<http://agent.mtconnect.org/sample?count=10>

```
<Header creationTime = "2012-12-26T13:55:15Z" sender =
"mtconnect" instanceId = "1340212647" version = "1.2.0.10"
bufferSize = "131072" nextSequence = "2933744389"
firstSequence = "2933744379"
lastSequence = "2933875450"/>
<Streams><DeviceStream name = "VMC-3Axis" uuid = "000">
```

Notice these bold XML attributes highlighted in the header. As a developer of applications, the **instanceId** is important. As was just pointed out in a previous section, the **instanceId** was created to facilitate recovery when the agent fails and the application is unaware. It is up to the developer to track sequence numbers. Version is important as there have been changes in the standard. The MTConnect specification is the best place to review these changes.

Please note that if you would like to simply cut-and-paste these commands into a browser, you can go to <http://ToMeasureIsToKnow.com>, where I have all of these examples listed. It is beyond the scope of this chapter to get into all the specifics of writing an application, so the reader is encouraged to go <http://ToMeasureIsToKnow.com> to learn more.

What is interesting for software developers is all the ways MTConnect data can be analyzed in the countless other non-shop-floor applications.

## 23.7 Your First MTConnect Hello World Application

---

The following is the simplest of Java programs. The program uses Java's basic networking and Input/Output classes to read `agent.MTConnect.org` with a probe command. Print the XML out until there is nothing left to print. *Corvette* is my prompt on my MacBook Pro in a terminal window. You can go to <http://ToMeasureIsToKnow.com> if you just want to simply cut and paste the following source code into your editor or IDE.

**Corvette:**more MTConnectHelloWorld.java

```
import java.net.*;
import java.io.*;
public class MTConnectHelloWorld {
    public static void main(String[] args) throws Exception {
        System.out.println("Your First Hello World Program" + "\n");
        URL MTConnect = new URL("http://agent.MTConnect.org/probe");
        BufferedReader in = new BufferedReader(
            new InputStreamReader(MTConnect.openStream()));
        String inputLine;
        while ((inputLine = in.readLine()) != null)
            System.out.println(inputLine);
        in.close();
        System.out.println("\n" + "XML from probe command printed above");
    }
}
```

Compile the Java source

**Corvette:**javac MTConnectHelloWorld.java  
 Execute the Java class  
**Corvette:**java MTConnectHelloWorld

At this point, you will see a few pages of XML coming from the simulator that is running as a CNC vertical mill doing a very simple part in an endless loop.

If you are on a \*nix (Mac OS X is obviously in this category as well) box, then you can accomplish the same as given earlier from a command line:

**Corvette:**curl http://agent.MTConnect.org/probe

If you are a PC user, cURL(Command URL) comes with the PowerShell terminal or you could FTP cURL from SourceForge as well. You could also simply enter the earlier-provided URL from a web browser by just putting in the URL http://agent.MTConnect.org/probe. You can put these in your browser to see the results. Using a browser to enter in MTConnect commands is a great way to learn about MTConnect and do testing as well.

## 23.8 Summary

---

MTConnect is not an evolution in manufacturing, but it is a revolution and a true game changer. MTConnect is making possible the dreams and desires of generations of manufacturers, machine tool builders, and manufacturing equipment providers who all want to see the same goal of different devices having a common connection on the plant floor. This is why at the MTConnect Institute, we say, “MTConnect: *Different Devices, Common Connection*.”

### 24.1 Introduction

---

The international standard Manufacturing Message Specification (MMS) is an OSI application layer messaging protocol designed for the remote control and monitoring of devices such as remote terminal units, programmable logic controllers (PLCs), numerical controllers, or robot controllers. It provides a set of services allowing the remote manipulation of variables, programs, semaphores, events, journals, etc. MMS offers a wide range of services satisfying both simple and complex applications.

For years, the automation of technical processes has been marked by increasing requirements with regard to flexible functionalities for the transparent control and visualization of any kind of processes. The mere cyclic data exchange will more and more be replaced by systems that join together independent yet coordinated systems—like communication, processing, open and closed loop control,

quality protection, monitoring, configuring, and archiving systems—to a whole. These individual systems are interconnected and work together. As a common component, they require a suitable real-time communication system with adequate functions.

The MMS standard defines common functions for distributed automation systems. The expression *manufacturing*, which stands for the first M in MMS, has been badly chosen. The MMS standard does not contain any manufacturing-specific definitions. The application of MMS is as general as the application of a personal computer. MMS offers a platform for a variety of applications.

The first version of MMS documents was published in 1990 by ISO TC 184 (Industrial Automation) as an outcome of the GM initiative *Manufacturing Application Protocols* (MAPs). The current version has been published in 2003:

- *Part 1: ISO 9506-1 Services* (2003): describes the services that are provided to remotely manipulate the MMS objects. For each service, a description is given of the parameters carried by the service primitives. The services are described in an abstract way, which does not imply any particular implementation.
- *Part 2: ISO 9506-2 Protocol* (2003): specifies the MMS protocol in terms of messages. The messages are described with a notation ASN.1, which gives the syntax.

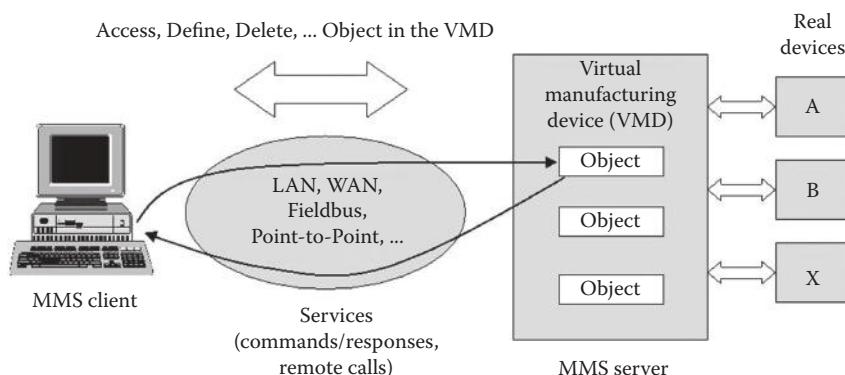

Today, MMS is being implemented on all common communication networks that support a safe transport of data. These can be networks like TCP/IP or ISO/OSI on Ethernet, a fieldbus, or simple point-to-point connections like HDLC, RS 485, or RS 232. MMS is independent of a seven-layer stack. Since MMS was originally developed in the MAP environment, it was generally believed earlier that MMS could be used only in connection with MAP.

MMS is the basis of the international projects IEC 60870-6-TASE.2 (*Inter-control center communication*), IEC 61850 (*Communication networks and systems for power utility automation*), and IEC 61400-25 (*Communications for monitoring and control of wind power plants*).

This chapter introduces the basic concepts of MMS applied in the standards mentioned earlier.

## 24.2 MMS Client/Server Model

MMS describes the behavior of two communicating devices by the client/server model (see Figure 24.1). The client can, for example, be an operating and monitoring system, a control center, or another intelligent device. The server represents one or several real devices or whole systems. MMS uses an object-oriented modeling method with object classes (Named Variable, Domain, Named Variable List, Journal, etc.), instances from the object classes, and methods (services like read, write, information report, download, and read journal).

**FIGURE 24.1** MMS client/server model.

The standard is comprehensive. This does not at all mean that an MMS implementation must be complex or complicated. If only a simple subset is used, then the implementation can also be simple. Meanwhile, MMS implementations are available in the third generation. They allow the use of MMS both on PC platforms and on embedded controllers.

The MMS server represents the objects that the MMS client can access. The virtual manufacturing device (VMD) object represents the outermost *container* in which all other objects are contained.

Real devices can play both roles (client and server) simultaneously. A server in a control center for its part can be a client with respect to a substation. MMS basically describes the behavior of the server. The server contains the MMS objects, and it also executes services. MMS can be regarded as *server centric*. In principle, in a system, more devices are installed than function as server (e.g., controllers and field devices) than devices that perform the client role (e.g., PC and workstation).

The *calls* that the client sends to the server are described in the part ISO 9506-1 (services). These *calls* are processed and answered by the server. The services can also be referred to as remote calls, commands, or methods. Using these services, the client can access the objects in the server. It can, for example, browse through the server, that is, making visible all available objects and their definitions (configurations). The client can define, delete, change, or access objects via reading and writing.

An MMS server models real data (e.g., temperature measurement, counted measurand, or other data of a device). These real data and their implementation are concealed or hidden by the server. MMS does not define any implementation details of the servers. It is only defined how the objects behave and represent themselves to the outside (from the point of view of the wire) and how a client can access them.

MMS provides the very common classes. The Named Variable, for example, allows structuring any information provided for access by an application. The content (the semantic of the exchanged information) of the Named Variables is outside of the MMS standard. Several other standards define common and domain-specific information models.

IEC 61850 defines the semantic of many *points* in electric substations. For example, *Atlanta26/XCBR3.Pos.stVal* is the position of the third circuit breaker in substation *Atlanta26*. The names *XCBR*, *Pos*, and *stVal* are standardized names.

The standard IEC 61400-25 (communication for wind power plants) defines a comprehensive list of named *points* specific for wind turbines. For example, *Tower24/WROT.RotSpd.mag* is the (deadbanded) measured value of the rotor position of Tower24. *RotSpd.avgVal* is the average value (calculated based on a configuration attribute *avgPer*). These information models are based on common data classes like measured value, three-phase value (delta and Y), single-point status.

## 24.3 Virtual Manufacturing Device

---

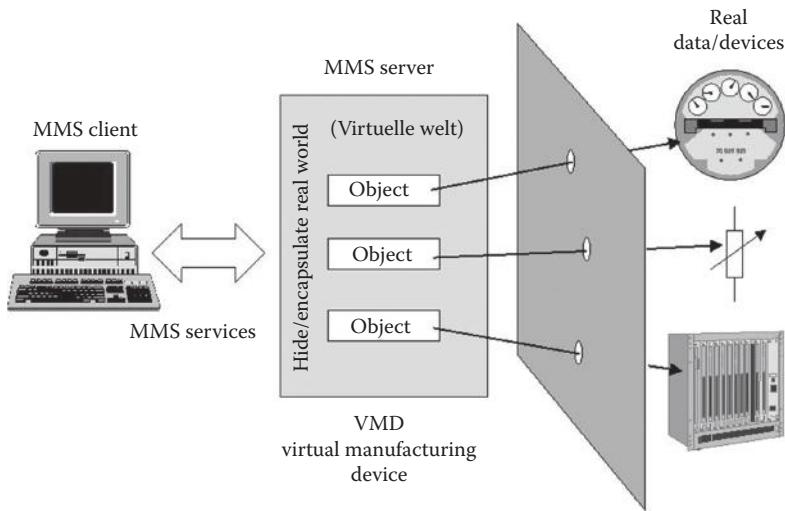

### 24.3.1 General Model

According to Figure 24.2, the real data and devices are represented—in the direction of a client—by the VMD). In this regard, the server represents a *standard driver* that maps the real world to a virtual one. The following definition helps to clarify the modeling in the form of a virtual device:

If it's there and you can see it	It's REAL
If it's there and you can't see it	It's TRANSPARENT
If it's not there and you can see it	It's VIRTUAL
If it's not there and you can't see it	It's GONE

Roy Wills

The VMD can represent, for example, a variable *Measurement3* whose value may not permanently exist in reality; only when the variable is being read, a measurand transducer will get started to determinate

**FIGURE 24.2** Hiding real devices in the virtual manufacturing device (VMD).

the value. All objects in a server can already be contained in a device before the delivery of a device. The objects are predefined in this case.

Independent of the implementation of a VMD, data and the access to data are always treated in the same way. This is completely independent of the operating system, the programming language, and memory management. Like printer drivers for a standard operating system hide the various real printers, so a VMD also hides real devices. The server can be understood as a communication driver that hides the specifics of real devices. From the point of view of the client, only the server with its objects and its behavior is visible. The real device is not visible directly.

MMS merely describes the server side of the communication (objects and services) and the messages that are exchanged between client and server.

The VMD describes a VMD completely. This virtual device represents the behavior of a real device as far as it is visible *over the wire*. It contains, for example, an identification of manufacturer, device type, and version. The virtual device contains objects like variables, lists, programs and data areas, semaphores, events, and journals.

The client can read the attributes of the VMD (see Figure 24.3), that is, it can browse through a device. If the client does not have any information about the device, it can view all the objects of the VMD and their attributes by means of the different Get services. With that, the client can perform a first plausibility check on a just installed device by means of a Get(Object-Attribute)-Service. It learns whether the installed device is the ordered device with the right model number (Model Name) and the expected issue number (Revision). All other attributes can also be checked (e.g., variable names and types).

The attributes of all objects represent a self-description of the device. Since they are stored in the device itself, a VMD always has the currently valid and thus consistent configuration information of the respective device. This information can be requested online directly from the device. In this way, the client receives always up-to-date information.

MMS defines some 80 functions:

- Browsing functions about the *contents* of the virtual device: “Which objects are available?”
- Functions for reading, reporting, and writing of arbitrarily structured variable values
- Functions for the transmission of data and programs, the control of programs, and many other functions

The individual groups of the MMS services and objects are shown in Figure 24.4. MMS describes such aspects of the real device that shall be open, that is, standardized. An open device must behave as

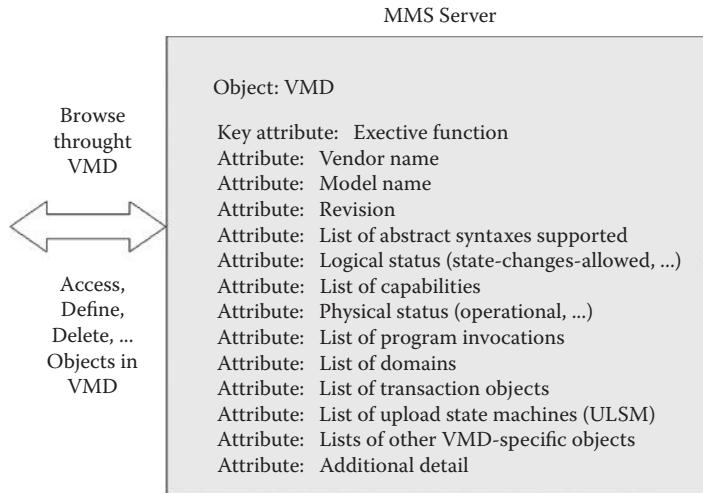

FIGURE 24.3 VMD attributes.

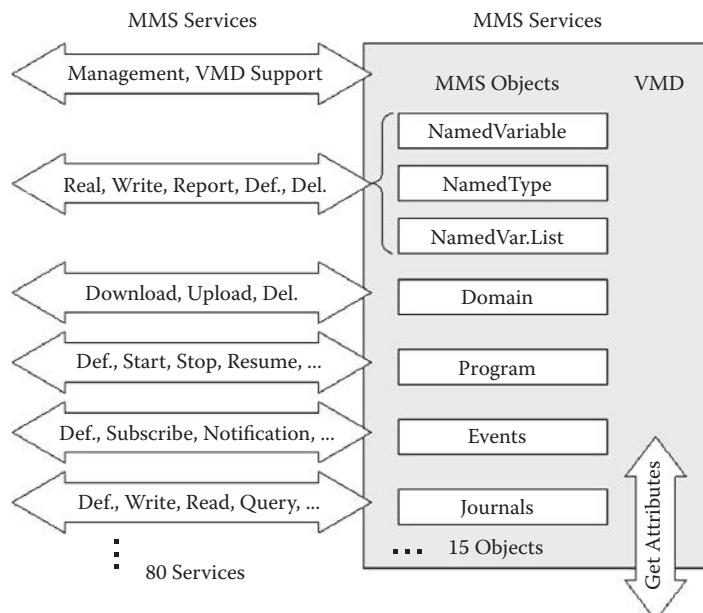

FIGURE 24.4 MMS objects and services.

described by the virtual device. How this behavior is achieved is not visible and also not relevant to the user that accesses the device externally. MMS does not define any local, specific interfaces in the real systems. The interfaces are independent of the functions that shall be used remotely. Interfaces in connection with MMS are always understood in the sense that MMS quasi represents an interface between the devices and not within the devices. This interface could be described as an external interface. Of course, interfaces are also needed for implementations of MMS functions in the individual real devices. These shall not and cannot be defined by a single standard. They are basically dependent on the real systems—and these vary to a great extent.

### 24.3.2 MMS Models and Services

#### 24.3.2.1 ISO 9506-1 (Part 1): Service Specification

##### 24.3.2.1.1 Environment and General Management Services

Two applications that want to communicate with each other can set up, maintain, and close a logical connection (initiate, conclude, and abort).

##### 24.3.2.1.2 VMD Support

The client can thereby query the status of a VMD or the status is reported (Unsolicited Status); the client can query the different lists of the objects (Get Name List), query the attributes of the VMD (Identify), or change the names of objects (Rename).

##### 24.3.2.1.3 Domain Management

Using a simple flow control (Download, Upload, Delete Domains, etc.), programs and data of arbitrary length can be transmitted between client and server and also a third station (and vice versa). In the case of simple devices, the receiver of the data stream determines the speed of the transmission.

##### 24.3.2.1.4 Program Invocation Management

Services to create, start, stop, and delete modularly structured programs by the client (start, stop, resume, kill, delete, etc.).

##### 24.3.2.1.5 Variable Access

This service allows the client to read and write variables that are defined in the server or a server is enabled to report the contents to a client without being requested (information report). The structures of these data are simple (octet string) to arbitrarily complex (structure of array of ...). In addition, data types and arbitrary variables can be defined (Read, Write, information report, define variable, etc.). The variables constitute the core functionality of every MMS application; therefore, the variable access model will be explained in detail later.

##### 24.3.2.1.6 Event Management

It allows an event-driven operation, that is, a given service (e.g., Read) is only carried out if a given event has occurred in the server. An alarm strategy is integrated. Alarms will be reported to one or more clients if certain events occur. These have the possibility to acknowledge the alarms later (define, alter event condition monitoring, get alarm summary, event notification, acknowledge event notification, etc.). This model is not explained further.

##### 24.3.2.1.7 Semaphore Management

The synchronization of several clients and the coordinated access to the resources of real devices is carried out hereby (define semaphore, take/relinquish control, etc.). This model is not explained further.

##### 24.3.2.1.8 Operator Communication

Simple services for the communication with operating consoles integrated in the VMD (input and output). This model is not explained further.

##### 24.3.2.1.9 Journal Management

Several clients can enter data into journals (archives and logbooks) that are defined in the server. Then these data can selectively be retrieved through filters (Write Journal, Read Journal, etc.). This model is not explained further.

### 24.3.2.2 ISO 9506-2 (Part 2): Protocol Specification

If a client invokes a service, then the server must be informed about the requested type of the service. For a Read service, for example, the name of the variables must be sent to the server. This information that the server needs for the execution is exchanged in so-called protocol data units (PDUs). The set of all the PDUs that can be exchanged between client and server constitutes the MMS protocol.

In other words, the protocol specification—using the standards ISO 8824 (Abstract Syntax Notation One, ASN.1) and 8825 (ASN.1 Basic Encoding Rules, BER)—describes the abstract and concrete syntax of the functions defined in part 1. The syntax is explained later exemplarily.

### 24.3.3 Locality of the VMD

VMDs are virtual descriptions of real data and devices (e.g., protection devices, measurand transducers, wind turbine, and any other automation device or system). Regarding the implementation of a VMD, there are three very different possibilities where a VMD can be located (see Figure 24.5):

1. In the end device: One or several VMDs are in the real device that is represented by the VMD. The implementations of the VMD have direct access to the data in the device. The modeling can be carried out in such a way that each application field in the device is assigned to its own VMD. The individual VMDs are independent of each other.
2. In the gateway: One or several VMDs are implemented in a separate computer (a so-called gateway or agent). In this case, all MMS objects that describe the access to real data in the devices are at a central location. While being accessed, the data of a VMD can be in the memory of the gateway—or they must be retrieved from the end device only after the request. The modeling can be carried out in such a way that for each device or application, a VMD of its own will be implemented. The VMDs are independent of each other.

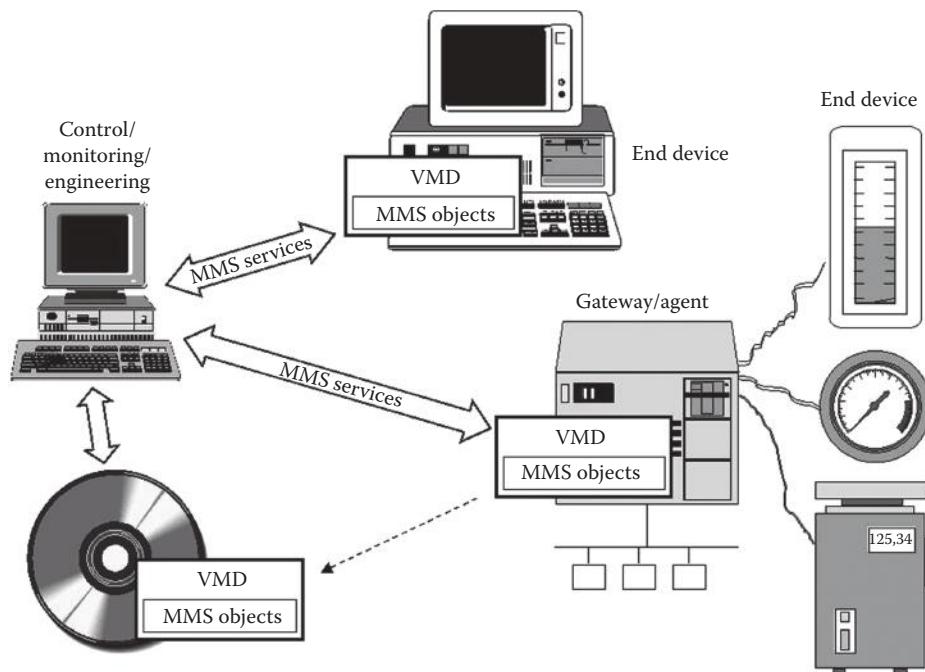

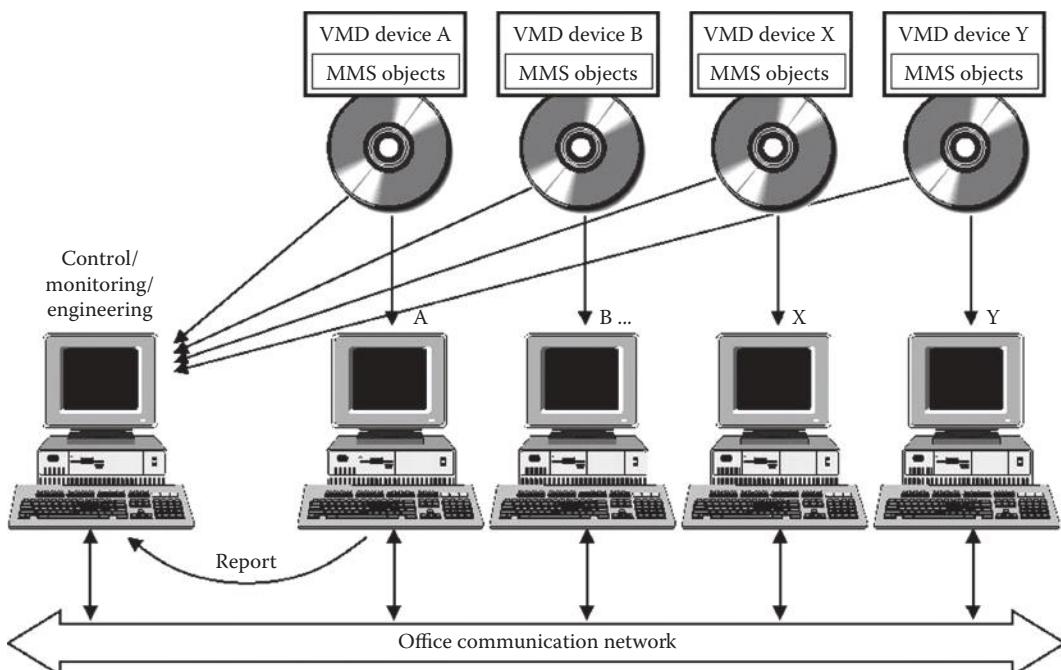

FIGURE 24.5 Location of VMDs.

