then sending it to the MTConnect agent. There are many examples of this where the CNC controller speaks a specific protocol and you most likely need to license a software development kit or software library to be able to speak to the CNC controller in the language that it knows. There are a variety of adapters at [github.com/MTConnect](https://github.com/MTConnect)

A connection-dependent device is a device that could be hardware and/or software that acts as a translator between whatever proprietary hardware and/or software interface that the manufacturing equipment speaks and MTConnect applications. Sometimes there is confusion between a translation unit and a connection unit. Here is the key difference: the translation unit device is speaking to a device that has an API whereas a connection unit has no API. This typically means a connection unit is talking to an older piece of manufacturing equipment and pulling off very low-level signals, such as doing an A/D conversion, which are then transformed and sent to the agent. The simplest example of this might be an old lathe. The only piece of data that can be easily derived is whether the lathe is off, on, or in the process of cutting. A connection unit would have the appropriate ports to determine whether it was off, on, or in the process of cutting, and the adapter would pass the information along to the agent. The agent then would respond to client requests where only those three data items could be requested. While it might be argued that only knowing those three are not that helpful, the truth is that it is much better than a stack light, and even with this low-level example of MTConnect enabling a simple device, there are advantages above and beyond a stack light replacement. For example, with the electrical information, the costs of running that lathe could easily be calculated. Now the manufacturer knows the electrical cost of that device and what percent of the time the device is running and not running. The MTConnect connection unit black boxes are literally plug-n-play for these types of older pieces of manufacturing equipment.

## 23.5 Technical Pillars of MTConnect

---

From a software developer's perspective and at an 80,000 ft view, MTConnect has four key pillars:

1. Adapter
2. Agent
3. MTConnect's Data Dictionary aka Namespace or the XML Schema Definition
4. Application

Here are the big picture points to remember:

- Applications speak to an agent.
- The agent speaks to adapters (adapters are optional).
- Adapters or agents speak to manufacturing equipment.

### 23.5.1 Adapter

The adapter is the optional piece of software that can be thought of as the bridge between the manufacturing equipment and the agent. On one side, the adapter is speaking whatever protocol, as well as providing whatever physical mechanism, that is needed to speak to a piece of manufacturing equipment (could be a machine tool, bar feeder, coordinate measuring machine [CMM], etc.), normalizing that data, putting it into a modified version of the Simple Hierarchical Data Representation (SHDR) format, and sending it to the agent. The adapter is optional because for those pieces of manufacturing equipment where MTConnect is native, there is no need for an adapter.

The following are some key points to remember about MTConnect adapters:

- Do not appear in the MTConnect standard
- Are optional (for nonnative MTConnect devices)
- Speak to devices on one side of the equation
- Constantly stream output to agent(s)
- Typically do not speak to applications directly as this would involve bypassing the agent that makes little logical sense
- Can send data to multiple agents or just one agent—it is a design and implementation choice

The point to remember is that adapters speak to an agent(s) on one side of the equation and manufacturing equipment on the other.

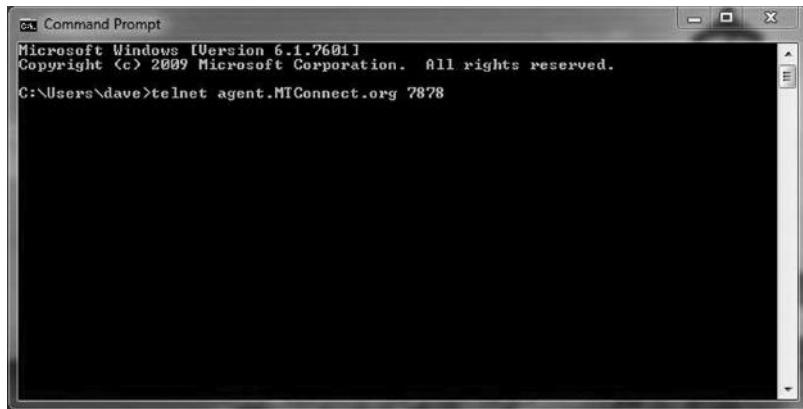

The reference adapter is the adapter that the MTConnect Institute provides at the MTConnect location on [github.com](https://github.com). What sometimes is confusing is that the MTConnect Institute provides a reference adapter and a reference agent to make it easy for developers to create these two pieces of software. Keep in mind that *reference* means it is either a binary or the source code that you can use to develop your agent or adapter. You can *refer* to it as you develop your own adapters or agents. This is a standard type of model used in software development. What confuses those outside of software is whether or not the MTConnect Institute mandates the reference agent or adapter—the answer to that is no. A software developer could simply read the MTConnect standard and write their own agents and adapters without ever viewing the reference software. It has been proven that by providing the reference adapters and agents, we have decreased the development time for those who are writing MTConnect agents and adapters.