3. In a file: One or several VMDs are implemented in a database on a computer, on an FTP server, or on a CD ROM (the possibilities under (1) and (2) are also valid here). Thus, all VMDs and all included objects with all their configuration information can be entered directly into engineering systems. Such a CD ROM, which represents the device description, also could be used, for example, to provide a monitoring system with the configuration information: names, data types, object attributes, etc. Before devices are delivered, the engineering tools can already process the accompanying device configuration information (electronic data sheet)! The configuration information can also be read later online from the respective VMD via corresponding MMS requests.

The VMD is independent of the location. This also allows, for example—besides the support during configuration—that several VMDs can be installed for testing purposes on another computer than the final system (see Figure 24.6). Thus, the VMD of several large robots can be tested in the laboratory or office. The VMD will be installed on one or several computers (the computers emulate the real robots). Using a suitable communication (e.g., intranet or also a simple RS 232 connection—available on every PC), the original client (a control system that controls and supervises the robots) can now access and test the VMD in the laboratory. This way, whole systems can be tested beforehand regarding the interaction of individual devices (e.g., monitoring and control system).

If the Internet is used instead of the intranet, global access is possible to any VMD that is connected to the Internet. The author himself tested the access from Germany to a VMD that was implemented on a PLC in the United States. That is to say, through standards like MMS and open transmission systems, it has become possible to set up global communication networks for the real-time process data exchange.

The previous statements about the VMD are valid in full extent also for all standards that are based on MMS.

**FIGURE 24.6** VMD testing using PC in an office environment.

## 24.4 Interfaces

The increasing distribution of automation applications and the exploding amount of information require more and more and increasingly more complex interfaces for operation and monitoring. Complex interfaces turn into complicated interfaces very fast. Interfaces *cut* components into two pieces; through this, interactions between the emerged subcomponents—which were hidden in one component before—become visible. An interface discloses which functions are carried out in the individual subcomponents and how they act in combination.

Transmitter and receiver of information must likewise be able to understand these definitions. The request *Read T142* must be formulated *understandably*, transmitted correctly, and understood unambiguously (see Figure 24.7). The semantic (named terms that represent something) of the services and the service parameters are defined in MMS. The content, for example, of Named Variables is defined in domain-specific standards like IE 61850.

Interfaces occur in two forms:

1. Internal program-program interfaces or APIs
2. External interfaces over a network (WAN, LAN, fieldbus, etc.)

Both interfaces affect each other. MMS defines an external interface. The necessity of complex interfaces (complex because of the necessary functionality, not because of an end in itself) is generally known and accepted. To keep the number of complex interfaces as small as possible, they are defined in standards or industry standards—mostly as open interfaces. Open interfaces are in the meantime an integral component of every modern automation. In mid-1997, it was already explained in [17] that the trend in automation engineering obviously leads away from the proprietary solutions to open standardized interfaces—that is, to open systems.

The reason why open interfaces are complicated is not because they were standardized. Proprietary interfaces tend more toward being complicated or even very complicated. The major reasons for the latter observation are found in the permanent *improvement* of the interfaces that expresses itself in the quick changes of version and in the permanent development of new—apparently better—interfaces. Automation systems of one manufacturer often offer—for identical functions—a variety of complicated interfaces that are incompatible to each other.

At first, interfaces can be divided up into two classes (see Figure 24.8): internal interfaces (e.g., in a computer) and external interfaces (over a communication network). The following consideration is strongly simplified because, for example, in reality, both internally and externally several interfaces can lie one above the other. However, it nevertheless shows the differences in principle that must be paid attention to. MMS defines an external interface. Many understand MMS in such a way that it offers—or at least also offers—an internal interface. This notion results in completely false ideas. Therefore, the following consideration is very helpful.

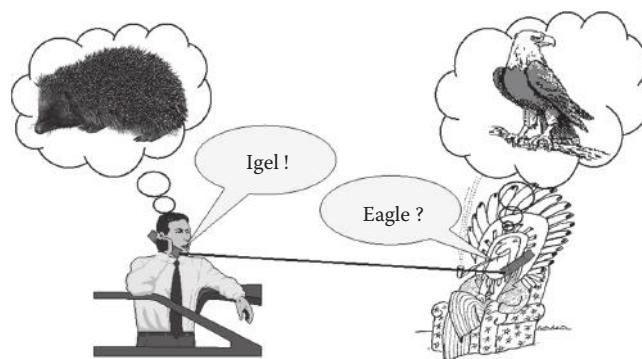

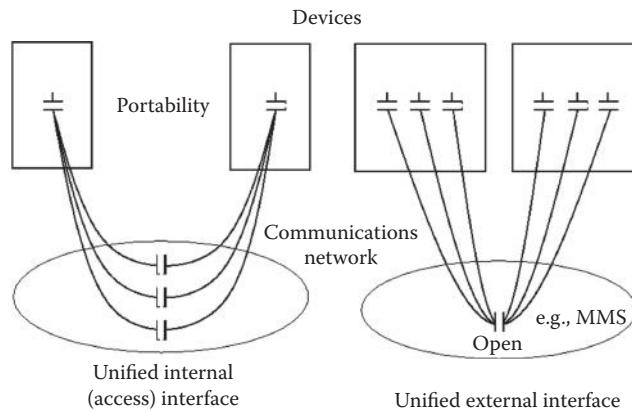

FIGURE 24.7 Sender and receiver of information.

**FIGURE 24.8** Internal and external interfaces.

The left-hand side of the figure shows the case with a uniform internal interface and varying external interfaces. This uniform internal interface allows many applications to access the same functions with the same parameters and perhaps the same programming language—*independent of the external interface*. Uniform internal interfaces basically allow the portability of the application programs over different external interfaces.

The right-hand side of the figure shows the case with the external interface being uniform. The internal interfaces are various (since the programming languages or the operating systems, e.g., are various). The uniform external interface is independent of the internal interface. The consequence of this is, for example, that devices whose local interfaces differ and are implemented in diverse environments can communicate together. Differences can result, for example, from an interface being integrated into the application in a certain device, but being available explicitly in another device. The essential feature of this uniform external interface is the interoperability of different devices. The ISO/OSI reference model is aimed at exactly this feature.

The (internal) MMS interface, for example, in a client (perhaps: \$READ [Par. 1, Par. 2, ..., Par. N]) depends on the manufacturer, the operating system, and the programming language. MMS implementations are, for example, available for UNIX or Windows NT. On the one hand, this is a disadvantage because applications that want to access an MMS server would have to support—depending on the environment—various real program interfaces. On the other hand, the MMS protocol is completely independent of the—fast changing—operating system platforms. Standardized external interfaces like MMS offer a high degree on stability, because in the first place, the communication can hardly be changed arbitrarily by a manufacturer, and in the second place, several design cycles of devices can survive.

Openness describes in the ISO/OSI world the interface on the *wire*. The protocol of this external interface executes according to defined standardized rules. For an interaction of two components, these rules have to be taken into account on the two sides; otherwise, the two will not understand each other.

## 24.5 Environment and General Management Services

MMS uses a connection-oriented mode of operation. That is to say, before, for example, a computer can read a value from a PLC for the first time, a connection must be set up between the two.

MMS connections have particular quality features such as the following:

- Exclusive allocation of computer and memory resources to a connection. This is necessary to guarantee that all services (e.g., five Read) that are allowed to be carried out simultaneously find sufficient resources on both sides of the connection.
- Flow control in order to avoid blockages and vain transmissions, if, for example, the receive buffers are full.

- Segmentation of long messages.
- Routing of messages over different networks.
- Supervision of the connection if no communication takes place.
- Acknowledgment of the transmitted data.
- Authentication, access protection (password), and encoding of the messages.

Connections are generally established once and then remain established as long as a device is connected (at least during permanently necessary communication). If, for example, a device is only seldom accessed by a diagnostics system, a connection then does not need to be established permanently (waste of resources). It suffices to establish a connection and, later, to close it to release the needed resources again. The connection can remain established for rare but time-critical transmissions. The subordinate layers supervise the connection permanently. Through this, the interruption of a connection is quickly recognized.

The MMS services for the connection management are

- *Initiate* (connection setup)
- *Conclude* (orderly connection teardown, waiting requests are still being answered)
- *Abort* (abrupt connection teardown, waiting requests are deleted)

Besides these services that are all mapped to the subordinate layers, there are two further services:

- *Cancel*
- *Reject*

After the MMS client has sent a Read request to the MMS server, for example, it may happen that the server leaves the service in its request queue and—for whatever reason—does not process it. Using the service cancel, the client can now delete the request in the server. On the other hand, it may occur that the server shall carry out a service with *forbidden* parameters. Using reject, it rejects the faulty request and reports this back to the client.

Although MMS was originally developed for ISO/OSI networks, a number of implementations are available in the meantime that also use other networks such as the known TCP/IP network. From the point of view of MMS, this is insignificant as long as the necessary quality of the connection is guaranteed.

## 24.6 VMD Support

---

The VMD object consists of 12 attributes. The key attribute identifies the *executive function*. The executive function corresponds directly with the entity of a VMD. A VMD is identified by a presentation address):

Object: VMD

Key Attribute:	Executive Function
Attribute:	Vendor Name
Attribute:	Model Name
Attribute:	Revision
Attribute:	Logical Status (STATE-CHANGES-ALLOWED, NO-STATE-CHANGES-ALLOWED, LIMITED-SERVICES-SUPPORTED)
Attribute:	List of Capabilities
Attribute:	Physical Status (OPERATIONAL, PARTIALLY-OPERATIONAL, INOPERABLE NEEDS-COMMISSIONING)
Attribute:	List of Program Invocations
Attribute:	List of Domains
Attribute:	List of Transaction Objects
Attribute:	List of Upload State Machines (ULSM)
Attribute:	List of Other VMD-specific Objects

The attributes Vendor Name, Model Name, and Revision inform about the manufacturer and the device.

The Logical status defines which services may be carried out. The status Limited-Services-Supported allows that only such services may be executed that have read access to the VMD.

The Physical status indicates whether the device works in principle.

The two following services

1. *Unsolicited Status*
2. *Status*

are used to get the status unsolicited (Unsolicited Status) or explicitly requested (Status). Thus, a client can recognize whether a given server—from the point of view of the communication—works at all.

The List of Capabilities offers clients and servers a possibility to define application-specific agreements in the form of features. The available memory of a device, for example, could be a capability. Through the Service Get Capability List, the current value can be queried. The remaining attributes contain the lists of all the MMS objects available in a VMD. The VMD contains therefore an object dictionary in which all objects of a VMD are recorded.

The following three services complete the services of the VMD:

1. *Identify* supplies the VMD attributes Vendor Name, Model Name, and Revision. With that, a plausibility check can be carried out from the side of the client.
2. *Get Name List* returns the names of all MMS objects. It can be selectively determined from which classes of objects (e.g., Named Variable or event condition) the names of the stored objects shall be queried. Let's assume a VMD is not yet known to the client till now (because it is, e.g., a maintenance device); the client can then browse through the VMD and systematically query all names of the objects. Using the Get services, which are defined for every object class (e.g., Get Variable Access Attributes), the client can get detailed knowledge about a given object (e.g., the Named Variable *T142*).
3. *Rename* allows a client to rename the name of an object.

## 24.7 Domain Management

---

### 24.7.1 Model Basics

Domains are to be viewed as containers that represent memory areas. Domain contents can be interchanged between different devices. The object type *domain* with its 12 attributes and 12 direct operations, which create, manipulate, delete a domain, etc., are part of the model.

The abstract structure of the domain object consists of the following attributes:

Object: Domain

Key Attribute:	Domain Name
Attribute:	List of Capabilities
Attribute:	State (LOADING, COMPLETE, INCOMPLETE, READY, IN-USE)
Constraint:	State = (LOADING, COMPLETE, INCOMPLETE)
Attribute:	Assigned Application Association
Attribute:	MMS Deletable
Attribute:	Sharable (TRUE, FALSE)
Attribute:	Domain Content
Attribute:	List of Subordinate Objects
Constraint:	State = (IN-USE)
Attribute:	List of Program Invocation References
Attribute:	Upload In Progress
Attribute:	Additional Detail

The domain name is an identifier of a domain within a VMD.

*Domain Content* is a dummy for the information that is within a domain. The contents of the data to be transmitted can be coded transparently or according to certain rules agreed upon before. Using the MMS version (2003), the data stream can be coded per default in such a way that a VMD can be transmitted completely—including all MMS object definitions that it contains. This means on the one hand that the contents of a VMD can be loaded from a configuration tool into a device (or saved from a device) and, on the other hand, that the contents can be stored on a disk per default.

Using a visible string, *List of Capabilities* describes which resources are to be provided—by the real device—for the domain of a VMD.

*MMS Deletable* indicates whether this domain may be deleted by means of an MMS operation.

*Sharable* indicates whether a domain may be used by more than one program invocation.

*List of Program Invocation* lists those program invocation objects that use this domain.

*List of Subordinate Objects* lists those MMS objects (no domains or program invocations) that are defined within this domain: objects that were (a) created by the domain loading, (b) created dynamically by a program invocation, (c) created dynamically by MMS operations, or (d) created locally.

*State* describes one of the 10 states in which a domain can be.

*Upload in Progress* indicates whether the domain content of this domain is being copied to the client at the moment.

MMS defines loading in two directions:

1. Data transmission from the client to the server (download)
2. Data transmission from the server to the client (upload)

Three phases can be distinguished during loading:

1. Open transmission
2. Segmented transmission, controlled by the data sink
3. Close transmission

Transmission during download and upload is initiated by the client, respectively. If the server initiates, then it has the possibility to initiate the transmission indirectly (see Figure 24.9). For this purpose,

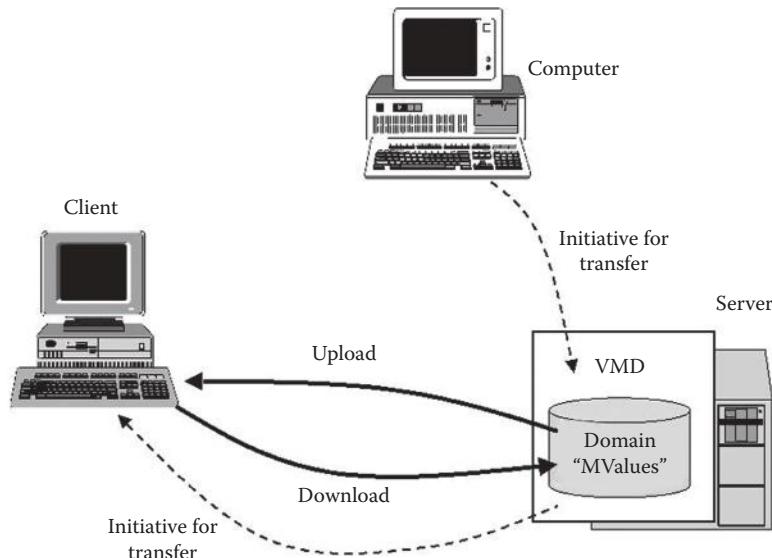

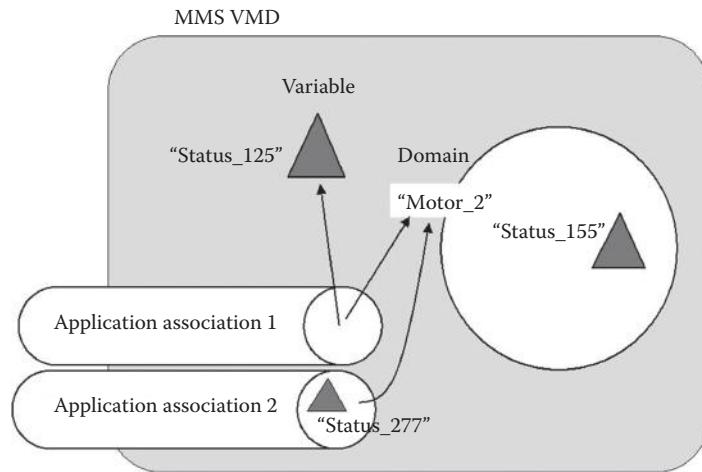

FIGURE 24.9 MMS domain transfer.

**FIGURE 24.10** VMD and domain scope.

the server informs the client that it (the client) shall initiate the loading. Even a third station can initiate the transmission by informing the server, which then informs the client.

### 24.7.2 What Is the Domain Scope?

Further MMS objects can be defined within a domain: variable objects, event objects, and semaphore objects. That is to say a domain forms a scope (validity range) in which named MMS objects are reversibly unambiguous.

MMS objects can be defined in three different scopes, as shown in Figure 24.10. Objects with VMD-specific scope (e.g., the variable *Status\_125*) can be addressed directly through this name by all clients. If an object has domain-specific scope such as the object *Status\_155*, then it is identified by two identifiers:

Domain Identifier *Motor\_2* and Object Identifier *Status\_155*.

A third scope is defined by the Application Association. The object *Status\_277* is part of the corresponding connection. This object can be accessed only through this connection. When the connection is closed, all objects are deleted in this scope.

MMS objects can be organized using different scopes. The object names (with or without domain scope) can be compounded from the following character set:

The identifiers can contain 1–32 characters, and they must not start with a number.

The object names can be structured by agreement in a further standard or other specification. Many standards that reference MMS make much use of this possibility. This way, all named variables with the Prefix *RWE\_* and similar prefixes, for example, could describe the membership of the data (in a trans-European information network) to a specific utility of an interconnected operation.

## 24.8 Program Invocation Management

### 24.8.1 Model Basics

A program invocation object is a dynamic element that corresponds with the program executions in multitasking environments. Program invocations are created by linking several domains. They are either predefined or created dynamically by MMS services or created locally.

A program invocation object is defined by its name, its status (idle, starting, running, stopping, stopped, resuming, unrunnable), the list of the domains to be used, and nine operations.

### Object: Program Invocation

Key Attribute:	Program Invocation Name
Attribute:	State (IDLE, STARTING, RUNNING, STOPPING, STOPPED, RESUMING, RESETTING, UNRUNNABLE)
Attribute:	List of Domain References
Attribute:	MMS Deletable (TRUE, FALSE)
Attribute:	Reusable (TRUE, FALSE)
Attribute:	Monitor (TRUE, FALSE)
Constraint:	Monitor = TRUE
Attribute:	Event Condition Reference
Attribute:	Event Action Reference
Attribute:	Event Enrollment Reference
Attribute:	Execution Argument
Attribute:	Additional Detail

Program invocations are structured flatly—though several program invocations can reference the same domains (shared domains). The contents of the individual domains are absolutely transparent both from the point of view of the domain and from the point of view of the program invocations. What is semantically connected with the program invocations is outside the scope of MMS. The user of the MMS objects must therefore define the contents; the semantics result from this context. If a program invocation connects two domains, then the domain contents must define what these domains shall do together—MMS actually only provides a wrapper.

*The Program Invocation Name* is a clear identifier of a program invocation within a VMD.

*State* describes the status in which a program invocation can be. Altogether seven states are defined.

*List of Domains* contains the names of the domains that are combined to a program invocation.

This list also includes such domains that are created by the program invocation itself (this can be a domain into which some output is written).

*MMS Deletable* indicates whether this program invocation may be deleted by means of an MMS operation.

*Reusable* indicates whether a program invocation can be started again after the program execution. If it cannot be started again, then the program invocation can only be deleted.

*Monitor* indicates whether the program invocation reports a transition to the client when exiting the running status.

*Start Argument* contains an application-specific character string that was transferred to a program invocation during the last start operation; this string, for example, could indicate which function has started the program last.

Additional detail allows the companion standards to make application-specific definitions.

### 24.8.2 Program Invocation Services

*Create Program Invocations*: This service arranges an operational program, which consists of the indicated domains, in the server. After installation, the program invocation is in the status *idle* from where it can be started. The monitor and the monitor type indicate whether and how the program invocation shall be monitored.

*Delete Program Invocation*: Deletable program invocations are deleted through this service. Primarily, that is to say that the resources bound to a program invocation are released again.

*Start*: The start service causes the server to transfer the specified program invocation from the idle into the running state. Further information can be transferred to the VMD through a character string in the start argument. A further parameter (start detail) contains once again additional information that can be defined by companion standards.

*Stop:* The stop service changes a specified program invocation from the running into the stopped state.

*Resume:* The resume service changes a specified program invocation from the stopped into the running state.

*Reset:* The reset service changes a specified program invocation from the running or stopped into the idle state.

*Kill:* The kill service changes a specified program invocation from arbitrary states into the unrunnable state.

*Get Program Invocation Attribute:* Through this service, the client can read all attributes of certain program invocations.

## 24.9 MMS Variable Model

### 24.9.1 Model Basics

MMS Named Variables are addressed using identifiers made up of the domain name and the Named Variable name within the domain. Components of an MMS Named Variable may also be individually addressed using a scheme called alternate access. The alternate access address of a component consists of the domain name and the Named Variable name, along with a sequence of enclosing component names of the path down to the target component.

The variable access services contain an extensive variable model that offers the user a variety of advanced services for the description and offers the access to arbitrary data of a distributed system.

A wide variety of process data are processed by automation systems. The data, their definition, and representation are usually orientated at the technological requirements and at the available automation equipment. The methods the components employ for the representation of their data and the access to them correspond to the way of thinking of their implementers. This has resulted in a wide variety of data representations and access procedures for one and the same technological datum in different components. If, for example, a certain temperature measurement shall be accessed to in different devices, then a huge quantity of internal details must generally be taken into account for every device (request, parameter, coding of the data, etc.).

As shown in Figure 24.11, the number of the protocols for the access of a client (on the left in the figure) to the data from  $n$  servers ( $S_1-S_n$ ) can be reduced to a single protocol (on the right in the figure). Through this, the data rate required for the communication primarily in central devices can be reduced drastically.

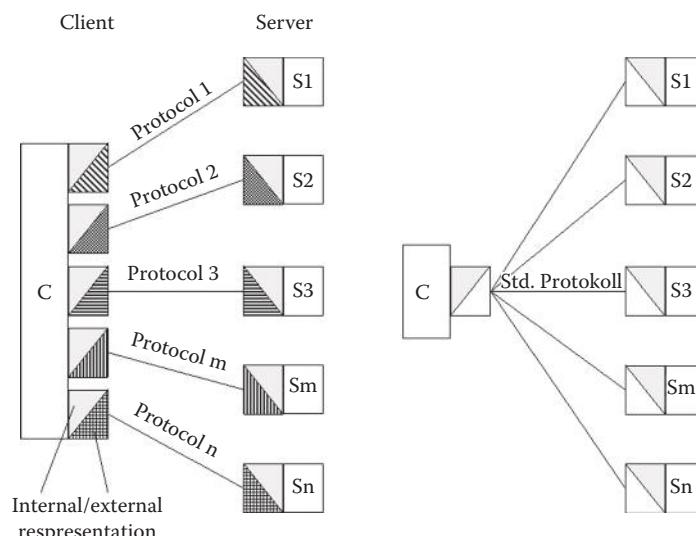

FIGURE 24.11 Unified protocols.

In programs, variables are declared, that is, they get a name, a type, and a value. Described in a simplified way, both the name and the type are converted by the compiler into a memory location and into a reference that is accessible only to the compiled program. Without any further measures, the data of the variable are not identifiable outside the program. It is concealed for the user of the program how a compiler carries out the translation into the representation of a certain real machine.

The data are stored in different ways depending on the processor, that is, primarily that the data are stored in various memory locations. During the runtime of the program, only this representation is available.

These data are not visible from the outside. They must first be made visible for the access from the outside. To enable this, an entity must be provided in the implementation of the application. It is insignificant here whether this entity is separated from or integrated into the program. This entity is acting for all data that shall be accessible from the outside.

This consideration is helpful to the explanation of the MMS variable model: what do protocols through which process data are accessed have in common? Figure 24.12 shows the characteristics in principle. On the right is the memory with the real process data that shall be read. The client must be able to identify the data to be read (gray shade). For this purpose, pointer (start address) and length of the data must be known. By means of this information, the data can be identified in the memory.

Yet, how can a client know the pointer of the data and what the length of the data is? It could have this information somehow and indicate it when reading. Yet, if the data should move some time, then the pointer of the data is not correct any more. There can also be the case that the data do not exist at all at the time of reading but must be calculated first. In this case, there is no pointer. To avoid this, references to the data, which are mapped to the actual pointers (table or algorithm), are used in most cases. In our case, the reference *B* is mapped by table to the corresponding pointer and the length.

The pointer and the length are stored in the type description of the table. The pointer is a system-specific value that generally is not visible on the outside. The length is dependent on the internal representation of the memory and on the type. An individual bit can, for example, be stored as an individual bit in the memory or also as a whole octet. However, this is not relevant from the point of view of the communication.

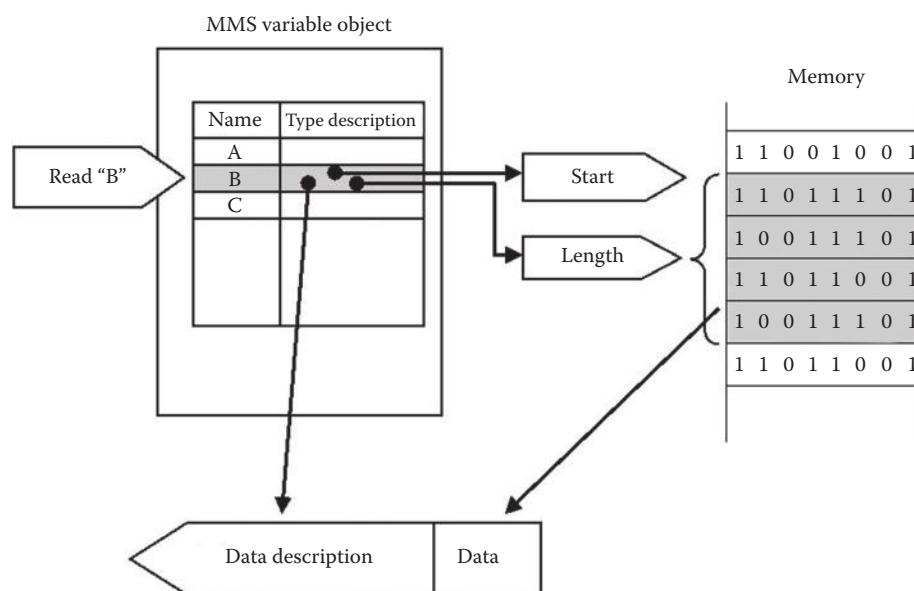

FIGURE 24.12 Data access principle.

The data themselves and their description are important for the message response of the read service. The question of the external representation (is, e.g., an individual bit encoded as a bit or as an octet?) is—unlike the internal representation—of special importance here! The various receivers of the data must be able to interpret the data unambiguously. For this purpose, they need the representation, which is a substantial component of the MMS variable model. The data description is therefore derived from the type description.

For the deeper understanding of the variable model, three aspects have to be explained more exactly:

1. Objects and their functions
2. Services (read, write, etc.) that access the MMS variable objects
3. Data description for the transmission of the data

The object model of an MMS variable object is conceptually different from a variable according to a programming language. The MMS objects describe the access path to structured data. In this sense, they do not have any variable value.

### 24.9.2 Access Paths

The access path represents an essential feature of the MMS variable model. Starting from a more complex hierarchical structure, we will consider the concept. The abstract and extremely simplified example is deliberately chosen. Here, we are merely concerned about the principle.

Certain data of a machine shall be modeled using MMS methods. The machine has a tool magazine with n similar tools. A tool is represented—according to Figure 24.13—by three components (tool type, number of blades, and remaining use time).

The machine with its tool magazine  $M$  is outlined in the figure on the right. The magazine contains three tools  $A$ ,  $B$ , and  $C$ . The appropriate data structure of the magazine is shown on the left. The structure is tree like; the root  $M$  is drawn as the topmost small circle (node).  $M$  has three components (branches)  $A$ ,  $B$ , and  $C$ , which are also represented as circles. These components in turn also have three components (branches). In this case, the branches end in a leaf (represented in the form of a square). Leaves represent the end-points of the branches. For each tool, three leaves are shown:  $T$  (tool type),  $A$  (number of edges), and  $R$  (remaining use time). The leaves represent the real data. The nodes ordered

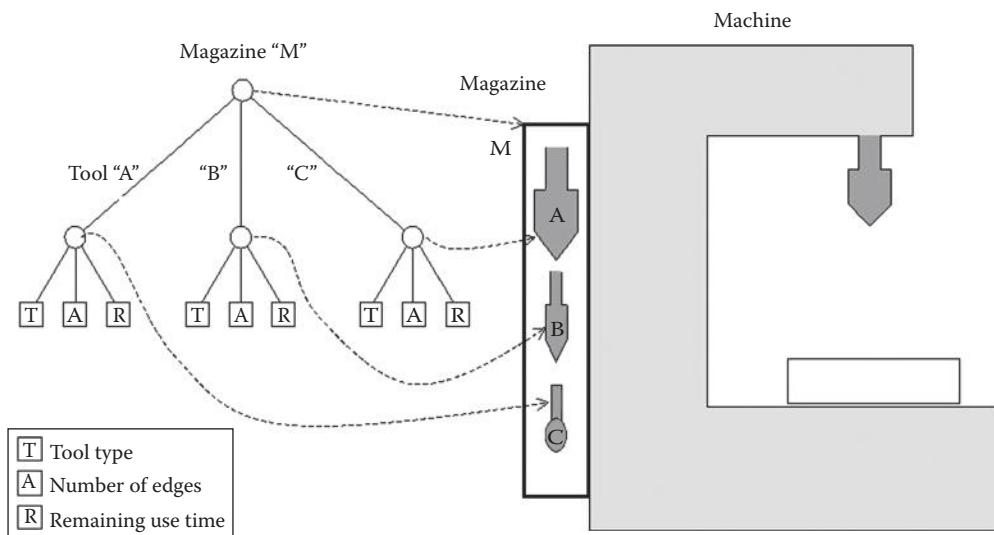

FIGURE 24.13 Data of a machine.

hierarchically are merely introduced for reasons of clustering. Leaves can occur at all nodes. A leaf with the information *magazine full/not full* could, for example, be attached at the topmost node.

With this structure, the MMS features are explained in more detail. The most essential aspect is the definition of the access path. The access to the data (and their use) can be carried out according to various task definitions:

1. Selecting all leaves for reading, writing, etc.
2. Selecting certain leaves for reading, writing, etc.
3. Selecting all leaves as component of a higher-level structure, for example, *machine* with the components *magazine M* and *drilling machine*
4. Selecting certain leaves as the component of a higher-level structure

Examples of the cases (1) and (2) are shown in Figure 24.14. The case that the complete structure is read is shown in the left top corner (the selected nodes, branches, and leaves are represented in bold lines or squares). All nine data are transmitted as response ( $3 \times (T + A + R)$ ). At first, the representation during transmission is deliberately refrained from here and also in the following examples.

Only a part of the data is read in the top right corner of the figure: respectively, only the leaf *R* of all three components *A*, *B*, and *C*. The notation for the description of the subset *M.A.R/B.R/C.R* is chosen arbitrarily.

The subset *M.A.R* represents a (access) path that leads from a root to a leaf. It can also be said that one or several paths represent a part of a tree. The read message contains three paths that must be described in the request completely. A path, for example, can also end at *A*. All three components of *A* will be transmitted in this case.

Besides the possibility to describe every conceivable subset, MMS also supports the possibility to read several objects *M1* and *M5* in a read request simultaneously (see lower half of the figure). Of course, every object can only be partly read too (which is, however, not represented).

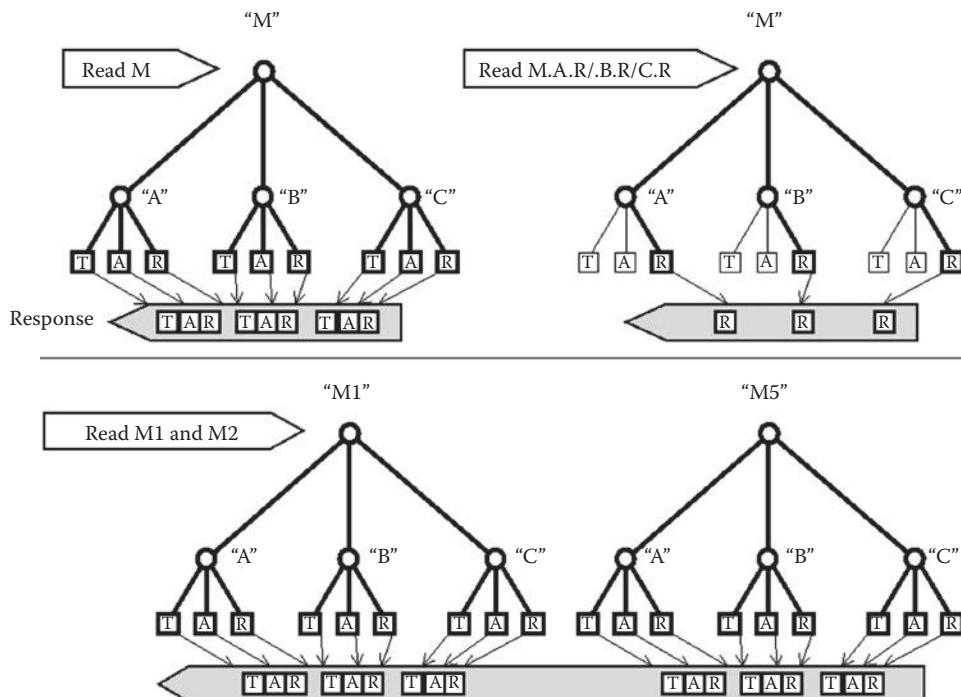

FIGURE 24.14 Access and partial access.

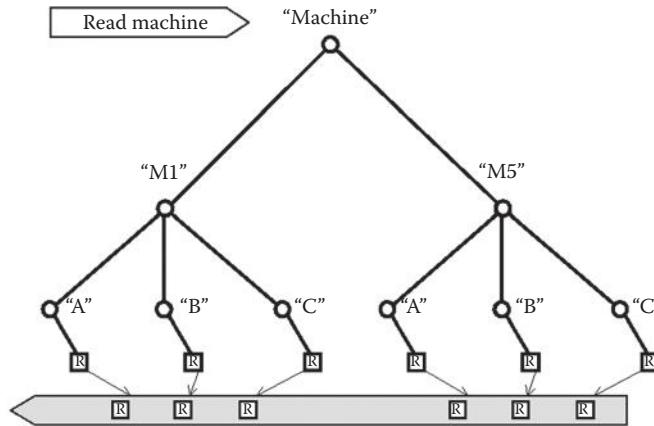

FIGURE 24.15 Partial trees.

An example of case 4 is shown in Figure 24.15 (case 4 has to be understood as the generalization of case 3). Here a new structure was defined using two substructures. The object *machine* contains only the *R* component of all six tools of the two magazines *M1* and *M5*. The object *machine* shall not be mixed up with a list (Named Variable List). Read *machine* supplies the six individual *R* values.

The component names, such as *A*, *B*, or *C*, need to be unambiguous only below a node—and only at the next lower level. Thus, *R* can always stand for the remaining life time. The position in the tree indicates the remaining life time of a particular tool. The new structure *machine* has all features that were described in the previous examples also for *M1* and *M5*.

These features of the MMS variable objects can be applied to (1) the definition of new variable objects and (2) the access to existing variable objects. The second case is also interesting. As shown in Figure 24.16, the same result as in Figure 24.15 can be reached by enclosing the description (only the *R* components of the tools shall be read from the two objects *M1* and *M5*) in the read request every time. The results (read answer) are absolutely identical in the two cases.

Every possibility, to assemble hierarchies from other hierarchies (1) or to, for example, read parts of a tree during the access (2), has its useful application. The first case is important in order to avoid enclosing

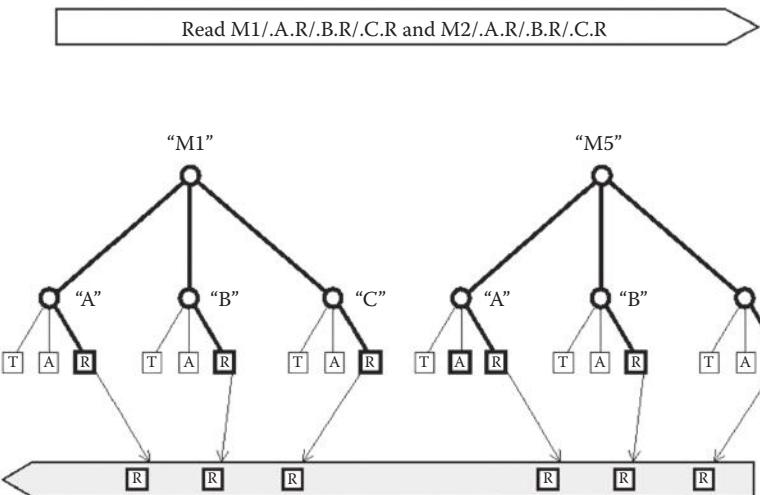

FIGURE 24.16 Partial trees used for read requests.

the complete path description every time when reading an extensive part of tree. The second case offers the possibility to construct complex structures based on standardized basic structures (e.g., the structure of *tool data* consisting of the components *T*, *A*, and *R*) and to use them for the definition of new objects.

Summarizing, it can be stated that the access paths accomplish two tasks:

1. Description of a subset of nodes, branches, and leaves of objects during reading, writing, etc.
2. Description of a subset of nodes, branches, and leaves of objects during the definition of new objects

In conclusion, this may again be expressed in the following way: Path descriptions describe the *way* or the *ways* to a single data (leaf) or to several data (leaves). A client can read the structure description (complete tree) through the MMS service Get Variable Access Attributes.

Another aspect is of special importance too. Till now, we have not considered the description of leaves. Every leaf has one of the following MMS basic data types:

- BOOLEAN
- BIT
- INTEGER
- UNSIGNED
- FLOATING POINT
- REAL
- OCTET STRING
- VISIBLE
- GENERALIZED TIME
- BINARY
- BCD

Every node in a tree is either an array or a structure. Arrays have  $n$  elements (0 to  $n - 1$ ) of the same type (this can be a basic type, an array, or a structure). When describing a part of a tree, any number of array elements can be selected (e.g., one element, two adjacent elements, and two arbitrary elements ).

Structures consist of one or several components. Every component can be marked by its position and if necessary by an *identifier*—the component name. This component name (e.g., *A*) is used for the access to a component. Parts of trees can describe every subset of the structure.

The path description contains the following three elements:

1. All of the possibilities of the description of the structures (individual and composite paths in the type description of the MMS variables) are defined in the form of an extensive abstract syntax.
2. For every leaf of a structure (these are MMS basic data types), the value range (size) is also defined besides the class. The value range of the class INTEGER can contain one, two, or more octets. The value range four (4) octets (often represented as Int32), for example, indicates that the value cannot exceed these four octets. On the other hand, with ASN.1 BER coding (explained later) and the value range Int32, the decimal value 5 will be transmitted in only one octet (not in four octets!). That is to say, only the length needed for the current value will be transmitted.
3. The aspect of the representation of the data and their structuring during transmission on the line (communication in the original meaning) is dealt with in the following text in the context of the encoding of messages.

The path description is used in a quintuple way (see Figure 24.17):

- During the access to and during the definition of variable objects
- In the type description of variable objects
- In the description of data during reading, for example
- During the definition of Named Type Objects (an object name of its own is assigned to the type description—i.e., to one or several paths—of those objects)
- When reading the attributes of variables and Named Type Objects

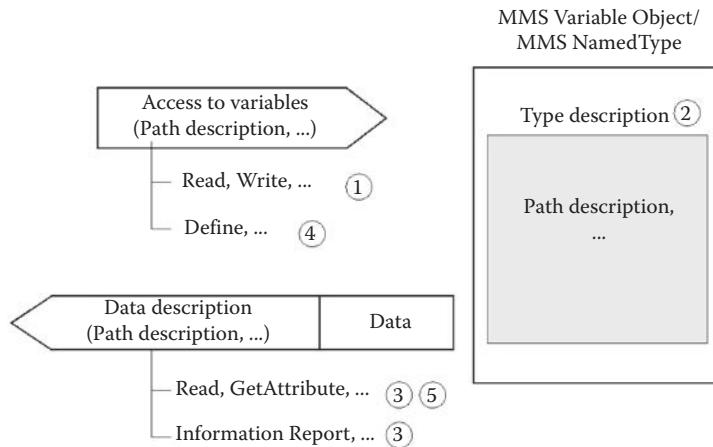

FIGURE 24.17 Application of path descriptions.

### 24.9.3 Objects of the MMS Variable Model

The five objects of the MMS variable model are as follows:

Description of simple or complex values

- Unnamed Variable
- Named Variable

List of several unnamed variables or named variables

- Named Variable List
- Scattered Access (is not explained here)

Description of the structure by means of a user-defined name

- Named Type

### 24.9.4 Unnamed Variable

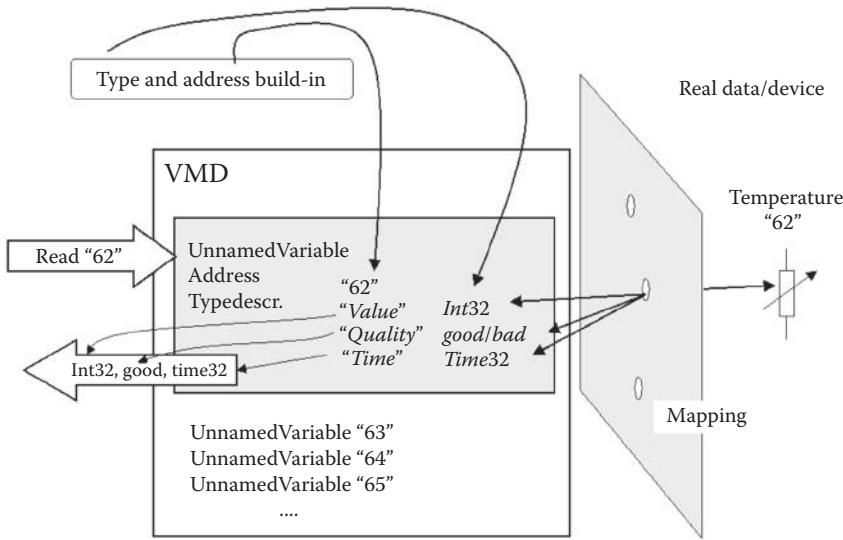

The Unnamed Variable Object describes the assignment of an individual MMS variable to a real variable that is located at a definite address in the device. An Unnamed Variable Object can never be created or deleted. The Unnamed Variable has the following attributes:

Object: Unnamed Variable

- Key Attribute: Address
- Attribute: MMS Deletable (FALSE)
- Attribute: Access Method (PUBLIC)
- Attribute: Type Description

*Address:* Address is used to reference the object. There are three different kinds:

1. Numeric Address (nonnegative integer values)
2. Symbolic Address (character string)
3. Unconstrained Address (implementation-specific format)

**FIGURE 24.18** Unnamed Variable Object.

Even though in (2) the address is represented by character strings, this kind of addressing has absolutely to be distinguished from the Object Name of a Named Variable (see domain scope and explanations later).

*MMS Deletable:* The attribute is always FALSE here.

*Access Method:* The attribute is always PUBLIC here.

*Type Description:* The attribute points to the inherent abstract type of the subordinate real variable as it is seen by MMS. It specifies the class (bitstring, integer, floating-point, etc.), the value range of the values, and the group formation of the real variable (arrays of structures). The attribute type description is completely independent of the addressing.

Figure 24.18 represents the Unnamed Variable roughly sketched. The Unnamed Variable with the address 62 (MMSString) has three components with the names: Value, Quality, and Time. These component names are required only if individual components (specifying the path, e.g., 62/Value) shall be accessed.

## 24.9.5 MMS Address of the Unnamed Variable

The MMS Address is a system-specific reference that is used by the system for the internal addressing—it is quasi released for the access via MMS. There the address can assume one of three forms (here the ASN.1 notation is deliberately used for the first time):

```
Address:: = CHOICE {
    NumericAddress      [0] IMPLICIT Unsigned32,
    SymbolicAddress     [1] MMSString,
    UnconstrainedAddress [2] IMPLICIT OCTET STRING
}
```

This definition has to be read as follows: Address defines as (:: =) a selection (keyword CHOICE) of three possibilities. The possibilities are numbered here from [0] to [2] to be able to distinguish them. The keyword IMPLICIT is discussed later.

The numeric address is defined as Unsigned32 (four octets). Thus, the addresses can be defined as an index with a value range of up to  $2^{*32}$ . Since only the actual length (e.g., only one octet for the value 65) will be transmitted for an Unsigned32, the minimal length of the index, which can thus be used, is merely one octet. Already 255 objects (of arbitrary complexity!) can be addressed with one octet.

The symbolic address can transmit an arbitrarily long MMSString (e.g., DB5\_DW6).

The Unconstrained Address represents an arbitrarily long octet string (e.g., 24FE23F2A1hex). The meaning and the structure of these addresses are outside the scope of the standard.

These addresses can be used in MMS Unnamed Variable and Named Variable Objects and in the corresponding services. MMS can neither define nor change these addresses. The address offers a possibility to reference objects by short indexes.