The difficulty in writing an adapter varies from very easy and quick to very difficult and time consuming. The reason for the range is as follows:

- How much documentation do you have for the device you are trying to connect?
- What is the physical medium that is needed to get information?
- Is there a similar adapter that has been written?
- How much information are you trying to get out?
- Are the costs to get the documentation prohibitive?

Also consider the following examples of reference adapter and agent responsibilities.

1. The term *reference* agent is used loosely in this context because there is no standard for an adapter. This was done by design. While this is true, it is also true that many agent developers have used the SHDR protocol as the mechanism for the adapter to send data to the agent. Again, we give flexibility to the developers.
2. Adapters can provide a socket connection to which a process can connect and receive updates.
3. Adapters send data only when it changes (this is very important) and sends data only after handshake with agent. In other words, the adapter will not just send out data with no known agent.
4. Adapters should make sure all data conforms to a controlled vocabulary, fixed set of values, and only communicate those values. Examples are ControllerMode and Execution.

**FIGURE 23.4** Talking directly to an adapter.

5. Agents can support multiple connections for testing.
6. Agents send all initial values to new clients when they connect.
7. Adapters format the data according to the SHDR specification.
8. There is a heartbeat between the reference adapter and the agent. For example,
  - a. Agent sends a *ping* to the adapter.
  - b. Adapter responds with a *pong*.
    - i. If the agent does not receive a pong, then first assumption is this is a legacy adapter; if no response after 20 s, then the agent considers the adapter to be dead.
  - c. There is a heartbeat between both the adapter and the agent every 10 s, but that can be changed.
  - d. If one does not respond to the other's heartbeat for two times the interval, then that (agent/adapter) is considered dead.
9. Adapters perform the connection(s) to the manufacturing equipment interfaces and gather data.

Figure 23.4 shows the simplicity of talking to the adapter by using the standard telnet command. The user can simply telnet to the port defined for your adapter and see output that is going to the agent (Figure 23.5). This is very helpful for troubleshooting when you are developing your adapters and agents or you simply want to verify the adapter is putting out data.

Notice that the reference adapter output is very simple and is delimited by |. The agent is reading the adapter output, puts in a buffer that can then be read from an MTConnect-enabled application or from any application that can speak HTTP and read XML—such as a simple browser.

The following are a few examples of what comes out of the adapter:

```
2012-08-20T01:34:21.650493|Xact|-1.7883759737|Yact|-0.3661781847|Xcom|-
1.7899452213|Ycom|-0.3595617390
2012-08-20T01:34:21.666492|Xact|-1.7894827127|Yact|-0.3615075648|Xcom|-
1.7908221776|Ycom|-0.3556611774|path_feedrate|0.3061054894
2012-08-20T01:34:21.682492|Xact|-1.7905533314|Yact|-0.3568308055|Xcom|-
1.7916012147|Ycom|-0.3517520805|path_feedrate|0.2972257736
```

The screen will be racing by with this type of information coming above from the adapter. The adapter determines the sampling rate.

**Note:** This connection to the machine tool interface and the gathering of data is where all of the hard and time-consuming work is done. Remember, the adapter is *not* part of the standard, and this just provides background on the reference adapter.

FIGURE 23.5 The output of the adapter. Above is SHDR output.

### 23.5.2 Agent

The agent can be thought of as a very efficient web server that bridges between adapter(s) and application(s). As a developer of client applications, expertise in what the agent is doing and understanding the standard is critical.

The agent *represents* one or more MTConnect-compliant machines. It makes machine data available in uniform MTConnect representations, responds to MTConnect commands, and allows clients to specify/select which data are of interest. The agent can *listen* to multiple adapters. Figure 23.6 is a picture of what the agent is doing.

Think of the agent as having two buckets or buffers that the controller deposits data into:

Samples Events Conditions Buffer default is 131,072, which is also known as 2<sup>17</sup>.