The addresses can be structured arbitrarily. Unnamed Variables could, for example, contain measurements in the address range [1000–1999], status information in the address range [3000–3999], and limit values in the address range [7000–7999].

#### 24.9.6 Services for the Unnamed Variable Object

*Read:* This service uses the V-Get function to transmit the current value of the real variable, which is described by the Unnamed Variable Object, from a server to a client. Variable Get represents the internal, system-specific function through which an implementation gets the actual data and provides them for the communication.

*Write:* This service uses the V-Put function to replace the current value of the real variable, which is described by the Unnamed Variable Object, by the enclosed value.

*Information Report:* As Read, though without prior request by the client. Only the Read.response is sent by the server to the client without being asked. The information report corresponds to a spontaneous message. The application itself determines when the transmission is to be activated.

*Get Variable Access Attributes:* Through this operation, a client can query the attributes of an Unnamed Variable Object.

#### 24.9.7 Explanation of the Type Description

Features of the structure description of MMS variable objects were explained earlier in principle. For those interested in the details, the formal definition of the MMS type specification is explained according to Figure 24.19.

The description in ASN.1 was also deliberately selected here. The type specification is a CHOICE (selection) of 15 possibilities (Tags [0] to [13] and [15]). Tags are qualifications of the selected possibility. The first possibility is the specification of an Object Name, a Named Type Object. If we remember that one Named Type Object describes one or several paths, then the use is obvious. The path description referenced by the name can be used to define a Named Variable Object. Or, if during reading the path must be specified, it can be referenced by a Named Type Object in the server.

Note that the ASN.1 definitions in MMS are comparable with XML schema. ASN.1 BER (basic encoding rules) provides very efficient message encoding compared to XML documents. The standard IEC 61400-25 provides ASN.1 as well as XML schema for the specification of messages.

The two next possibilities (array and structure) have a common feature. Both refer—through their element type or component type—back to the beginning of the complete definition (type specification). This recursive definition allows the definition of arbitrarily complex structures. Thus, an element of a structure can in turn be a structure or an array.

<b>TypeSpecification</b>	<b>::= CHOICE {</b>	
<b>typeName</b>	<b>[0] ObjectName,</b>	
<b>array</b>	<b>[1] IMPLICIT SEQUENCE {</b>	
<b>packed</b>	<b>[0] IMPLICIT BOOLEAN DEFAULT FALSE,</b>

FIGURE 24.19 MMS Type specification.

Arrays are defined by three features. Packed defines whether the data are stored optimized. Number-Of Elements indicates the number of the elements of the array of equal type (ElementType).

The data of structures can also be saved as packed. Structures consist of a series of components (components [1] IMPLICIT SEQUENCE OF SEQUENCE). This series is marked by the keyword SEQUENCE OF..., which describes a repetition of the following definition. Next in the list is SEQUENCE {component Name und component Type}, which describes the individual component. Since the SEQUENCE OF... (repetition) can be arbitrarily long, the number of the components at a node is also arbitrary.

Then follow the *simple data types*. They start at the tag [3]. The length of the types is typical for the simple data types. For example, integers of different lengths can be defined. The length (size) is defined as Unsigned8, which allows for an integer with the length of 255 octets.

It should be mentioned here that—in the ASN.1 description of the MMS syntax—expressions like integer (written in small letters) show that they are replaced by another definition (in this case by the Tag [5] with the IMPLICIT Unsigned8 definition). Capital letters at the beginning indicate that the definition is terminated here—it is not replaced any more. It is here a basic definition.

Figure 24.20 shows an example of an object defined in IEC 61850-7-4. The circuit breaker class is instantiated as XCBR1. The hierarchical components of the object are mapped to MMS (according to IEC 61850-8-1). The circuit breaker is defined as a comprehensive MMS Named Variable.

The components of the hierarchical model can be accessed by the description of the Alternate Access: “XCBR1” → component “ST” → component “Pos” → component “stVal.” Another possibility of mapping the hierarchy to a flat name is depicted in Figure 24.21. Each path is defined as a character string.

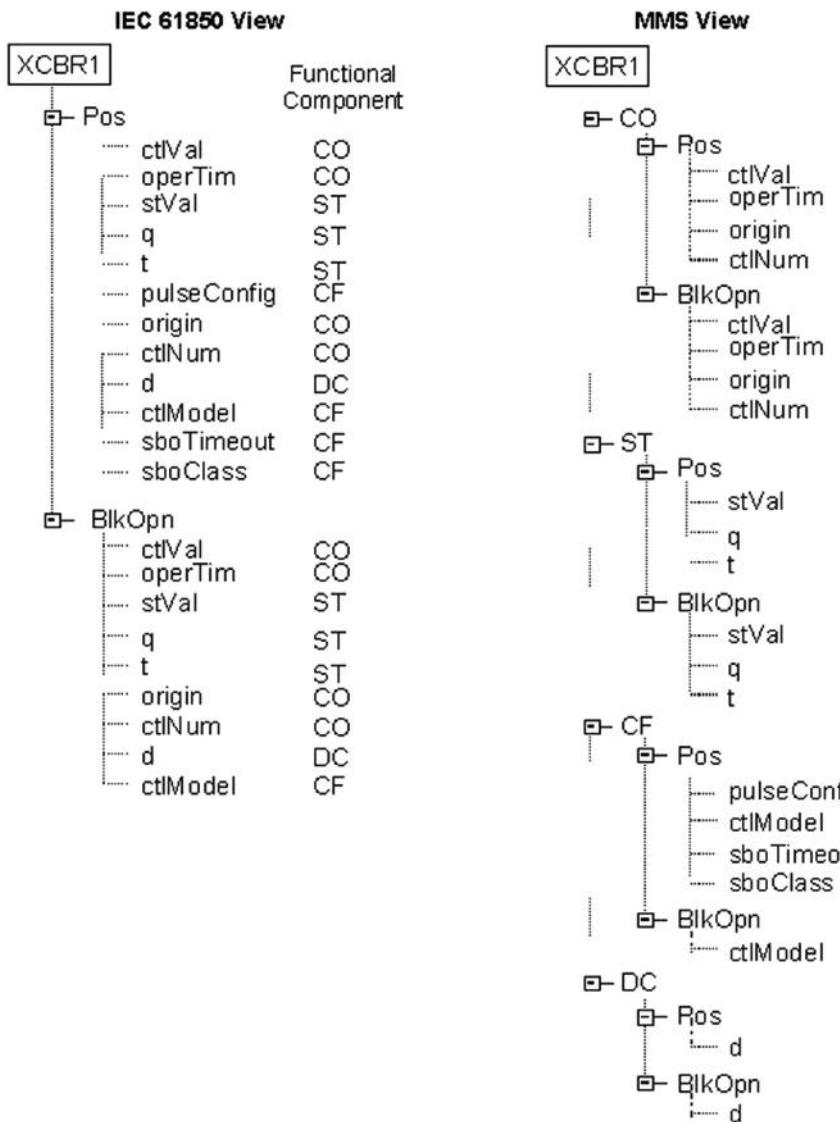

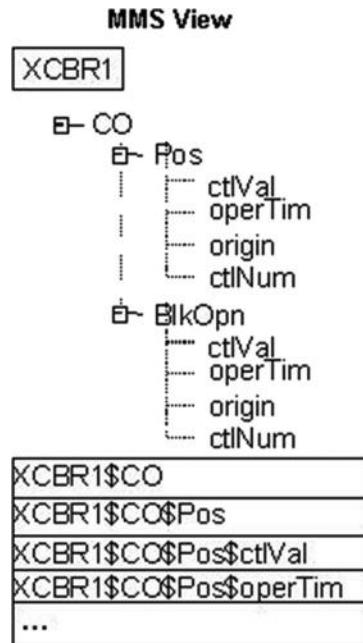

FIGURE 24.20 Example MMS Named Variable.

### 24.9.8 Named Variable

The Named Variable Object describes the assignment of a named MMS variable to a real variable. Only one Named Variable Object should be assigned to a real variable. The attributes of the object are as follows:

Object: Named Variable

- Key Attribute: Variable Name
- Attribute: MMS Deletable
- Attribute: Type Description
- Attribute: Access Method (PUBLIC,...)
- Constraint: Access Method = PUBLIC
- Attribute: Address

**FIGURE 24.21** Example MMS Named Variable.

**Variable Name:** The Variable Name unambiguously defines the Named Variable Object in a given scope (VMD specific, domain specific, or Application Association specific). The Variable Name can be 32 characters long (plus 32 characters if the object has a domain scope).

**MMS Deletable:** This attribute shows whether the object may be deleted using a service.

**Type Description:** This attribute describes the abstract type of the subordinate real variable as it represents itself to the external user. This attribute is not inherent in the system unlike the Unnamed Variable Object; that is, this type description can be defined from the outside.

**Access Method:** This attribute contains the information that a device needs to identify the real variable. It contains values that are necessary and adequate to find the memory location. The contents lie outside MMS. A special method, the method PUBLIC, is standardized. The attribute Address is also available in the case of PUBLIC. This is the address that identifies an Unnamed Variable Object. Named Variables can thus be addressed by the name and the ADDRESS (see Figure 24.22).

**Address:** See Unnamed Variable Object. Defining a Named Variable Object does not allocate any memory either, because the real variable must already exist; it is assigned to the Named Variable Object with the corresponding name.

Altogether, six operations are defined on the object:

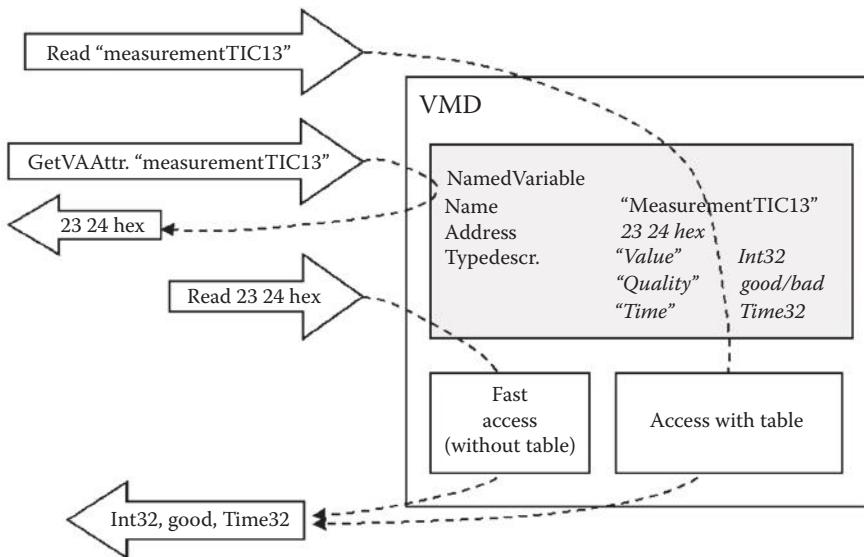

**Read:** The service uses the V-Get function to retrieve the current value of the real data that is described by the Object.

**Write:** The service uses the V-Put function to replace the current value of the real data, which is described by the Object, by the enclosed value.

**Define Named Variable:** This service creates a new Named Variable Object that is assigned to real data.

**Get Variable Access Attribute:** Through this operation, a client can query the attributes of a Named Variable Object.

**Delete Variable Access:** This service deletes a Named Variable Object if Attribute Deletable is (= TRUE).

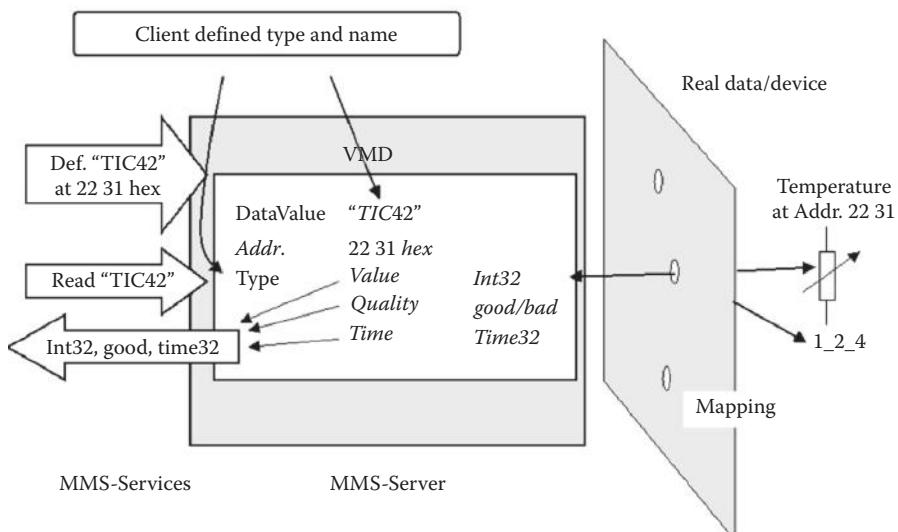

**FIGURE 24.22** Address and Variable Name of Named Variable Objects.

Figure 24.23 shows the possibilities to reference a Named Variable Object by names and, if it is required, also by Address (optimal access reference of a given system). For a given name, a client can query the Address by means of the service Get Variable Access Attribute.

This possibility allows the access through technological names (MeasurementTIC13) or with the optimal (index-) address 23 24 hex.

As shown in Figure 24.23, an essential feature of the VMD is the possibility for the client application to define by request Named Variable Objects in the server via the communication. This includes the definition of the name, the type, and the structure. The name by which the client would like to reference the Named Variable later is *TIC42* here. The first component *Value* is of the type Integer32, the second is *Quality* with the values *good* or *bad*, the third is *Time* of the type Time32. The type of the Data Value

**FIGURE 24.23** Client-defined Named Variable Object.

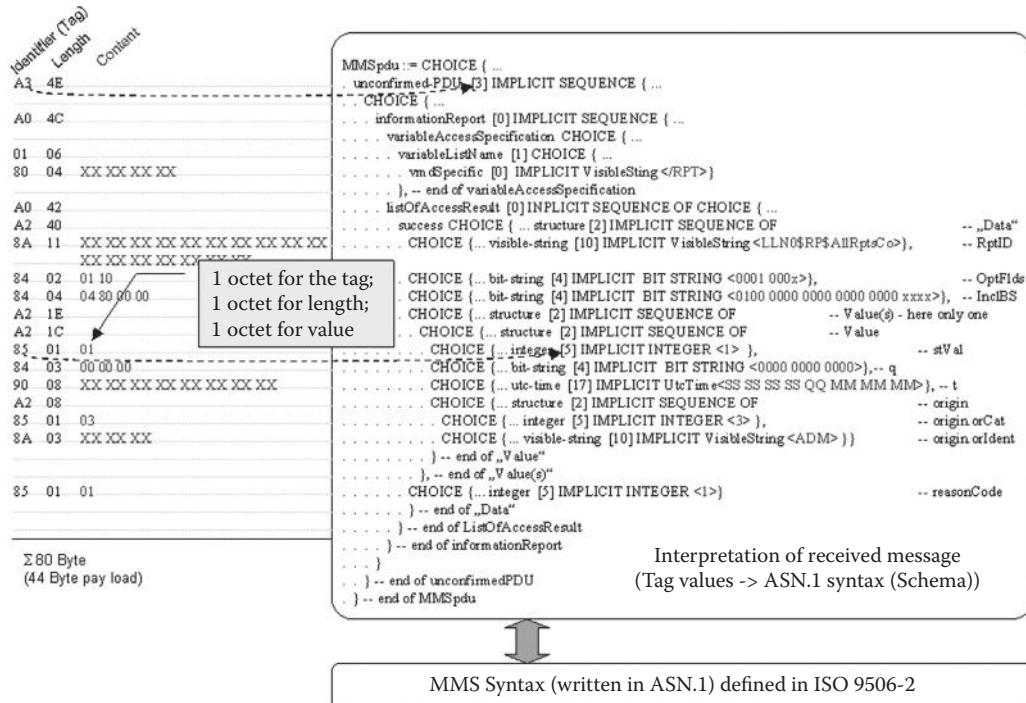

FIGURE 24.24 MMS information report (spontaneous message).

Object can be arbitrarily simple (flat) or complex (hierarchical). As a rule, the Data Value Objects are implicitly created by the local configuring or programming of the server (they are predefined).

The internal assignment of the variable to the real temperature measurement is made by a system-specific optimal reference. This reference whose structure and contents are transparent must be known when defining the Named Variable, though. The reference can, for example, be a relative memory address (e.g., DB5 DW15 of a PLC). So a quick access to the data is allowed.

The Named Variable Object describes how data for the communication are modeled, accessed, encoded, and transmitted. What is transmitted is described independently of the function. From the point of view of the communication, it is not relevant where the data in the server actually come from or where in the client they actually go to and how they are managed—this is deliberately concealed.

Figure 24.24 shows the concrete encoding of the information report message. The message is encoded according to ASN.1 BER (the basic encoding rule for abstract syntax notation number one—ISO 8825).

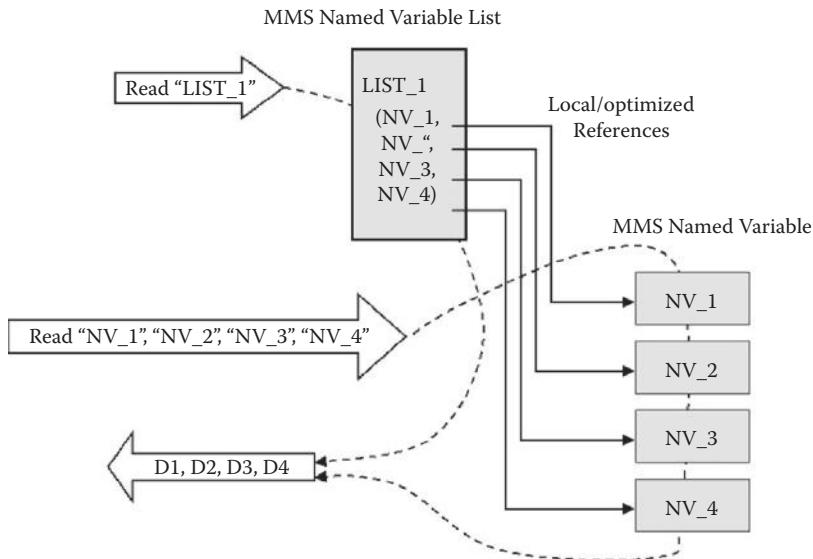

The encoding using XML would be several times longer as using ASN.1 BER. These octets are packed into further messages that add lower layer-specific control and address information, for example, the TCP header, IP header, and Ethernet frames.

The receiving IED is able to interpret the report message according to the identifier, lengths, names, and other values. The interpretation of the message requires the same stack, that is, knowledge of all layers involved—including the definitions of IEC 61850-7-4, IEC 61850-7-3, IEC 61850-7-2, and IEC 61850-7-1.

## 24.9.9 Access to Several Variables

### 24.9.9.1 Named Variable List

The Named Variable List allows to define a single name for a group of references to arbitrary MMS Unnamed Variables and Named Variables. Thus, the Named Variable List offers a grouping for the frequently repeated access to several variables (see Figure 24.25). Although the simultaneous access to

**FIGURE 24.25** MMS Named Type and Named Variable.

several MMS variables can be carried out also in a single service (Read or Write), the Named Variable List offers a substantial advantage.

When reading several variables in a Read request, the individual names and the internal access parameters (pointers and lengths), corresponding to the names in the request, must be searched for in a server. This search can last for some time in the case of many names or a low processor performance. By using the Named Variable List Object, the search is not required—except for the search of a single name (the name of the Named Variable List Object)—if the references, for example, have been entered into the Named Variables on the list system specifically and thus optimally. Once the name of the list has been found, the appropriate data can be provided quickly.

Thus, the Named Variable List Object provides optimal access features for the applications. This object class is used in the known applications of MMS very intensively.

The structure of the Named Variable List Object is as follows:

**Object: Named Variable List**

Key Attribute: Variable List Name

Attribute: MMS Deletable (TRUE, FALSE)

Attribute: List of Variable

Attribute: Kind of Reference (NAMED, UNNAMED, SCATTERED)

Attribute: Reference

Attribute: Access Description

**Variable List Name:** The Variable List Name unambiguously identifies the Named Variable List Object in a given scope (VMD specific, domain specific, or Application Association specific).

See also MMS Object Names provided earlier.

**MMS Deletable:** This attribute shows whether the object may be deleted.

**List of Variable:** A list can contain an arbitrary number of objects (Unnamed Variable, Named Variable, or Scattered-Access Object).

**Kind of Reference:** Lists can refer to three object classes: Named Variables, Unnamed Variables, and Scattered Access; no Named Variable Lists can be included.

*Reference:* An optimal internal reference to the actual data is assigned to every element of the list. If a referenced object is not (any more) available, the entry into the list will indicate it. When accessing the list, for example, by Read, no data but an error indication will be transmitted to the client for this element.

*Access Description:* In the same way as for the access of a variable—for example, in the request during Read—could be defined that only parts (part of a tree) of a variable shall be read, can this also be applied to every element of the Named Variable List.

#### 24.9.9.1.1 Services

*Read:* This service reads the data of all objects being part of the list (Unnamed Variable, Named Variable, and Scattered Access Object). For objects that are not defined, an error is reported in the corresponding place of the list of the returned values.

*Write:* This service writes the data from the write request into the objects being part of the list (Unnamed Variable, Named Variable, and Scattered Access Object). For objects that are not defined, an error is reported in the corresponding place of the list of the returned values.

*Information Report:* As the Read service; as if the read data were sent by the server to the client without prior request (Read Request) by the client, that is, as if only a Read Response would be transmitted.

*Define Named Variable List:* Using this service, a client can create a Named Variable List Object.

*Get Named Variable List Attributes:* This service queries the attributes of a Named Variable List Object.

*Delete Named Variable List:* This service deletes the specified Named Variable List Object.

#### 24.9.9.2 Named Type Object

The Named Type Object merely describes structures. The object model is very simple:

Object: Named Type

Key Attribute: Type Name

Attribute: MMS Deletable (TRUE, FALSE)

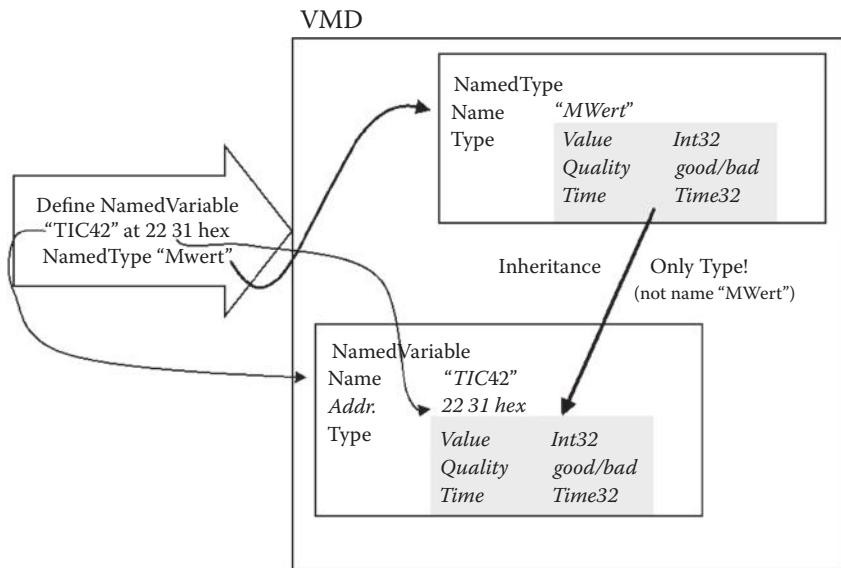

Attribute: Type Description

Essential attribute is the type description, which was already discussed before for Named and Unnamed Variables. On the one hand, TASE.2 standard data structures can be specified by means of Named Types. This is the most frequent application of the Named Type Objects. On the other hand, Named Types can be used for the access to the server. The read request can refer to a Named Type Object. Or the Named Type Object will be used to define Named Variables.

Figure 24.26 describes the application of the Named Type Objects for the definition of a Named Variable. A variable will be created by the request Define Named Variable.

It shall have the name *TIC42*, the address 22 31 hex, and the type that is defined in the Named Type Object *MWert*. The variable inherits the type from the Named Type Object. The inheritance has the consequence that the variable will only have the type but not the name of the Named Type Object. This inheritance was defined so strictly in order to avoid that through deleting the Named Type, the type of the variable would get undefined or that by subsequent definition of a differently structured Named Type with the old type name *MWert*, the type of the variable would be changed (the Named Type Object and with that the new type description would be referenced by the old name).

Perhaps it is objected now that this strict inheritance has the consequence that also the type would have to be saved for each variable (even though many variables have the same type description). Since these variables can internally be implemented in a system in whatever way the programmer likes it, they can refer through an internal index to a single (!) type description. He must only make sure that this

**FIGURE 24.26** Inheritance of the Type of the MMS Named Type Objects.

type description is not deleted. If the accompanying Named Type Object gets deleted, then the referenced type description must remain preserved for these many variables.

The disadvantage that the name of the “structure mother,” that is, the Named Type, is not known any more as an attribute of the variables has been eliminated in the MMS Revision.

#### 24.9.9.2.1 Services

*Define Named Type:* This service creates a Named Type Object.

*Get Named Type Attribute:* This service delivers all attributes of a Named Type Object.

Read, Write, Define Named Variable, Define Scattered Access, Define Named Variable List, and Define Named Type use the type description of the Named Type Object when carrying out their tasks.

## 24.10 Resume

MMS is a standard messaging specification (comparable to web services), widely implemented by industrial device manufacturers like ABB, Alstom, General Electric, and Siemens. It solves problems of heterogeneity so often found in automation applications. MMS is the lingua franca of industrial devices.

MMS provides much more than TCP/IP, which essentially offers a transfer stream of bytes. MMS transfers commands with parameters between machines.

MMS allows a user to concentrate on the applications, application data to be accessible—and not on communication problems, which are already solved. It provides a basis for the definition of common and domain-specific semantic. Examples are the standards IEC 60870-6 TASE.2, IEC 61850, and IEC 61400-25.

### 25.1 Introduction and Overview

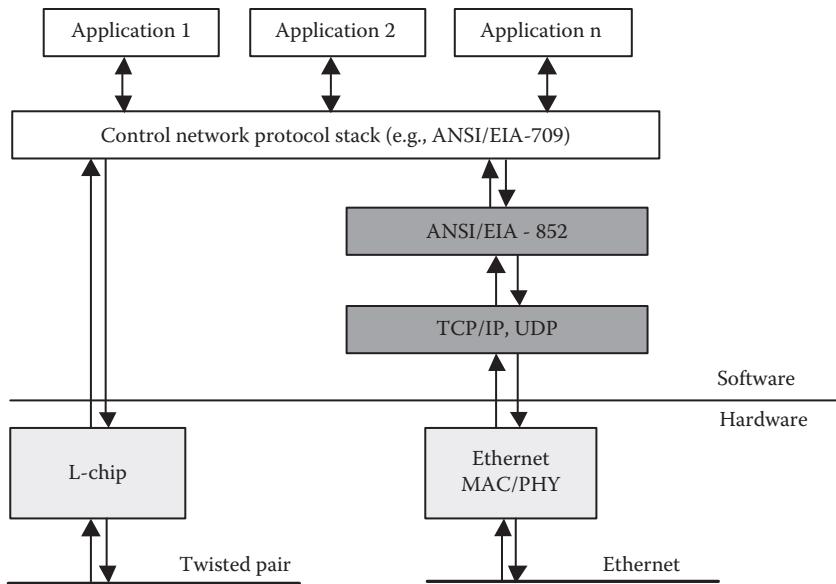

---

Control networks (CNs), also known as fieldbus systems, started to emerge rapidly in the early 1990s [1,2]. Back then, CNs were designed to be used in closed systems exchanging data packets on dedicated network channels. These channels included twisted pair media, power-line networks, wireless, and infrared communication. Dedicated network channels have more or less well-defined properties for bit error rates, propagation delays, and average and maximum response times, and they guarantee to maintain the packet order on the network.

With the upcoming hype of the Internet in the late 1990s, requests were made to extend CNs to not only span local communication within relatively small areas but also cover networks that are spread out over cities, countries, and even continents. In building automation, facility managers wanted to connect facilities to a central location for monitoring, logging, alarming, trending, and remote maintenance [3].

This meant for the engineers to either go back to the drawing board and to redesign the CN protocol to make it work in large networks or to use the existing technology like the IP service available on the Internet to transport CN data packets across continents [4]. Of course, there are still restrictions regarding defined maximum response times, proper packet ordering, and defined packet loss—all properties that are easily manageable on dedicated network channels but can be more or less unknown or undefined in Internet Protocol (IP) networks. Nevertheless, all major building automation systems offer IP-based protocols or protocol extensions [5].

When making the transition from dedicated networks to IP channels, the major engineering challenge is to introduce a layer of software, which manages to hide the different behaviors of the IP network and

**FIGURE 25.1** A dedicated software layer named ANSI/CEA-852 hides limitations of the IP transport service from the control network protocol stack and encapsulates the control network data packet into an IP frame.

ensures that certain CN properties still work by filtering invalid packets (e.g., stale packets). Figure 25.1 shows the software architecture for a typical fieldbus node connected to a dedicated network channel on the left side and a port using the IP transport service on the right side. One can see the software layer called ANSI/CEA-852 [6], which was added between the CN protocol stack and the TCP/IP and UDP socket interface. This layer is responsible to abstract the IP network. It implements the necessary mechanisms to encapsulate CN packets in order to convey them transparently over the IP network. In this chapter, we concentrate on the ANSI/EIA-709 CN protocol [3].

The challenge in tunneling CN data packets through IP networks is to minimize the effect of the unpredictable IP timing parameters on the CN protocol stack. This is a fundamentally different approach than gateways, which try to abstract some application-oriented part of the fieldbus [7,8]. Other aspects to be covered are channel formation and member management, security, and firewall traversal in Internet environments.

## 25.2 ANSI/CEA-852 Standard

The ANSI/CEA-852 standard [6] was created to ensure interoperability of CN devices, which communicate over an IP network using a native CN protocol. It has since evolved to revision ANSI/CEA-852-B and has been standardized as an ISO standard ISO/IEC14908 [9]. Devices conforming to ANSI/CEA-852 are widely deployed in today's building automation systems. The follow-up standard CEA-852.1 [10] overcomes some of the limitations of ANSI/CEA-852 but achieves this at the cost of dropping backward compatibility. Because ANSI/CEA-852 and CEA-852.1 devices cannot interoperate in the same system, CEA-852.1 devices are still not accepted on the market.

The basic idea is to exchange CN packets over an IP network by embedding them in IP packets. This technique is known as tunneling. In ANSI/CEA-852, there are no application layer transformations involved as in other approaches that use gateways. The tunneling approach is beneficial in systems where a number of CN devices communicate and use the IP network purely as another medium.

One major design criterion of the ANSI/CEA-852 standard is to be generic enough to apply it to different CN networks. Currently, the usage for ANSI/CEA-709 (LonMark IP-852) and EIA-600 (CEBus)

is defined. Most ANSI/CEA-852 implementations on the market today are LonWorks based. Therefore, the description of the standard is focused on its application to ANSI/CEA-709.

The network elements defined in the context of the ANSI/CEA-852 standard are CN devices. These CN devices are computing systems (e.g., PCs and embedded systems) equipped with a TCP/IP stack, the ANSI/CEA-852 software, and a LonWorks protocol stack. A number of CN devices are connected over the IP network where they form a logical network known as the *IP channel*. The IP channel functions as a LonWorks communication channel (IP-852 channel), and CN devices exchange data over the IP channel. The CN devices, which are part of the IP channel, are referred to as *channel members*.

It shall be noted that there may exist more than one IP channel on the same IP network. Although the CN devices are connected to the same physical network in this case (e.g., Ethernet), the IP channels are still isolated in the LonWorks domain.

CN devices can have different functions. Depending on their primary function, the ANSI/CEA-852 standard defines the following CN device types:

- CN nodes: They operate solely as nodes in a distributed control application and are members of one IP channel. They have the same functionality as LonWorks nodes on their native communication channels and are connected to the IP channel only.
- CN/IP routers: These CN devices are LonWorks routers that connect one native LonWorks channel with one IP channel. These devices are available on the market as stand-alone LonWorks/ IP routers or ANSI/CEA-852 routers, for example, the L-IP by LOYTEC or the i.LON 600 by Echelon Corp.
- IP/IP routers: These CN devices are LonWorks routers that connect two IP channels. These devices are less common on the market today.
- CN proxies: These are CN devices, which, for example, function as LonWorks proxy nodes to establish cross-domain communication.

The ANSI/CEA-852 addressing scheme defines two address types. First, there are IP addresses associated with each CN device on the channel. Second, there are logical CN addresses based on the LonWorks address space. The Unique ID is equivalent to the LonWorks node ID, or Neuron ID, and functions as a unique hardware address. Each CN device is accessible by its unique ID. Logical network addresses include a subnet/node (S/N) scheme. In this addressing scheme, subnet numbers are assigned to individual channels and node addresses to the CN devices on those channels. As a convention, subnets must not span over multiple channels, if the CN routers are used as configured LonWorks routers. The group address identifies a number of nodes independently from subnet addresses. Consequently, groups can span different channels. Finally, those logical addresses are local to a domain.

The mechanisms in the ANSI/CEA-852 standard are designed to take care of typical CN protocol properties, which differentiate them from common IP application protocols such as e-mail, web access, or multimedia streaming. The key characteristics of CN traffic are

- Low throughput
- Small packet sizes
- Higher sensitivity to packet loss and latency

While low throughput allows CN devices to perform more lengthy per-packet calculations, small packet sizes will lead to significant overhead in the encapsulation process. The implications of packet loss and latency on the IP network are twofold in ANSI/CEA-852 systems:

- The control application has to be designed to cope with timing parameters, which differ from native CN channels. This has an impact on the soft real-time properties of some applications. It is important to know the time constants in the application and determine whether the application still operates correctly when run over an IP channel [11,12].

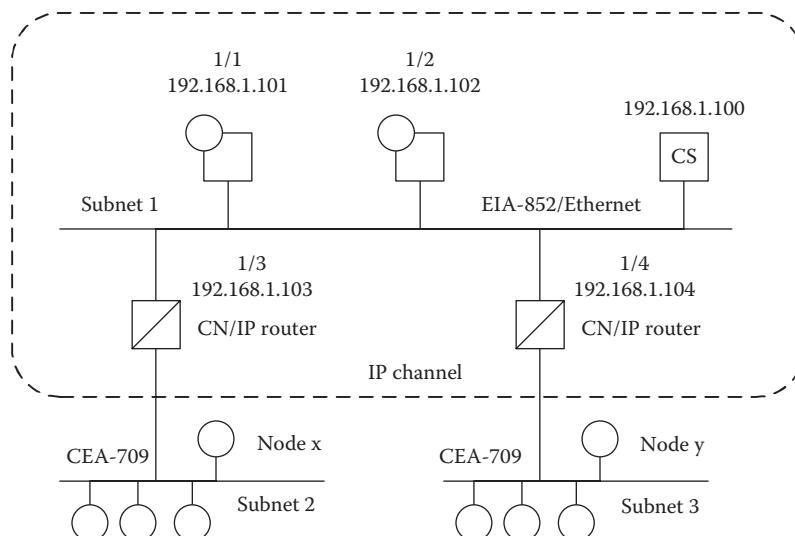

- The ANSI/CEA-852 standard has to ensure the functionality of the CN protocol itself. LonWorks, for instance, makes strict assumptions on the maximum end-to-end delay and packet ordering.

The resulting functional domains defined in the ANSI/CEA-852 standard to implement a CN protocol tunnel over an IP-based network can be summarized as follows:

- Assuring correct and efficient data communication: CN packets must be encapsulated and decapsulated, packet ordering must be ensured, message overhead must be minimized, timeliness must be checked, and optional security measures can be used.
- Routing CN payload to their correct destination on the IP network: The ANSI/CEA-852 standard defines two ways to choose destination CN devices, either by using IP multicasting or by performing selective forwarding.
- Channel formation and managing IP channel members: Configuring the CN devices, distributing information between the CN devices, performing access control on the IP channel, and retrieving statistic information.

## 25.3 System Components

In addition to assigning logical addresses to the network node as specified in the CN protocol, network nodes on an IP channel must also have an IP address. Thus, when an IP-based node needs to transmit data packets to another node on the network, it must know not only the CN address but also the IP address of the target node. A system component is required that manages the relationship between the CN address and the IP address for a logical IP channel. In the ANSI/CEA-852 standard, this component is the configuration server (CS). Figure 25.2 outlines the system components required to operate and manage an IP channel. The network in Figure 25.2 is partitioned into three parts: two traditional ANSI/CEA-709 networks with subnet numbers 2 and 3 and an IP channel with subnet number 1. The IP channel consists of four CN/IP client devices and a CS. Two IP client devices are routers between the traditional ANSI/CEA-709 network channels and the IP-852 channel (CN/IP router). The other two devices are native IP-based CN nodes. Let us assume that the node with subnet/node address 1/1 on the IP-852 channel wants to send a data packet to the network node with subnet/node address 1/2,

**FIGURE 25.2** System components constituting an IP channel including the IP channel, the configuration server (CS), and IP-based nodes acting as configuration clients.

which is also connected to the IP-852 channel. In order for node 1/1 to send out a packet to node 1/2, it must know its peer IP address 192.168.1.102. This information is maintained by the CS hosted on IP node 192.168.1.100 and distributed to all nodes on the IP-852 channel. The node 1/1 queries this information from the CS and therefore knows the mappings between subnet/node addresses and IP addresses for each node on the IP-852 channel. In our example, node 1/1 generates a UDP packet that is sent to node 1/2 at IP address 192.168.1.102. If this packet is sent using acknowledged service, node 1/2 replies with an acknowledgment packet to node 1/1. This is the same behavior as on a traditional ANSI/CEA-709 channel except that node 1/2 must know not only the source subnet/node address to send the reply but also under which IP address this subnet/node address is reachable. The reply packet must be addressed to the IP address of node 1/1, which is 192.168.1.101. To summarize this, the process of selecting an appropriate IP address corresponding to a specific ANSI/CEA-709 destination address is called *channel routing* (CR). Each node that joins an IP channel must send out the information about its assigned ANSI/CEA-709 address information to the CS, which associates this address information with the IP address. This is called CR information. Whenever the CR information changes, a client node on the IP channel must create a new CR packet and send it to the CS, which in turn distributes the new information to all other members on the IP channel.

CN/IP router devices bridge the gap between traditional ANSI/CEA-709 networks and IP channels as shown in Figure 25.2. For example, if node x on Subnet 2 wants to send a message to node y on Subnet 3, then the router with IP address 192.168.1.103 forwards the packet to the router with IP address 192.168.1.104, which forwards the packet to the destination node y on Subnet 3. One can see that even though there is an IP channel on the communication path between node x on Subnet 2 and node y on Subnet 3, the source node x on Subnet 2 does not even notice this IP channel in between the source and the destination node. As a result, it is now possible to connect any two local CNs with IP channels that can span either intranets or the Internet.

The IP channel can be operated on different network media that are offering the IP service. Commonly, 10 BaseT or 100 BaseT Ethernet networks are used for the IP channel. But emerging wireless technologies such as 802.11b or 802.11a and Bluetooth, as well as POTS and ISDN lines, cable networks, and fiber-optic cables are used as well. This opens new application areas to existing CN protocols that could not be satisfied with the traditional technology.

## 25.4 Data Communication

---

CN devices exchange CN data packets over the IP channel. This is referred to as data communication to distinguish the traffic from management communication between the CS and the CN devices. There is always a source of a CN data packet and a sink. In the following, we shall refer to a CN device that acts as a source as the sender, to the CN device that acts as the sink as the receiver. It shall be noted that this sender-receiver relation is valid only in the context of a single data packet, or a series of data packets, in the same direction. Generally, each CN device can act as a sender as well as a receiver on the IP channel at the same time.

CN nodes are true sources and sinks of CN data. CN/IP routers are intermediary devices between the actual sources and sinks of the communication. This detail shall be neglected as the CN/IP routers appear on the IP channel as senders and receivers as well.

The diagram in Figure 25.3 shows the functional blocks in the sender and receiver. When a data packet is generated in the CN node or has to be passed on to the IP channel by a CN/IP router, the sender packs the CN packet in an ANSI/CEA-852 data packet, adds a sequence number and a timestamp, routes the ANSI/CEA-852 packet to the appropriate channel members, and finally may collect a bunch of packets before actually sending them on the wire (bunching). The receiver performs the reverse operations: It separates the aggregated packets (debunch), runs them through a sequencer, a stale packet detector, and unpacks the original CN frames. These details of these functions are explained in more detail in the following sections.

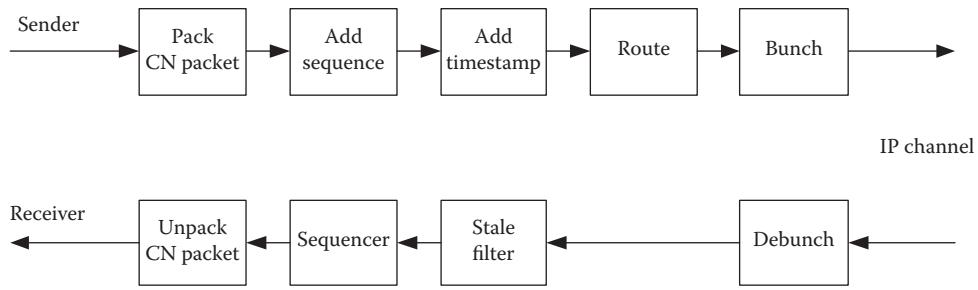

FIGURE 25.3 Functional blocks in ANSI/CEA-852 Data Communication: sender and receiver.

#### 25.4.1 Encapsulation

The process of embedding ANSI/CEA-709 frames in ANSI/CEA-852 data packets is referred to as encapsulating. The native ANSI/CEA-709 packets are encapsulated in UDP frames and routed to the respective CN devices on the IP channel. ANSI/CEA-852 uses the reserved port number 1628 for ANSI/CEA-852 communication on CN devices. The CS uses port 1629. This makes it possible to combine a CS and a CN device on the same system.

The choice of UDP transport over TCP has several advantages: First, because of the connectionless nature of LonWorks communication, it would incur unnecessary overhead to manage connection setup in TCP. Second, TCP ensures delivery through retransmissions. Because of the (soft) real-time requirements of control applications, retransmissions will most likely miss the deadlines. Third, the LonWorks protocol implements its own retransmission scheme where necessary.

Figure 25.4 shows the format of the native LonWorks packet format. The preamble bits and the code violation after the CRC are used for bus arbitration and end-of-frame marking on native ANSI/CEA-709 channels. Not all parts of the native frame are subject to encapsulation. The fields starting with the control field and ending with the CRC information are taken from the native LonWorks frame and encapsulated in the UDP frame. Figure 25.5 shows the ANSI/CEA-852 common header encapsulation format, which

FIGURE 25.4 Native ANSI/CEA-709 frame format.

Byte 0	Byte 1	Byte 2	Byte 3

FIGURE 25.5 ANSI/CEA-852 common header format.

**TABLE 25.1** ANSI/CEA-852 Packet Types

Packet Name	Packet Type	Function
Data packet	0x01	Encapsulates the CN frame.
Device configuration request (DC-REQ)	0x63	Request a DC from the CN device.
Device registration (DEVREG)	0x03	Device registers with the CS.
Device configuration (DC)	0x71	DC requested from the device or unsolicited DC sent by the CS.
Channel List Request (REQ-CM)	0x64	Device requests CM from the CS.
Channel List (CM)	0x04	The CS responds with the CM.
Send List Request (REQ-SL)	0x66	Request the send list from the CS.
Send List (SL)	0x06	The CS responds with the send list.
Channel Routing Request (REQ-CR)	0x68	The CN device requests a CR from the CS for a specific member.
Channel Routing (CR) Packet	0x08	The CS responds to a CR request.
Acknowledge (ACK)	0x07	Acknowledgment message from device or CS.
Segment (SEG)	0x7F	Segment of a large data structure.
Statistic Request (REQ-STAT)	0x60	Request statistics from a CN device.
Statistic Response (STAT)	0x70	CN device responds with statistic data.

is the payload of a UDP frame. Data fields in ANSI/CEA-852 packets are defined in network order, transmitting the most significant byte first. The data packet length specifies the complete length of the ANSI/CEA-852 packet including the two length bytes. The version number is currently set to 1. The packet type specifies how the ANSI/CEA-852 payload after the common header is to be interpreted.

An ANSI/CEA-852 data packet, which encapsulates the CN frame, is of type 0x01. For more packet types, refer to Table 25.1. The extended header size can be used to add more fields to the common header. It specifies them in quantities of 4 bytes. This ensures that the common header is always a multiple of 4 bytes. The protocol flags define which CN protocol is to be tunneled (0x00 for LonWorks). The vendor code allows implementers to include their own vendor-specific extensions, which can be transported along with standard ANSI/CEA-852 messages. The session ID is a 32-bit value that a CN device keeps at random. After a CN device reboots or resets, the session ID must be different than the previous one. The sequence number field is valid for ANSI/CEA-852 data packets and is used to detect out-of-sequence packets. The timestamp is also used for ANSI/CEA-852 data messages and is a millisecond value. Therefore, it wraps around every 49 days.

## 25.4.2 Packet Sequencing

Packet sequencing in ANSI/CEA-852 is based on the pair session ID and sequence number, which are both part of the ANSI/CEA-852 common header. An ANSI/CEA-852 receiver remembers the session ID/sequence number pair for each sending CN device (i.e., for each source IP address). If ANSI/CEA-852 data packets from a given source are received with the same session ID, they are in sequence, provided their sequence numbers are increasing. If data packets get reordered or are dropped on the network, there appear gaps in the sequence numbers. A receiver basically has two choices: (1) continue and drop the missing packets later or (2) wait for the missing packets.

If the receiver waits, it has to keep data packets after such a gap in escrow until a defined escrow timeout (ETO). If the missing packets arrive before the timeout, the packets are passed on in their correct sequence. If they do not arrive in time, they will be dropped later. Without escrowing, all out-of-sequence packets are dropped immediately. This may cause unnecessary packet loss on IP channels where packets may get reordered in a small time window.