*Note:* This must be a factor of two for speed purposes.

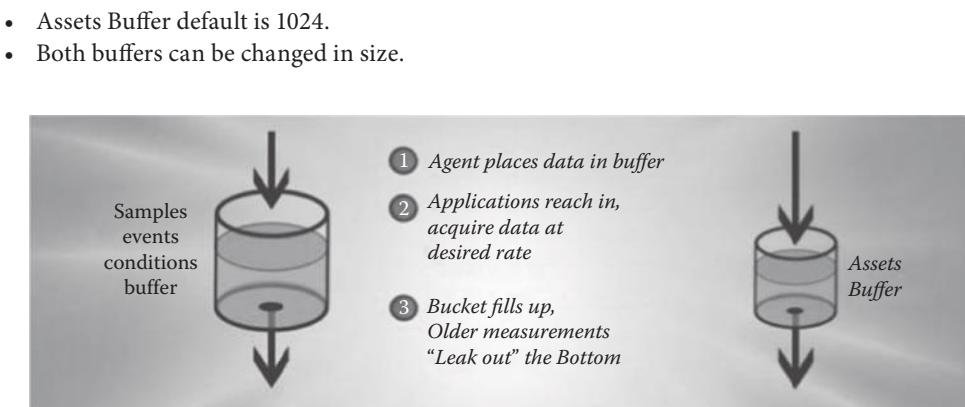

FIGURE 23.6 The agent *bucket* buffer model.

- Both of these can be changed to different sizes based on need. Each application *reaches into the bucket* at the rate it wants. As the bucket fills up, older measurements *leak out* the bottom depending on whether or not any applications have read them and the capacity of bucket, which depends on agent implementation.
- The ability to keep or persist the data can be done either at the application level or by creating a custom agent—whichever is the developer's design choice.

### 23.5.3 Programmatic Conceptual Terms

The following terms are key conceptual terms that software developers will need to know and understand when developing an application that will speak to the MTConnect agent.

- *Header*. Protocol-related information.
- *Components*. The building blocks of the device.
- *Data Items*. The description of the data available from the device.
- *Streams*. A set of samples or events for components and devices.
- *Samples*. A point-in-time measurement of a data item that is continuously changing.
- *Events*. Unexpected or discrete occurrence in a component. This includes state changes and conditions.
- *Conditions Are Normal, Warning, or Fault*. Warning is trending toward a fault, and fault means the device has stopped and needs intervention to get it working.

## 23.6 MTConnect's Powerful Data Dictionary

A very powerful component of the MTConnect standard (tons of hard work went into creating this) is the XML schema or the data dictionary. The file [http://www.mtconnect.org/schemas/MTConnectDevices\\_1.2.xsd](http://www.mtconnect.org/schemas/MTConnectDevices_1.2.xsd) is over 600 lines long. It is this data dictionary that makes the job of the client application developer much easier. Applications that do not provide a schema place the burden on determining what each value means, as well as the allowable values, back onto the shoulders of the application developer. Figure 23.7 drives home this point.

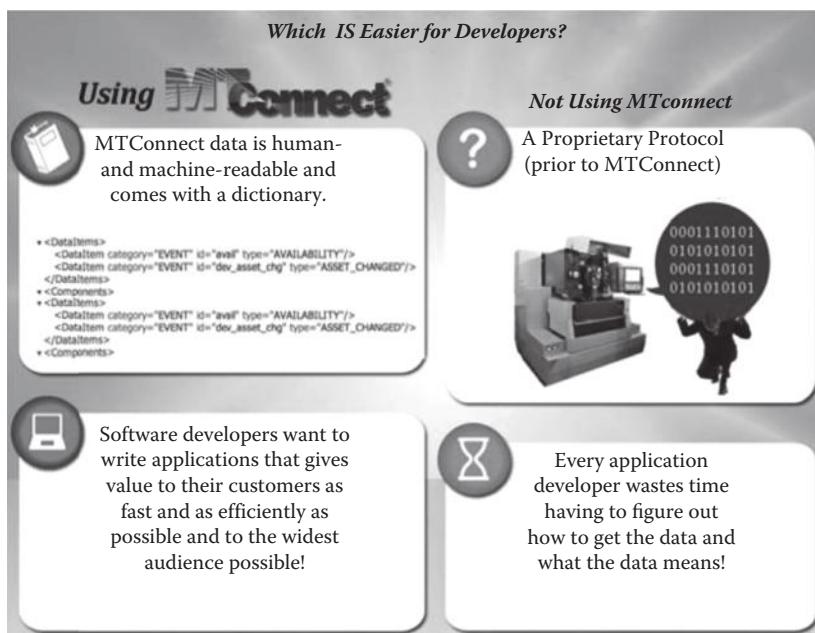

FIGURE 23.7 Using MTConnect vs. not using MTConnect.