If the session ID changes, the receiver has to assume that the source has been reset, and it accepts the first packet with that new session ID as in sequence, clearing the sequence numbers from the previous session. This is a design choice of ANSI/CEA-852 and can cause problems with replay attacks. See the section on security for more detail on this issue.

The ETO is a CN device parameter in most implementations. This time constant has to be considered when designing a control application. It is always a trade-off that has to be made between unnecessary loss of reordered packets and delay of escrowed packets for too long when packets actually are lost on the IP link. If the ETO is big, more packets can be reordered because the wait time for them is longer. For the same reason, if a packet is actually lost on the IP link, the wait time can approach the ETO in the worst case.

Applications that primarily rely on request/response-style communication on LANs should choose a small ETO (e.g., 5 ms) or disable it. Applications that are based on a continuous unidirectional sample stream over a WAN link should choose a large enough ETO. A typical default value on most implementations is 64 ms.

### 25.4.3 Packet Aggregation

The native message sizes of typical CN traffic are small, around 10–20 bytes in LonWorks. Encapsulating each CN packet into a UDP frame adds the UDP, IP, and Ethernet headers (or other media-specific headers), which account for more than 40 bytes. This incurs unnecessary overhead that may lead to noticeable performance problems on embedded implementations. Those systems typically suffer from an IP transmission bottleneck.

A technique to reduce this overhead is to aggregate more than one ANSI/CEA-852 data packet in a single UDP frame (packet bunching). Clearly, the more packets are bunched, the less per-CN packet overhead is added by the encapsulation. When aggregated, ANSI/CEA-852 data messages are concatenated in the UDP frame. The UDP packet is then transmitted to the destination IP address. Therefore, messages can be aggregated only when they share the same destination. The sender may thus be configured to keep data packets and aggregate them until an aggregation timeout (ATO) before sending the UDP frame on the IP link. The ATO value is a CN device parameter in most implementations.

The effect of packet bunching has to be considered in the design of control applications. There is a trade-off between overhead reduction and extra delay. In the worst case, an ANSI/CEA-852 data packet is delayed for the full ATO until it finally gets on the wire. For highly responsive applications with low packet rates on LANs, packet bunching should be disabled. For applications with high packet rates over WANs, packet bunching should be enabled. A typical default value in most implementations is 16 ms.

### 25.4.4 Stale Packet Detection

Packet delay on the IP link is a big issue on IP channels. Packet delays can be highly random with a large standard deviation on wide area IP links [13]. There are two problems with this: (1) the control application may miss some of its deadlines, and (2) the CN protocol may break if packets are received after they are delayed too long. For example, the LonWorks duplicate detection mechanism is sensitive to high delay variance on the network. While the first problem must be solved by carefully designing the control application [14], the second problem can be eliminated by discarding packets that are delayed beyond a certain time limit (stale packets). The mechanism is called stale packet detection and is based on one-way packet delay measurements. In order to make such measurements, CN devices must synchronize their clocks. Clock synchronization in ANSI/CEA-852 is performed via SNTP [15]. The sender generates a millisecond timestamp and puts it into the ANSI/CEA-852 common header. If its measured delay exceeds the channel timeout (CTO), the packet is called a stale packet, and the receiver discards it in the stale packet filter.

The CTO is a channel parameter and distributed among the CN devices. Applications on LANs can disable stale packet detection because the delay variance is typically very low and comparable with native LonWorks channels. On WAN links, it is recommended to enable the CTO. Typical values are the average ping delay on the IP channel plus ATO. The lower bound of the CTO is restricted by the resolution of the clock synchronization. On certain systems (e.g., Windows), the resolution may drop to 50 ms. Practical CTO values start at 200 ms. If certain CN devices are Windows implementations, it must be

**TABLE 25.2** ANSI/CEA-852 Statistics Data

Data	Explanation
Seconds since cleared	Number of seconds since the statistics have been reset
Date/time of clear (GMT)	Date and time when the statistics have been reset
No. of members	Current number of channel members
CN packets received	CN packets received from LonWorks
CN packets sent	CN packets sent to LonWorks
IP packets sent	CN packets sent onto the IP channel
IP bytes sent	Aggregate number of bytes in CN packets sent onto the IP channel
IP packets received	Number of CN packets received from the IP channel
IP bytes received	Aggregate number of bytes in CN packets received from the IP channel
CN stale packets	Number of packets dropped because they are stale
RFC packets sent	Number of management data packets sent to the CS
RFC packets received	Number of management data packets received from the CS
Avg. aggregation to IP	Average aggregation of transmitted CN packets on the IP channel
Avg. aggregation from IP	Average aggregation of received CN packets from the IP channel
UDP packets sent	Total number of UDP packets sent (including both data and management)
Multicast packets sent	Total number of multicast packets sent (only for send lists)

ensured that the Windows system clock is synchronized. Dropped packets due to stale packet detection can be observed in the ANSI/CEA-852 statistics of stale packets (see Table 25.2). Stale packet filtering also plays an important role in the context of security. Refer to the section on security for more detail.

### 25.4.5 ANSI/CEA-852 Data Packet Routing

One of the ANSI/CEA-852 CN device tasks is to route ANSI/CEA-852 data packets to the appropriate IP channel members. In this context, it is important to notice that each channel member is associated with an IP address. If a given CN data packet needs to be routed to multiple IP addresses, it is copied into several ANSI/CEA-852 data packets, each sent to one of the selected CN devices on the channel. It shall be noted that sequence numbers are associated per destination address. If CN data packets are routed to different IP addresses, the sequence numbers need not necessarily be the same among all destinations. This stems from the fact that some messages are routed to a specific destination and some are not.

Depending on the available channel data, three variants of routing the CN data packet are possible:

1. Send List (SL) Routing. An SL is an optimized list of IP addresses to reach all channel members. Typically, SLs are used when IP multicast addresses are assigned to groups of channel members. In the best case, all channel members are in the same IP multicast group. In this case, the SL contains this one multicast address. CN devices send ANSI/CEA-852 data packets to all destinations in the SL.
2. Channel Routing: CR is used when only unicast IP addresses are available. The basic idea is to select those destination IP addresses that will accept the packet based on the LonWorks address information. To advertise which LonWorks addresses a CN device accepts, it publishes CR information to the other channel members. Each channel member collects all the available CR and can route outgoing CN data packets in an optimized way. It shall be noted that with CR, all data packets have to be copied multiple times if there are multiple advertised recipients. Especially for large groups and broadcast addresses, SLs appear much more efficient. For subnet/node or NID addressed packets, CR is beneficial because the packets are routed to a single unicast address only not burdening other CN devices with packets that they do not want.
3. Brute Force: Neither SL nor CR information is available. The CN device resorts to the channel list and transmits every data packet to all channel members using unicast addresses. This mode is the least efficient.

The CR algorithm is based on the CR information provided by the CN devices on the channel. The CR information for each channel member contains the following fields:

- The CN device IP address and port
- The CN broadcast flag
- The CN device type (router, node, IPIP router, and proxy)
- The CN router mode (configured, bridge, and repeater)
- A list of node IDs
- A list of subnet/node addresses
- A list of domain items (including subnet and group forwarding flags)

The domain items deserve a more thorough discussion. First, they contain a domain number. Then they specify forwarding flags for both subnets and groups. If the  $n$ th subnet flag is set, the CN device accepts all packets destined for subnet  $n$ . If the  $m$ th group flag is set, the CN device accepts all group packets for group  $m$ . CN routers need to specify the subnet and group forwarding flags, while CN nodes only specify the group flags. This is because CN nodes do not forward any packets, but they can be members of multiple groups.

Figure 25.6 summarizes the CR algorithm implemented in most CN/IP router implementations. The CR algorithm iterates over all channel member CR information for each ANSI/CEA-852 data packet. § I checks the CN broadcast flag and routes all packets if the router type is a repeater and it has at least one domain item. The CN broadcast flag is set when the channel member is unconfigured and does not yet have a valid domain. Otherwise, those devices could not be reached over the IP channel by broadcasts.

Leaving the special case of unconfigured CN devices aside, there are two types of devices on a channel: (1) CN nodes, which accept only CN packets addressed to them (e.g., their subnet/node address, their NID, and their group), and (2) CN routers, which forward packets to other channels behind them. The CR algorithm therefore distinguished those two cases.

In § II, the packet is routed by looking at the channel member as a CN router (e.g., configured router and bridge). This step uses information contained in the domain items of the CR information. Therefore, a forwarding device must define at least one domain item in its CR information. § II(i) skips the CR for a certain domain item if the domain does not match. § II(ii) is responsible for forwarding group addressed messages if the corresponding group forwarding flag is set in the domain item. § II(iii) checks the destination subnet part for S/N, NID, and broadcast-addressed messages. If they are domain-wide (i.e., subnet equals "0"), the message is forwarded. Otherwise, those messages are forwarded in § II(iv) only if the corresponding subnet forwarding flag is set in the domain item. As a consequence, CN routers must supply domain items for all domains they need to receive packets in.

- I. If (CN broadcast flag is set and address == FMT\_BCAST) or (router type == REPEATER and there is a domain item) then route to member.
- II. Route to CN router
  - (i) If domain is incorrect skip to III.
  - (ii) If address == FMT\_GROUP and group forward flag is set for GROUP route to member.
  - (iii) If SUBNET == 0 route to member.
  - (iv) If subnet forward flag is set for SUBNET route to member.
- III. Route to CN device
  - (i) If address == NID and NID matches route to member.
  - (ii) If DOMAIN does not match skip to IV.
  - (iii) If address == FMT\_SN and subnet/node item matches route to member.
  - (iv) If address == FMT\_BCAST and SUBNET == 0 route to member
  - (v) If address == FMT\_BCAST and SUBNET matches subnet/node item route to member.
- IV. Go to next member CR information.

**FIGURE 25.6** Channel routing algorithm.

In § III, the message is routed by looking at the channel member as a CN node on the IP channel. The IP channel is assigned a separate individual subnet number, and all nodes on that channel get their individual node numbers. Therefore, devices that represent nodes on the IP channel must supply at least one subnet/node, one NID, and one domain entry in their CR information. § III(i) checks if an NID addressed message matches with one of the NID items in the member CR information. If the NID matches, the message is forwarded to that member ignoring any domain information. Therefore, unconfigured nodes on the IP channel can be reached via NID addressed messages. For all other messages, § III(ii) checks if the domain matches with one domain item. If it does not, the algorithm skips to § IV. In § III(iii), subnet/node addressed message are routed. A subnet/node addressed message is forwarded to a specific member if that member has a matching subnet/node entry in its CR information. § III(iv) routes all domain-wide broadcasts to a node on the IP channel. § III(v) routes all subnet broadcasts to the channel member if one of its subnet/node items has a matching subnet number. § IV iterates to the next member in the channel until the CR algorithm has gone through all channel members.

The CR mechanism has the following implications on the CR information, which CN devices must provide:

- Unconfigured channel members must set the CN broadcast flag in order to get configured by LonWorks network management tools (e.g., LonMaker).
- CN routers (configured router, bridges, etc.) must provide corresponding domain items in the CR for all domains they want to exchange packets in.
- CN nodes must provide corresponding subnet/node, NID, and domain items.

## 25.5 Management

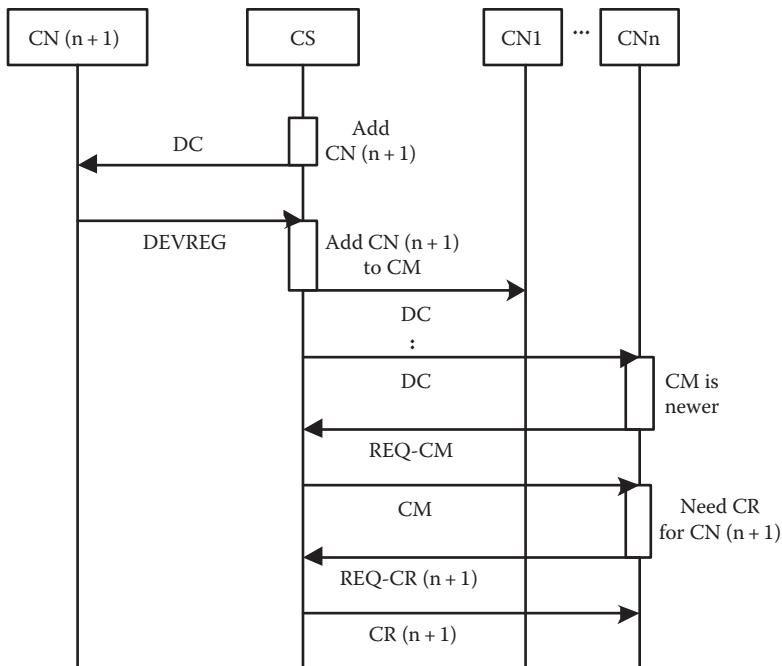

---

Apart from data communication, a big part of the ANSI/CEA-852 functionality is devoted to the management of IP channels. Management functions include channel formation, which defines the CN devices that are member of a specific IP channel, configuration of individual CN devices, distributing information between CN devices, and retrieving statistics information about CN devices. All relevant configuration data for a CN device is controlled by a device configuration (DC) structure.

The ANSI/CEA-852 management concept is based on a client/server model. A CS is the central part in the system, which is responsible for channel formation. CN devices act as configuration clients and request data structures from the CS. The CS only actively sends the DC to CN devices, if the IP channel has been updated and it needs to announce that change. Therefore, the DC is an unsolicited message from the CS. If no channel changes are pending, the CN devices can operate without a CS. As soon as the IP channel needs to be updated, for example, a CN device is added or recommissioned, the CS must be available again to distribute the change.

The management data structures include the per-device DC, a channel membership (CM) list specifying the members on the IP channel, an SL for SL routing, which is optional, and a per-device CR information. All management data in ANSI/CEA-852 are versioned. The version is a 32-bit value, which increases for newer versions. The version is usually date and time information in NTP second format, which may or may not be synchronized to UTC. Hence, the version is called datetime and is nonzero for valid data structures. Local data structures are checked against published datetime versions and requested if newer data are available. The CM, SL, and per-device DC are versioned by the CS, whereas the CR data are versioned by the individual CN devices.

The CN devices, which constitute the IP channel, are defined in the channel list on the CS. Each CN device is uniquely identified by its IP address in the channel list. An important restriction in ANSI/CEA-852 is that there cannot be two CN devices on a channel, which share the same IP address but have different IP ports.

**FIGURE 25.7** CS configuration data distribution.

Each CN device in the channel list is configured by a DC. The DC is entered on the CS, for example, through a serial console or a web interface. The following information needs to be supplied in order to add a CN device to an IP channel:

- IP address and port of the CN device
- Name of the CN device (typically 15 characters)

Figure 25.7 depicts the message flow when adding or configuring a CN device. The CS adds a CN device to the channel by sending an updated and unsolicited DC message to the device. Once a CN device is added or has accepted a new configuration, it registers with the CS by sending a device registration (DEVREG). Knowing the channel is updated, the CS sends a new unsolicited DC to all the other members to announce the channel update. The other CN devices in turn request the updated data structures from the CS starting to request the channel list (REQ-CM). If the CN device finds out that the CM advertises new CR information for certain members, it requests them from the CS (REQ-CR) one by one.

If a CN device is not available when it is added on the CS, it is usually marked as *unregistered* in the channel list. In this case, the CS tries to recontact the CN device using an exponential back-off for the retry interval. It starts at 1 s, doubles each time, and is limited by 32 s. As a consequence, it may take up to 32 s for a device to become functional on the IP channel when it was not reachable at the time of adding it. CS implementations usually display CN devices, which have registered successfully as *registered*. If a device has been registered once but is not responding to a channel update, a CS may display it as *not responding*. The operator then can take appropriate action for those devices.

Access control on the CS is also defined through the channel list. If a CN device tries to register with a CS that does not include this particular device in its channel list, the CN device is rejected from the IP channel. Rejected CN devices cannot send or receive CN packets over the IP channel and usually indicate this condition as an error, for example, a red status LED. Some CS implementations collect information about those CN devices in a so-called orphan list. The operator then can select an orphan device and add it manually to a given IP channel.

An important part of ANSI/CEA-852 is the routing of CN packets to the correct CN devices over the IP network. As described in the previous section, there are two possibilities: (1) creating an SL or (2) distributing CR information. The CS generates the SL by looking at the IP address information in the channel list. By appropriately grouping IP multicast addresses and unicast addresses, the SL typically gets much shorter than the channel list. The SL is also versioned and distributed to the CN devices by sending an updated DC to the members.

The other possibility is to distribute CR information. The CR, however, does not originate at the CS, but at the individual CN devices because they are commissioned and only they have knowledge of their CN address information. Each CN device sends a CR update to the CS if its CR changes. The CS in turn generates a new channel list, which reflects the updated CR datetime version of the device. The other devices will request the new channel list and discover that a specific device has a new CR. The other devices then request this CR from the CS as described before. If more than one CR information has changed, the CN devices request all newer CR data from the CS. This is an important detail, because CN devices never request the new CR from the original device directly. Therefore, the CS must be available, if any CN device is recommissioned.

The management part of ANSI/CEA-852 also defines a statistics information structure. This structure can be requested outside of the client/server model. Any CN device or the CS can request the statistic information from a CN device. The statistic data supplied are listed in Table 25.2.

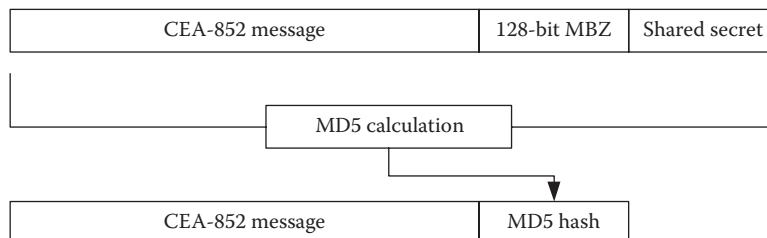

## 25.6 Security

Security is a growing area of concern for IP networks. This also includes ANSI/CEA-852 traffic. While native LonWorks channels are local (e.g., to a building) and can be accessed only locally, IP channels are established on an open media that may even span across WAN links. Typical security issues are privacy, authenticity, and integrity [16]. Security measures defined in ANSI/CEA-852 refer to the problem of authenticity only. They assure that a received data packet is actually sent by an authentic channel member and not by an attacker.

The principle is based on secure message authentication codes and a shared secret. The secure hash function algorithm MD5 [17] is used to create a unique fingerprint of an ANSI/CEA-852 message. Included in the fingerprint calculation is a secret key, which is not transmitted over the wire. The receiver can perform the same calculation, supplying its own copy of the secret key, and compare the hash codes. If they match, the message is authentic.

The MD5 hash is transmitted right after the ANSI/CEA-852 message. Its fixed length is 128 bits and is not included in the ANSI/CEA-852 packet size field. Instead, channel members are configured for secure operation (MD5 mode) and expect the extra 128 bits after each ANSI/CEA-852 packet. This is especially important for bunched UDP frames. If packets are bunched, the next ANSI/CEA-852 message follows the MD5 hash.

The calculation principle is depicted in Figure 25.8. The MD5 hash following the ANSI/CEA-852 message is set to zero (MBZ). The MD5 algorithm is run over the ANSI/CEA-852 message, the zero hash

**FIGURE 25.8** MD5 authentication of ANSI/CEA-852 packets.

placeholder, and the 128-bit shared secret. The calculated hash value is copied into the placeholder, and the message is transmitted excluding the shared secret. The receiver performs the same calculation. It just saves the MD5 hash and then sets it to zero before calculating the MD5 hash locally. If the saved and the locally computed hash values match, the message contents are authentic.

To prevent replay attacks, stale packet detection must be enabled. The reason for this is the sequencing algorithm in ANSI/CEA-852. An attacker may record a sequence of authenticated messages known to trigger a specific action. These messages will share a common session ID. At a later point in time, the CN device may have chosen a different session ID (e.g., after a power outage). At this moment, the recorded sequence can be replayed successfully because the CN device would accept the old session ID as a new one and start over with counting the sequence numbers. Stale packet detection solves this problem because the ANSI/CEA-852 messages include timestamps in addition. Since the CN devices are synchronized to UTC, a playback at a later time is not possible. The CN devices would drop those packets as stale packets.

Another security aspect in modern networks are firewalls and network address translators (NATs). Firewalls, in principle, only filter traffic. Therefore, CN devices can be operated behind a firewall if the filter rules are set accordingly, namely, allowing UDP traffic on ports 1628 and 1629 to pass.

The case with NAT routers is different. NATs, actually, alter IP addresses and port numbers. This is a problem for ANSI/CEA-852 because channel members on the IP channel are uniquely identified by their IP address and port. If that address or port is changed in the public realm, they could not be part of the IP channel. Some implementations of CN/IP routers therefore allow for a special NAT mode (e.g., the L-IP by LOYTEC). In this mode, a CN device is configured with the public address and port of its NAT router. It represents this public address combination in its DC, and other members will see its public address in the channel list and CR information. The NAT itself must be configured with a port-forwarding rule to route all ANSI/CEA-852 packets from the public interface to the CN device in the private realm. Figure 25.9 illustrates this setup. NAT1 contains a port-forwarding rule to route all packets it receives at IP address 80.41.6.3 on ports 1628 and 1629 to the private IP address 192.168.1.250 on the respective ports.

The drawback of this solution is that only one CN device per IP channel can be operated behind a NAT. If two or more devices would be operated behind the same NAT router, CN devices would need additional information to decide whether the public or private address combination should be used. To overcome this problem, modern devices implement the *extended NAT mode*. This mode uses an extended header format, which contains both private and public addresses of the sender. This makes it possible for senders and receivers to choose the correct address realm. The CS as the central instance for channel formation must be configured with NAT router addresses and private addresses. Since this mode uses an extended header, which is not part of the ANSI/CEA-852 standard, devices that do not support this mode will not be able to join the IP channel. Figure 25.10 shows a possible solution where one IP channel is established over the public realm having two CN devices behind the NAT router 135.23.2.1.

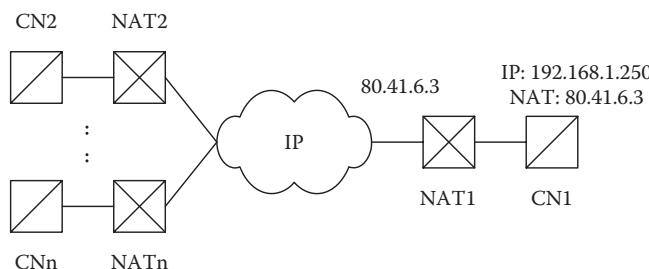

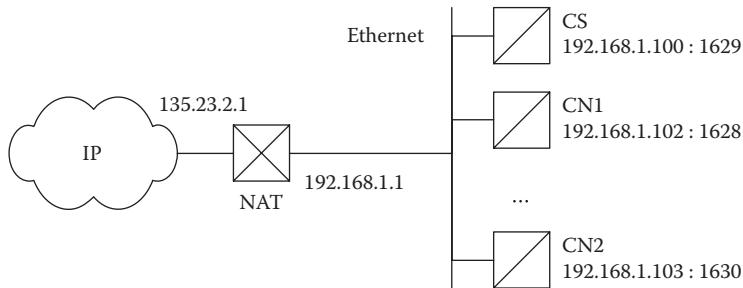

FIGURE 25.9 Simple NAT configuration.

**FIGURE 25.10** Complex NAT configuration.

**TABLE 25.3** ANSI/CEA-852 Extended NAT Table

Device Name	Local Address	NAT Address
CS	192.168.1.100:1629	135.23.2.1:1629
CN1	192.168.1.100:1628	135.23.2.1:1628
CN2	192.168.1.100:1630	135.23.2.1:1630

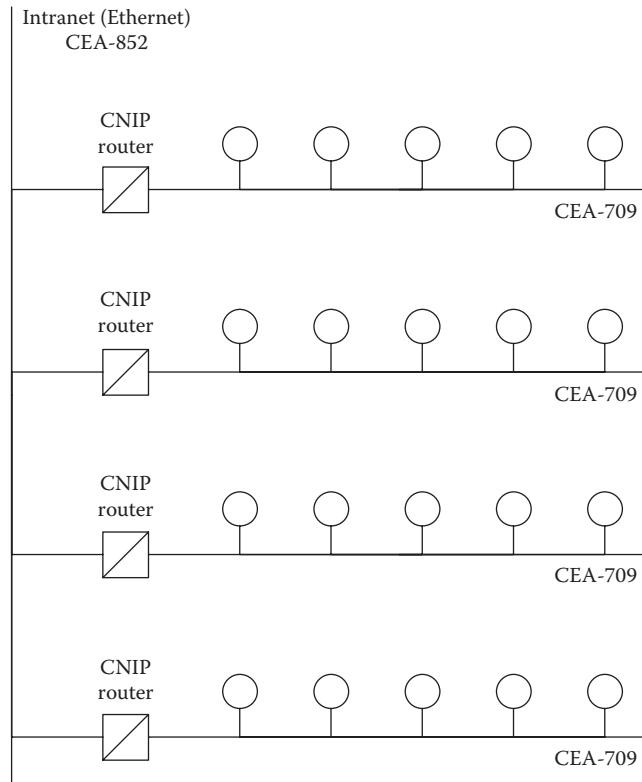

Complex NAT configurations require a careful and handcrafted configuration on the NAT routers to make port-forwardings work correctly. Each device needs a separate port-forwarding rule in the NAT router. This implies that each device must use a unique client port (e.g., 1628, 1629, and 1630). The port-forwarding rules must be set up so that each port points to one of the ANSI/CEA-852 devices. In the example shown in Figure 25.10, the CS is located at the private address 192.168.1.100. If the CS is located behind a NAT router, the NAT router must have a fixed public IP address. Table 25.3 shows the extended NAT configuration in the CS. For each device, a local and NAT address needs to be specified in order to form the IP channel.

A modern alternative to direct NAT configuration is embedding the IP channel into a virtual private network (VPN). VPNs are standard IT technology and overcome complex NAT configurations. In addition, strong VPN security such as encryption is added to the IP channel communication. However, a VPN solution requires special VPN routers and is not an end-to-end solution. Using a VPN over the Internet is, however, the most secure method available today.

## 25.7 Applications

So far, we have learned what the new IP tunneling technology following the ANSI/ANSI/CEA-852 standard can do in theory. Here we show the application scenarios that utilize this new technology. We have seen that it is possible to connect CNs via intranets, and this is exactly what is starting to emerge in larger buildings. Typically, office buildings do have a sophisticated IP infrastructure; therefore, it is beneficial to utilize this IP infrastructure for services other than PC networking. As shown in Figure 25.11, CN to IP routers like the L-IP from LOYTEC can utilize the existing IP infrastructure to form a high-speed backbone network in order to connect the CNs on different floors. This setup allows transparent communication between offices on different floors and to a central SCADA system using the IP backbone.

Another steadily growing application area is internetworking between different buildings that are either connected via an intranet or the Internet. Once the building infrastructure is *online*, it is only a small step to remote facility management and remote maintenance. Figure 25.12 shows a typical scenario how building complexes are networked to form one large CN. A management PC connected anywhere to the network allows remote network maintenance, remote trending, alarming, logging, and preventive system repairs.

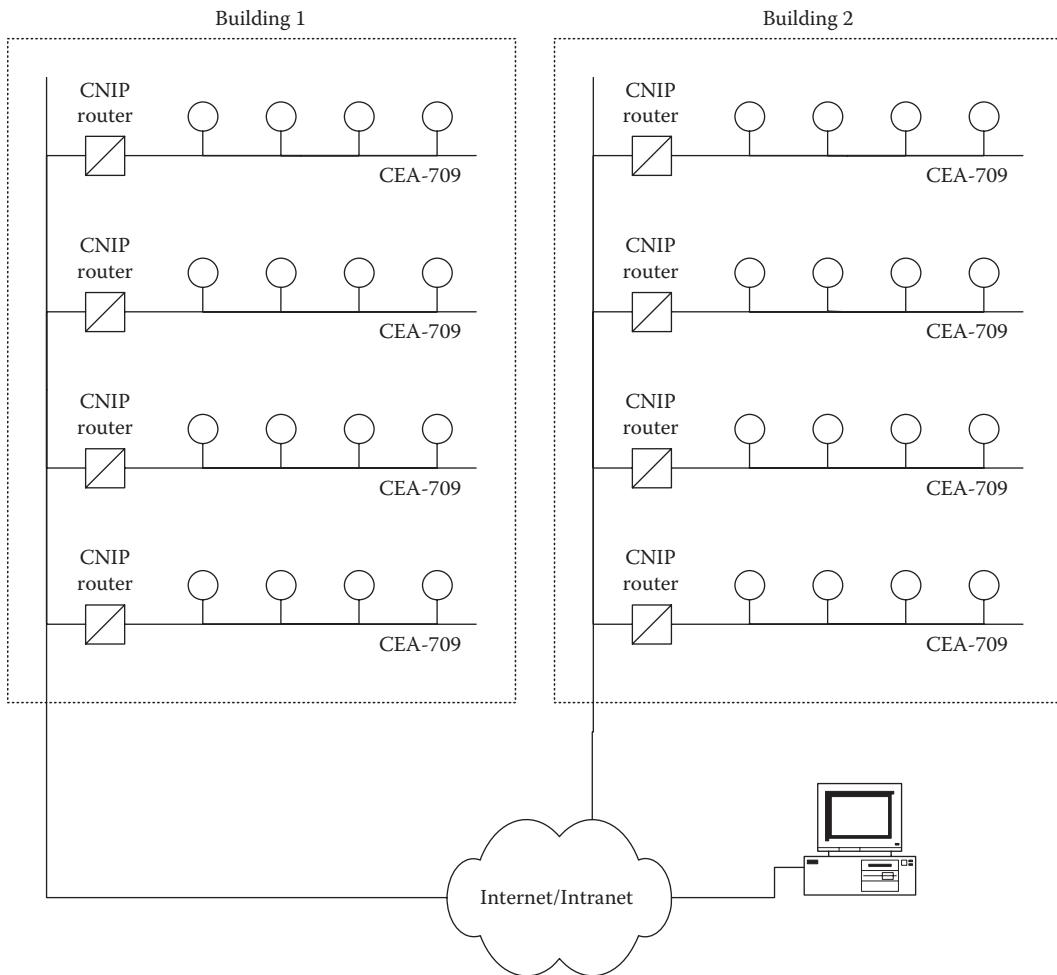

**FIGURE 25.11** The IP channel can utilize the existing IP infrastructure in a building to connect several control networks to a large building automation network.

Another advantage, which was initially not quite obvious, is the fact that network management tools and network-troubleshooting tools can be used together with the new IP technology. This means that thousands of installers and system integrators that have been trained over the past 10 years will use this knowledge with a little bit of additional training to install networks that span intranets and the Internet.

Once the CN is able to use the IP service as a transport media, modern wireless technologies can be utilized to create new application areas. One can, for example, walk around a building with a smart-phone or tablet and control the building infrastructure such as lighting, heating, AC, blinds, and even carry out network maintenance tasks on the spot by himself or herself. It is now possible to monitor and control remote wastewater pump stations that are connected to the control center via an RF link.

## 25.8 Conclusion

The world is getting more and more connected, and one of the driving factors is the IP. Connecting PCs to the Internet was the hype of the 1990s; connecting everyday devices to the Internet is the challenge of the new millennium. Modern building automation systems are built on IP-based backbone technologies. With ANSI/CEA-852, this technology is the base of most LonMark systems. NAT support has enabled cross-building automation networks and access ports for remote facility management. Modern installations frequently embed their ANSI/CEA-852 channels in a VPN, which is a widely accepted IT standard today. This method eliminates cumbersome NAT router configuration and provides the enhanced security mechanisms missing in ANSI/CEA-852 such as strong encryption.

**FIGURE 25.12** Connecting different buildings over an intranet or the Internet allows transparent communication of control network data between nodes on either network.

The incompatibility of the enhanced version CEA-852.1 has until now prohibited wide acceptance. Most features such as better authentication and more flexible channel management are currently offset by using VPNs. This is also the only solution to use IPv6 until the enhanced version CEA-852.1 is revised to be natively compatible with IPv6.

### 26.1 Introduction

---

In recent years, an increasing demand for highly automated, process-oriented, and distributed systems consisting of a large number of interconnected heterogeneous hardware and software components is noticeable. These systems—usually composed of components from different manufacturers—require a high interoperability across heterogeneous physical media, platforms, programming languages, and application domains facing several problems:

- Proprietary interfaces. Components have mostly proprietary interfaces weakening compatibility, and developers must know them in order to use such components.
- Limitations in the awareness. Component users are often not aware of other component's functionality.
- Limited discovery capabilities. Component users do not know how to search for a component with certain functionality nor do they know which components are available in a certain scope.
- Proprietary methods for interactions. The interaction mechanisms between components are mostly bound to their application and application domain. The formats for exchanging message as well as the used data formats are mostly proprietary.
- Constrained composition capabilities. Processes/workflows describing the interaction between components are designed for specific applications and domains and seldom applicable for other components and applications.

Hardware components have additional requirements in comparison to software components. Among them are

- Location awareness. In contrast to software components, the location of hardware components is usually important for their application. Offered functionality is often bound to a specific location. For example, the location of a printer is important to its users as it has to be in reachable distance. Therefore, also the printing functionality is bound to the location of the printer, whereas software components can be made available anywhere and where their functionality is required.
- Mobility support. Furthermore, mobile devices can roam between networks possibly resulting in changing addresses of the network protocols.
- Statefulness. From the outside-in view, a software component can be designed in a stateless way by starting a new instance with default values when the component is invoked. Device components mostly have a state that has to be taken care of. For example, a printing device being invoked while printing has to queue the printing job.

These problems are solved for certain proprietary applications and in mostly homogeneous environments, but a solution applicable to a large heterogeneous system is still missing.

The service-oriented architecture (SOA) approach addresses these problems and represents the next step in the endeavor of component-based development and reusability.

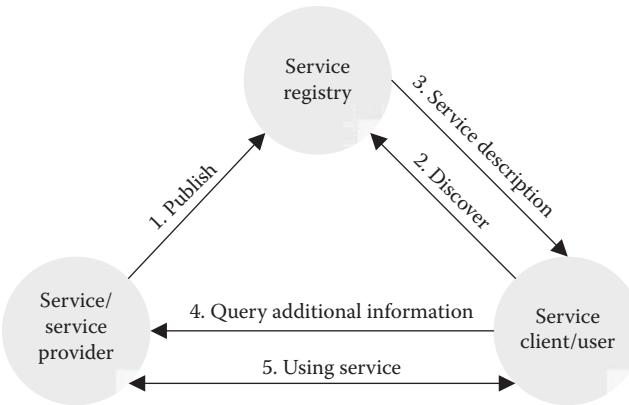

SOA [1] is a design paradigm for the interaction between heterogeneous components supporting autonomy and interoperability. The underlying philosophy is that every component offers certain functions that might interest other components or users. SOA provides an outside-in view (orientation) on the functionality of components—whose self-described interfaces to their functionality are called services—rather than deriving the interface from the implementation. This enables developers to build *architectures* from heterogeneous components depending on the needs of their applications.

The SOA paradigm is based on the following foundation and principles: service orientation is based on open *standards* ensuring interoperability. Although *security* is not an attribute of SOA, it is important to foster acceptance. SOA is based on *simplicity* in the sense of flexibility, reusability, and adaptability in the usage of services and the integration of services into heterogeneous service environments. The attribute *distribution* stands for the independence of services, which self-contain their functionality. New applications can be built by designing the interaction of services and the definition of policies (if needed) to formulate interaction constraints. Services are *loosely coupled*, allowing dynamic searching for finding and binding of services. Services are clearly abstracted from their implementation and application environment. The *registry* is a central repository for all available services in a certain environment. SOA implementations without a registry make use of other advanced search mechanisms. *Process orientation* in SOA shows a major advantage of SOAs and moves the technology closer to its application. Processes and workflows can be designed and mapped into an interaction of services by composing the corresponding services.

An SOA defines three roles: service provider, client/user, and optionally a registry. The *service provider* is generally known as *service* and offers its functionality via a service (interface) to the SOA. *Service clients/users* make use of the functionality offered by a service provider. A *service registry* is used by service providers to register themselves and by service clients/users to search for a specific service and to obtain information required to establish a connection to the service provider.

In this chapter, a service provider is simply called service, and a service client/user is called service client or just client, if ambiguity is impossible.

Every service owns a description of its properties and capabilities, which has to be described by the service developer. The format of the description is standardized and has to be machine readable (usually character based in an eXtensible Markup Language [XML] format) and contains all information needed to interact with a service.

**FIGURE 26.1** Roles in an SOA.

A classical SOA implementation involves five stages of service usage as shown in Figure 26.1 [2]:

- Stage 1. The service registers a limited description of itself including its general capabilities at the service registry (*publishing*). If no service registry is available, the service announces itself to the network by sending its description including basic capabilities (*announcement*). The limited description fosters scalability by reducing network load as service clients are normally interested only in specific functions of a service and not in all provided functionalities. Further description details are requested in a later step.
- Stage 2. The service client sends a description of the desired service to the service registry (*discovery*). In SOAs without a service registry, the discovery message will be sent to the network, or the service client listens for service announcements.
- Stage 3. The service registry answers either with a failure response or by sending all service descriptions matching the discovery request (*discovery response*). The service description also includes the network address of the matching service/service provider. In the absence of a service registry, the corresponding service providers will answer directly.
- Stage 4. In the next step, service clients will request a detailed description of the capabilities from the matching services to select the most reasonable one (*description query*).
- Stage 5. The last step is the usage of the service according to the rules defined between service provider and client (*service usage*). These rules are described in the detailed description of the service provider. If a service provider leaves the network, it should announce its intentions by sending a bye message to the registry and clients, respectively.

## 26.2 Device-Centric SOAs

There are several implementations following the SOA paradigm. The subsequent paragraphs briefly introduce the implementations being relevant in the context of this chapter.

### 26.2.1 SOA Implementations for Devices

The Open Service Gateway Initiative (OSGi) specification defines a service platform that serves as a common architecture for service providers, service developers, and software equipment vendors who want to deploy, develop, and manage services [3]. The specification is based on the Java platform and promotes application independence. Thereby, it is enabling the easy integration of existing technologies. Deployed services are called bundles and are plugged into the framework. An OSGi service is a simple Java interface, but the semantics of a service are not clearly specified. The main drawback of OSGi is its reliance on Java.

The Java Intelligent Network Infrastructure (Jini) was developed by Sun Microsystems for spontaneous networking of services and resources based on the Java technology [4]. Services/devices are registered and maintained at a centralized meta-service called Lookup Service but carry the code (proxy) needed to use them. This code is dynamically downloaded by clients when they wish to use the service. Each service access has to be performed by using the lookup service. Jini's main drawbacks are its reliance on Java and the need of a centralized service registry.

Universal Plug-and-Play (UPnP) is a simple, easy-to-use SOA for small networks [5]. It supports ad hoc networking of devices and interaction of services by defining their announcement, discovery, and usage. Programming languages and transmission media are not assumed. Only protocols and interfaces are specified instead. The UPnP specification divides the device life cycle into six phases: Addressing, Discovery, Description (specifying automatic integration of devices and services), Control (operating a remote service/device), Eventing (subscribing to state changes of a remote service/device), and Presentation (URL representation of a service/device specifying its usage). UPnP also specifies a usage profile for distributed audio/video application—the UPnP AV architecture [6]. UPnP supports smaller networks only. With an increasing amount of services/devices, the amount of broadcast messages grows exponentially in a UPnP network. Furthermore, UPnP supports IPv4 only.

Web services (WSs) can be considered as the SOA with the highest market penetration. The WS architecture provides a set of modular protocol building blocks that can be composed in varying ways (called profiles) to meet requirements on the interaction of heterogeneous software components such as interoperability, self-description, and security [7]. *Profiles* define the subset of protocols used for implementing a specific application, required adaptations of the protocols, and the way they should be used in order to achieve interoperability. WSs address networks of any size and provide a set of specifications for service discovery, service description, security, policy, and others. The implementation is entirely hidden from their interfaces and may be exchanged at runtime. WSs use widely accepted standards such as XML and Simple Object Access Protocol (SOAP) for message exchange. For a better adaptation of WSs for embedded environments, Devices Profile for Web Service (DPWS) was developed.

DPWS version 1.0 was announced in August 2004 and revised in May 2005 and February 2006 by a consortium led by Microsoft Corporation [8]. In 2010, DPWS became an Organization for the Advancement of Structured Information Standards (OASIS) standard with version 1.1 [9]. It is a profile identifying a core set of WS protocols that enables dynamic discovery of, and event capabilities for, WSs. The profile arranges several WS specifications such as WS-Addressing, WS-Discovery, WS-Metadata Exchange, and WS-Eventing for devices, particularly. In contrast to UPnP, it supports discovery and interoperability of WSs beyond local networks. Temporarily, DPWSs were considered to be the successor of UPnP and thus subtitled with *A Proposal for UPnP 2.0 Device Architecture* in one of its earlier versions. However, DPWS is not compatible to UPnP, and therefore, it presents an SOA implementation on its own. DPWS debuted in the Microsoft Operating Systems Windows Vista and Windows CE.

It is important to note that the concepts behind two SOA implementations might be entirely different. SOAs are just a paradigm of how future systems could look like and what requirements they should address. The SOA paradigm does neither define design specifications of such system nor address implementation aspects.

### 26.2.2 Evaluation of Device-Centric SOAs

Table 26.1 is based on previous published research work by Bohn et al. [10] and shows an excerpt of the evaluation results of mentioned SOA implementations with regard to the problems identified in the introduction of this chapter. Although the SOA paradigm theoretically addresses all problems, the individual SOA implementations differ in their support for devices' integration, integration of security concepts, and standards for service composition, plug and play capability, programming language and network media independence, and scalability as shown in Table 26.1.

**TABLE 26.1** Evaluation of Service-Oriented Middleware

	OSGi	JINI	UPnP	WS	DPWS
Common interfaces and awareness	✓	✓	✓	✓	✓
Discovery and standardized interaction	✓	✓	✓	✓	✓
Evolved composition standards				✓	
Support for hardware components	✓	✓	✓		✓
Plug and play capability		✓	✓		✓
Programming language independence			✓	✓	✓
Network media independence		✓	✓	✓	✓
Large scalability	✓	✓		✓	✓
Security concepts	✓	✓		✓	✓

Common interfaces and awareness indicated the capability of the standards to provide a common view on their components based on their functionality (called services). A requirement is self-describing interfaces in order that other components are aware of the service's functionality (*awareness*). Furthermore, a *standardized interaction* between clients and services must be ensured including defined protocol, message exchange patterns (MEPs), and data type specification. The capability of searching for certain functionality and the automatic announcement of new services (*discovery capability*) fosters automation in networked environments and applications. Networks of components reveal their full potential if standards that enable designers and nontechnical personnel to design complex applications by simply composing involved components/services (*evolved composition standards*) exist. Although niche solutions exist for other SOAs, only WSs offer a sophisticated set of standards for service composition. The support for hardware components involves addressing their specific requirements such as mobility, location awareness, and publish/subscribe mechanism. OSGi, Jini, UPnP, and DPWS support that in some way. *Plug and Play capabilities* refer to a network that is not dependent on a central service registry. Services and devices announce the entering and leaving of networks, and thereby, clients are informed of their functionality. This is provided by Jini, UPnP, and DPWS. Only UPnP, WS, and DPWS are *programming language independent*, which means clients and services can be developed in any kind of language and executed on any kind of execution environment. *Network media independence* corresponds to message exchanges over any kind of transport protocol. OSGi is somehow out of scope in that way as messages are exchanged over Java. Very complex applications require a *large scalability* supporting a large number of involved services. Furthermore, secure message exchanges based on standardized *security concepts* are often required for such applications. As UPnP mainly focuses on audio/video applications in small home networks, it is not highly scalable and has no security concepts defined yet.

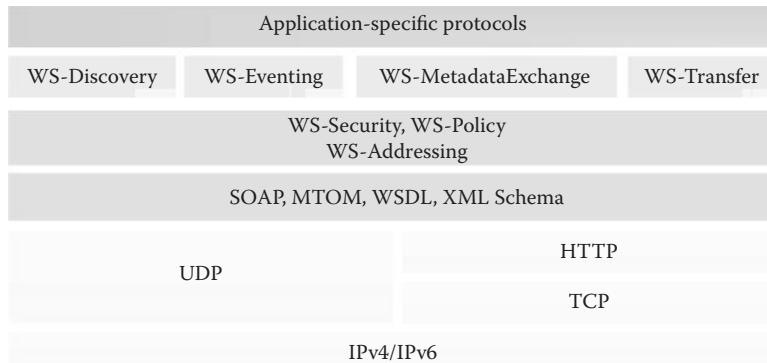

It is apparent that the DPWS is most appropriate to solve the problems stated at the beginning of the introduction. DPWS offers extensive features to support the interoperability between different devices/services. DPWS-compliant components are able to interact with each other forming a highly distributed application. However, each client and service has to be programmed manually. This may result in a huge effort for complex and dynamic applications. Process management capabilities as provided by basic WSs would leverage the easy integration of DPWS clients and services.

## 26.3 DPWS Inside Out

The DPWS was first announced in 2004 as a possible successor of UPnP, revised in May 2005, February 2006, and July 2009 [9]. It is a WS profile identifying a core set of WS protocols and profile-specific adaptations that enable secure WS messaging, dynamic discovery of, and event capabilities for resource-constrained devices and their services.

Figure 26.2 shows an overview of the WS protocols for DPWS.

Before going into detail, relevant XML basic technologies are briefly introduced.

**FIGURE 26.2** The Devices Profile for WSs protocol stack.

### 26.3.1 Interactions between Client, Device, and Service

Three participants are involved in a DPWS interaction: client, device, and the services residing on a device. A DPWS device is also designed as a service called *hosting service*. The hosting service contains information about itself (e.g., manufacturer and model name) and references to its *hosted services*.

Optionally, a DPWS may utilize a central service registry (called *Discovery Proxy* [DP]), which could also be used for device/service discovery spanning several networks.