In Figure 23.7, notice that AssetCountAttrType is *The number of assets*; it is an integer that has a minimum value of 0 and a maximum value of 4,294,967,295. I doubt 4,294,967,295 will be a limit for assets anytime in my lifetime.

It is impossible to overemphasize the importance and the time that went into creating MTConnect's powerful namespace or data dictionary. It takes years and thousands of man-hours to do it properly. There are standards out there that do not supply a data dictionary and place the entire burden of knowing what bits are coming to the application on the software developer writing client applications.

You may wonder, *How does one make suggestions for additions to the MTConnect standard?* There is a very good white paper at MTConnect.org titled, *Recommending the Addition of Devices, Components, and Data Items to the MTConnect Standard*, which addresses this question.

### 23.6.1 Application

The application or client is the software that speaks directly to the agent, requesting information and keeping track of the sequence numbers so it can continue to request and process XML information coming from the agent. The most obvious application when connecting to a piece of manufacturing equipment is shop floor monitoring software. A shop floor monitoring program typically requests information from the agent(s), processes that information, and then displays graphs or charts on what the piece of manufacturing equipment is doing.

Applications speak to an MTConnect agent using HTTP and sending simple verbs. The agent returns back well-formed and valid XML.

- Probe—tell me about yourself.
- Sample—information passed with parameters to get specific data back from the agent.
- Current—what is happening right now.
- Asset—to access information on mobile assets or those assets that are not always part of the device such as a cutting tool or a part. That cutting tools can be changed out is why they are mobile.

The sample command retrieves a series of data starting from a position and returns up to the requested number of samples or events. It allows the application to retrieve all data without missing anything. It can stream data as it arrives and be thought of as a window into the stream of data.

The sample request retrieves values for a component's data items.

*Path.* Xpath expression specifies components and/or data items.

Default is all components in device or devices if no device is specified.

*From.* Starting sequence number for events, samples, and conditions.

Default is 0.

*Interval.* Time in milliseconds that the agent should pause between sending samples for events, samples, and conditions.

Sample can be used with an interval in special cases, and this should be done only judiciously (app beware). The interval used to be limited to a minimum of 10 ms, but with the device integration, we allowed it to go down to 0.

When you specify an interval of zero, you are telling the agent that “when a value changes, notify me *immediately* and don't try to collect any additional data items.” This is great for processes that need to do real-time monitoring (<10 ms). It should always be used with a path since this will allow only specific events to trigger. Real time is like beauty; it is in the eye of the beholder, so do not think <10 ms is a universal definition; it is not, and the definition is absolutely context sensitive: 1000 ms is 1 s.

*Count.* Must return next sequence

Default is 100

Run the following MTConnect sample command in a browser—<http://agent.mtconnect.org/sample>

The following is a snippet from the sample request (with no additional parameters) to show you the streams node; the ComponentStream; the ComponentStream with the name of *VMC-3Axis*; and the various events, conditions, and data items.

```
<Streams>
  <DeviceStream name = "VMC-3Axis" uuid = "000">
    <ComponentStream component = "Rotary" name = "C" componentId = "c1">
      <Samples>
        <ComponentStream component = "Controller" name = "controller"
          componentId = "cn1">
          <Events>
            <EmergencyStop dataItemId = "estop" timestamp =
              "2012-12-31T04:12:51.242511Z" sequence = "2934232704">UNAVAILABLE
            </EmergencyStop>
          </Events>
          <Condition>
            <Unavailable dataItemId = "clp" timestamp =
              "2012-12-31T04:11:51.227979Z"
              sequence = "2934232644" type = "LOGIC_PROGRAM"/>
          </Condition>
        </ComponentStream>
      </Samples>
    </DeviceStream>
  </Streams>
```

The following is a snippet from running the following simple MTConnect command that runs a sample with a count of 10.