In order to increase scalability and reduce the network traffic, the invocation of hosted services on devices involve several phases: discovering desired devices/hosting services, obtaining a detailed description about replying device/hosting services and references to the services they host, retrieving further information on the desired hosted services, and finally invoking the desired service. If the client knows the references to desired services already, it may contact them directly. Additionally, DPWS defines constraints on the vertical issues messaging and security mechanisms that are offered for messaging.

The sequence diagram in Figure 26.3 [11] illustrates the phases showing the activities involved in a typical message exchange using DPWS. Details on participating protocols are provided at a later stage.

Message 1: A Probe message is sent from the client using UDP multicast to search for a specific device as described in WS-Discovery. The Probe message indicates if the client requests security. If a DP is available, multicast suppression is used as specified in WS-Discovery. Clients send their Probe messages directly to the DP (UDP unicast).

Message 2: All devices listen for Probe messages. In case the desired service matches one of its hosted services, the device responds with a ProbeMatch message using unicast UDP. The ProbeMatch message contains the device's endpoint reference (EPR), supported transport protocols, and security requirements and capabilities. EPRs are XML structures including a destination address (destination WS is called endpoint) and optional metadata describing the service (e.g., usage requirements) as defined by WS-Addressing. If security is desired, the client sets up a security channel in an additional message.

Messages 3 and 4: In case the EPR does not include a physical address, the client can use a Resolve message to retrieve it from the device. The device uses a ResolveMatch message for it.

Message 5: The client can directly request more information about the device using a GetMetadata message as it is defined in the WS-MetadataExchange (WS-MEX) specification.

Message 6: The desired device will respond either with included metadata or by providing a reference to the metadata. The metadata includes device details and EPR to each hosted service.

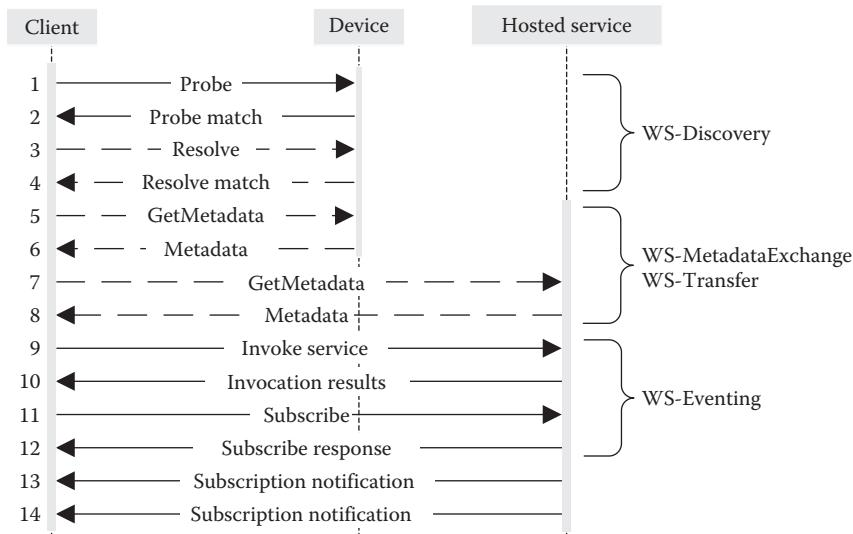

FIGURE 26.3 Typical message exchange using DPWS.

Message 7: Similar to message 3, the client requests more information about the desired hosted service.

Message 8: The desired hosted service sends its metadata to the client including its Web Service Description Language (WSDL) description.

Messages 9 and 10: Hosted services are invoked by receiving an invocation message from the client according to corresponding operation described in the WSDL. The implementation of the invocation of services is not specified in DPWS and left up to the service provider.

Message 11: A client may send a `Subscribe` message to the hosted service to get informed about updates of or the overall status of a service. The publish/subscribe pattern used in DPWS is described by WS-Eventing as well as specifications of subscription renewal and cancellation.

Message 12: The hosted service responds with a `SubscribeResponse` message including a subscription identifier and an expiration time.

Messages 13 and 14: The hosted service sends `Notification` messages to the client whenever a specific event occurs.

This chapter will simply refer to a hosting service as device and to a hosted service as service for easier readability.

### 26.3.2 Messaging

DPWS makes use of SOAP 1.2, SOAP-over-UDP, HTTP/1.1, WS-Addressing, the URI, and MTOM specifications. These specifications are restricted in such a way that they address the requirements of resource-constraint device implementations by ensuring high WS interoperability.

#### 26.3.2.1 SOAP

SOAP was originally an abbreviation for *Simple Object Access Protocol*, but since version 1.2, it is simply called SOAP [12]. SOAP is a protocol promoting interoperability by specifying an XML-based format for exchanging messages between different applications. SOAP messages consist of a header and a body enclosed by a *SOAP envelope*. The *SOAP header* contains metadata related to delivery and processing of

message content. The payload of the message is inserted into the *SOAP body*. The actual content of headers and bodies is not defined by SOAP. This is specified by the particular WS-\* protocols.

Since SOAP is independent of the underlying transport protocols, the *SOAP Protocol Binding Framework* describes the binding to transport protocols. Two bindings are officially documented by the W3C: *SOAP Email Binding* and *SOAP HTTP Binding*. The latter is the binding mostly used for historical reasons.

SOAP-over-HTTP/HTTPS has the disadvantages that address information is stored in the HTTP header and only synchronous messaging is supported. Recent trends try to attach SOAP to other binding protocols than HTTP. One approach is *SOAP-over-UDP*, which is also used by DPWS and reduces the network load when no acknowledgment is required (e.g., for WS-Discovery). Unicast as well as multicast transmissions are supported. The SOAP-over-UDP also provides a retransmission algorithm considering the delayed repetition of the same message. Another suggested binding uses Constrained Application Protocol (CoAP) as transport protocol [13]. SOAP-over-CoAP binding utilizes UDP as well; however, since CoAP is based on HTTP, it provides HTTP-like features such as management headers and transport reliability. Contrary to HTTP, CoAP is a binary-encoded protocol, which significantly reduces transport overhead.

### 26.3.2.2 SOAP Message Transmission Optimization Feature

The conventional way of conveying binary data in SOAP as well as other XML documents is to transform the data into a character-based representation using the *Base64 content-transfer-encoding scheme* as defined by Multipurpose Internet Mail Extensions. Unfortunately, this produces a message overhead of about 33% for large attachments and a possible processing overhead [14].

The *SOAP Message Transmission Optimization Mechanism* (MTOM) defines an *Abstract SOAP Transmission Optimization Feature*, which is encoding parts of the SOAP message while keeping the envelope intact (e.g., SOAP headers). The optimization feature works only if the sender knows or can determine the type of information of the binary element. Conveying binary data using SOAP-over-HTTP is one implementation of the Abstract SOAP Transmission Optimization Feature. This solution is based on *XML-binary Optimized Packaging* conventions, where the binary data are sent as an attachment.

MTOM does not address the general problem of including non-XML content in XML messages.

### 26.3.2.3 WS-Addressing

The *pure* SOAP has a strong binding to HTTP for historical reasons although meant to be transport protocol independent. This results in the disadvantage that the address of targeted services can only be found in the HTTP header and only synchronous messaging is supported. Message routing depends on HTTP, and publish/subscribe patterns are not supported. WS-Addressing remedies these deficiencies by specifying mechanisms to address WS and messages in a transport-neutral way [15]. SOAP messages can be sent over multiple hops and heterogeneous transport protocols in a consistent manner. Furthermore, it allows sending responses to a third party (WS or WS client). WS-Addressing introduces the concepts of EPRs and message information (MI) header, which are included into the SOAP header.

EPRs release SOAP from the strong binding to HTTP. They are XML structures addressing a message to a WS (destination WS is called *endpoint* including destination address, routing parameters for intermediary nodes, and optional metadata describing the service (e.g., WSDL description for a WS or policies).

MI headers enable asynchronous messaging as well as dispatch possible responses to other endpoints than the source. The mentioned *dispatching of the responses* is realized explicitly defined by assigning specific addresses to source, reply, and fault endpoints, or implicitly by leaving these entries unassigned (responses are sent back to the source). The *asynchronous messaging* is realized by the use of an optional unique message ID. Result messages can be referenced to it. The destination address as well as an *action* URI that identifies the semantics of a message (e.g., fault, subscription, or subscription response message)

is mandatory. WS-Addressing defines explicit as well as implicit associations of an action with input, output, and faults elements. Explicit associations are defined in the description of a WS. Implicit association of an action is composed of other message-related information. The optional definitions of relationships in MI headers indicate the nature of the relation to another message (e.g., indication of a response to specific message). It can also be indicated that the message relates to an *unspecified message*.

In case that an endpoint does not have a stable URI, the endpoint can use an *anonymous* URI. Such request must use some other mechanism for delivering replies or faults.

WS-Addressing can also be used to support request-response and solicit-response MEP using SOAP-over-UDP.

#### 26.3.2.4 Adaptations to DPWS

DPWS requires services to meet the *packet length limits* defined in the underlying IP protocol stack. A service retrieving messages exceeding that limit might not be able to process or reject them, which may result in incompatibilities. A hosted service must at least support *SOAP-HTTP-binding* in order to ensure highest possible interoperability as most applications use it. Furthermore, hosted services have to support the flexible HTTP chunked transfer coding. HTTP chunked transfer coding is used to transfer large content of unknown size in chunks. The end of the transmission is indicated by a zero-size chunk. Regarding the MEP, basic WS functionality is achieved by supporting the MEP request-response and one-way (at least).

As devices can also be mobile and roaming across networks, a globally unique UUID (universally unique identifier) for the address property of the EPR is required, which is persistent beyond reinitialization or changes of the device. Hosted services should use an HTTP transport address as the address property in their EPRs. Furthermore, hosted services must assign a reply action to the relationship field in the MI for response or fault messages.

Hosted services must also generate a failure on HTTP Request Message SOAP Envelopes not containing an anonymous reply EPR. This means that DPWS does not support the deferring of reply and fault messages to other endpoints (being different from the sending endpoint). The WS-Addressing 1.0 SOAP Binding specification defines for HTTP Request Message SOAP Envelopes containing an anonymous reply EPR address that their responses must be sent back to the requester in the same HTTP session. This means that DPWS only supports synchronous message exchanges for client–service interactions. The reason for that is the reduced size for the WS implementation for DPWS devices/services and clients. Especially, WS clients cut down on size as they do have to provide a callback interface.

In summary, only the concept of WS-Addressing EPRs and action URIs are used by DPWS. Asynchronous client–service interactions are not supported by DPWS.

A hosted service may support MTOM in order to be able to receive or transmit messages exceeding this packet length limits.

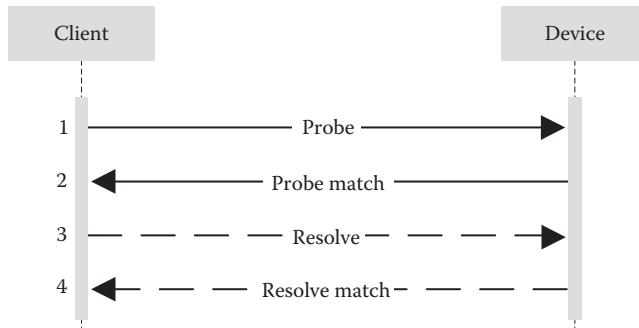

#### 26.3.3 Discovery

DPWS uses WS-Discovery for discovering devices. As illustrated in Figure 26.3, WS-Discovery is not used to search for specific hosted services. Instead, desired services are found by searching for devices and browsing the descriptions of their hosted services.

##### 26.3.3.1 Web Services Dynamic Discovery

WS based on the WS architecture can be used only if their addresses are known to WS clients or if they had registered to a *Universal Description, Discovery and Integration* (UDDI) server. UDDI is a central registry that can be queried for a desired service. The address of a UDDI server can also not be discovered and has to be known to interested WS clients.

The *Web Services Dynamic Discovery* (WS-Discovery) [16] extends the WS discovery mechanisms by concepts for the announcement of services when entering a network, dynamic discovery, and network

**FIGURE 26.4** Interactions in the discovery process defined by WS-Discovery.

spanning discovery of services. It introduces three types of endpoints: Target Service, Client, and DP. Clients are searching for Target Services. DPs enable forwarding of searches to other networks.

The announcement of a service is realized by sending a one-way multicast Hello message whenever a Target Service becomes available. This should be used by Clients for implicit discovery through storing the announcement information and thus reducing the amount of discovery messages in the network. When a Target Service intends to leave a network, it should send a one-way multicast Bye message.

Dynamic discovery is important for endpoints, which might change their transport addresses during lifetime (e.g., mobile WS traversing different subnets). In such cases, Target Services possess a logical address that can be dynamically resolved into their transport address. Dynamic discovery is realized in a two-stage process (as shown in Figure 26.4): Probe and Resolve. When searching for services, Clients must send a Probe message specifying the type of the Target Service and/or its Scope. The specification of the Type and its semantics are left up to the provider. The Scope is a logical group of WSs. The matched Target Services answer to the requester using a unicast ProbeMatch message containing the mandatory EPR. Optionally, the ProbeMatch can also provide a list of the Target Service addresses (avoiding a following resolve), types, and/or scopes. The next step is to resolve the EPR into a list of Target Service addresses by sending a multicast Resolve message containing the EPR. The corresponding Target Service answers with a ResolveMatch message including a list of addresses and optionally a list of types and/or scopes.

WS-Discovery also defines a basic set of matching rules for the resolution of URIs, UUIDs, and case-sensitive string.

Network spanning discovery can be realized using DP by relaying discovery messages to other networks. A DP enables the scaling of a large number of endpoints. When a DP receives a multicast Probe or Resolve message, it announces itself using a Hello message to suppress multicast messaging. Clients send their request via unicast to the DP and ignore Hello and Bye messages from Target Services while the DP is available. Further functionality of the DP is not specified by WS-Discovery.

WS-Discovery uses UDP for messaging. The implementations are mostly bound to SOAP-over-UDP. WS-Addressing is used for the specification of EPRs, action, and fault properties.

### 26.3.3.2 Adaptations to DPWS

Discovery in DPWS only relates to searching for devices/hosting services. As described at the beginning of this section, hosted services can be found by following the references in the descriptions starting from the device/hosting service description.

A device/hosting service must be a Target Service as defined in WS-Discovery. Furthermore, a device/hosting service is required to support unicast as well as multicast-over-UDP (required by WS-Discovery). In case the HTTP address of a device is known, the discovery client may send a Probe message over HTTP (unicast). Due to this, a device must support receiving Probe SOAP envelopes as

HTTP requests and be able to send a ProbeMatch SOAP envelope in an HTTP response or send an HTTP response with an HTTP 202 Accepted.

Devices might not be discoverable if residing in a different subnet than the discovery client. Nevertheless, discovery clients disposed of an EPR and transport address for targeted devices might be able to communicate with the corresponding device. If transport address and EPR of a DP in another subnet are known, this DP can be used to discover devices in that subnet.

Devices must announce the support of DPWS by including the type `wsdp:Device` and may include other types or scopes in Hello, ProbeMatch, or ResolveMatch SOAP envelopes. To be able to match URIs and strings, devices must at least facilitate URI and case-sensitive string comparison defined by the scope matching rules defined by WS-Discovery.

Except for `wsdp:Device`, semantics and classifications of types and scopes are not defined in DPWS. When a device receives a Probe message, it uses some internal mechanism to decide if it responds or not. Devices responding to Probe messages are not required to publish their supported types and scopes. This might complicate the discovery process if no out-of-band information about responding devices is available. In addition, as messages should not exceed the size of a maximum transmission unit, messages being sent via UDP might be too small to convey supported types and scopes. The support of UDP fragmentation is also not required by DPWS. In such a case, another Probe could be sent via HTTP chunked transfer coding as it must be supported. However, this also requires the device to send supported types and scopes in the ProbeMatch.

### 26.3.3.3 Current Research in WS-Discovery

The drawback of the original WS-Discovery standard is the low scalability due to a static application delay—maximum waiting time before sending a response. The rising number of devices leads to an increasing network load and especially to an increasing device processing load as a result of the discovery process, for example, in smart metering or building automation networks. In the worst case, the device can be set out of operation due to buffer overflow or some devices will not be discovered due to packet rejection.

In [17], Altmann et al. provide an approximation formula for the peak data rate estimation of WS-Discovery in Ethernet networks. According to the simulation results, the authors propose optimizations for WS-Discovery to improve its scalability. The proposed approach includes MAC addresses in WS-Discovery requests avoiding large traffic volumes due to the address resolution protocol. Moreover, dynamic adaptation of the application delay in order to reduce the peak data rate on the client is suggested. Furthermore, the suggested additional node aggregation can reduce the data rate independent of the application delay by more than 50%. The optimization of packet repetition allows avoiding the packet interference between original and repeated WS-Discovery responses. For this purpose, the authors propose the division of timing interval into two parts for the first and second responses, respectively. In order to properly set the dynamic values, the knowledge of the network size is required. A new approach for network size discovery is proposed to gain this knowledge. All optimizations allow steady packet processing and significantly relieve the client. The suggested approach can be applied for any network size due to its dynamic nature and consequently provides improved scalability for ad hoc WS-Discovery. The suggested optimization is backward compatible with the standard WS-Discovery specification.

### 26.3.4 Description

DPWS uses WSDL for describing the functionality and capabilities of hosted services. Devices do not possess a WSDL description as they cannot be invoked by WS clients. The capabilities of a device including the references to its hosted services are defined in a metadata description as defined by WS-MEX. WS-Transfer is used to retrieve such metadata descriptions. Furthermore, hosted services can define their usage requirements by using WS-Policy. All protocols are described in the remainder of this subsection.

### 26.3.4.1 Web Service Description Language

The WSDL is an XML document format containing definitions used to describe WS as a set of endpoints and its interactions using messages [18]. An endpoint is the location for accessing a service. A WSDL document (or simply referred to as a WSDL) contains an abstract and a concrete part as shown in Figure 26.5 [2].

#### 26.3.4.1.1 Abstract Part

The abstract part of a WSDL document promotes reusability by describing the functionality of the services independent of its technical details such as underlying transport protocols and message format. Firstly, the *data types* that are needed for message exchange are defined. In order to ensure highest interoperability, WSDL refers to XML Schema Definition as the preferred data type scheme. *Messages* are abstract definitions of data being transmitted from and to a WS. Messages consist of one or more *logical parts*. The *port types* definition can be seen as abstract interfaces to services offered by the WSDL. Port types are a set of abstract operations. An *operation* is a set of messages exchanged by following a certain pattern. WSDL supports the following four MEP: one-way, request-response, solicit-response, and notification. They are implicitly identified in the WSDL by the appearing order of input and output messages. Request-response and solicit-response operations may also define one or more fault messages in case a response cannot be sent.

#### 26.3.4.1.2 Concrete Part

The concrete part encloses the technical details of a WS. The *binding* associates a port type, its operations, and messages to specific protocols and data formats. Several bindings to one port type are possible. All port types defined in the abstract part must be reflected here. Concrete fault messages are not defined because they are provided by the protocols. Furthermore, a *service* definition is a collection of ports. *Ports* are network addresses for service endpoints. Each uniquely identified *port* constitutes an endpoint for a binding.

WSDL specifies and recommends the binding to SOAP but is not restricted to it. The WSDL Binding Extension for SOAP defines four *encoding styles*. The style can be either RPC or document. The use can be either literal or SOAP encoded making it to four styles. Each binding has to specify the encoding style it wants to use when translating XML data of a WSDL into a SOAP document. The differences between the encoding styles are as follows:

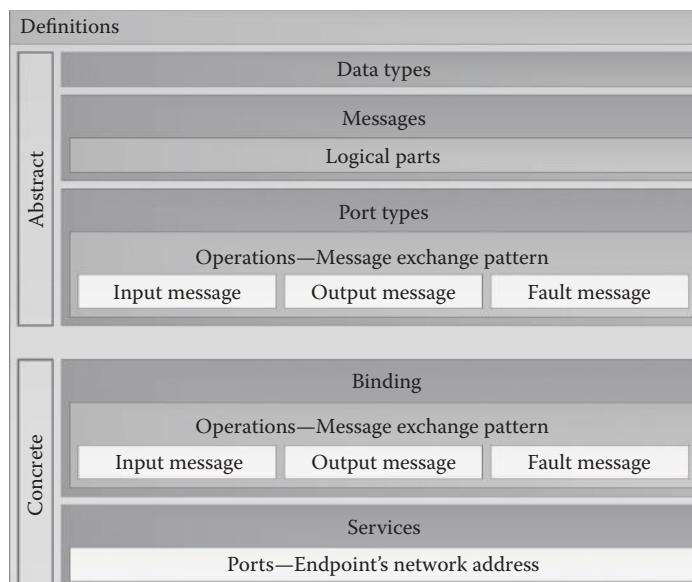

FIGURE 26.5 Major components of a WSDL description.

The *RPC-style* structures the SOAP body into operations embedding a set of parameters (data types and values). Using the *document style*, the SOAP body can be structured in an arbitrary way. The *literal encoding* uses XML Schema to validate the SOAP data. Therefore, the SOAP body must be conforming to specific XML Schema. In contrast, *SOAP encoding* employs a set of rules based on the XML Schema data types to transform the data. A message is not required to comply with a specific schema.

RPC/encoding was the original style but will eventually go away. Document/encoded is rarely supported. Recently, a fifth style was developed—called Document/literal/wrapped, where the parameters are wrapped in an element bearing the operation name. An elaborated comparison of the coding styles can be found in the article by Butek [19]. In most cases, Butek recommends the Document/literal/wrapped encoding style, which is also supported by the .NET framework. The impact of the choice of encoding style on performance, scalability, and reliability of WS interactions is presented in Cohen [20].

#### 26.3.4.2 WS-Policy

WS implementations might rely on certain restrictions although the WS architecture is platform, programming language, and transport protocol independent.

*WS-Policy* [21] provides a framework to define restrictions, requirements, capabilities, and characteristics of partners in WS interactions as a number of policies. As illustrated in Figure 26.6, a *policy* is an assortment of policy alternatives. In order to comply with a certain policy, an interaction partner can select the best suiting policy alternative from the defined set. If a WS or a client makes use of policies, its interaction partners have to comply with those by choosing one of the offered policy alternatives. A *policy alternative* is defined as a collection of policy assertions. A *policy assertion* is an XML Infoset representing a requirement or capability. A policy assertion can also be optional. Policy assertions can be combined to more complex requirements or capabilities using *policy operators*. Two policy operators are defined by WS-Policy. The *ExactlyOne operator* requires the compliance to one of the stated policy assertions, whereas the *All operator* requires the compliance to all. WS-Policy does not specify how policy assertions are expressed. A way to do so is described in the *Web Services Policy Assertions Language* (WS-PolicyAssertions).

WS-Policy does specify neither the location of policy definitions nor their discovery. This is left to other WS protocols such as WS-PolicyAttachment.

#### 26.3.4.3 WS-PolicyAttachment

WS-PolicyAttachment [22] describes general-purpose mechanisms, how associations between policy expressions and the subject to which they apply can be defined (e.g., associations with WSDL port or binding). Two approaches are offered: policy assertion is part of the subject or externally defined and bound to the subject. WS-PolicyAttachment also describes the mechanisms for WSDL and UDDI.

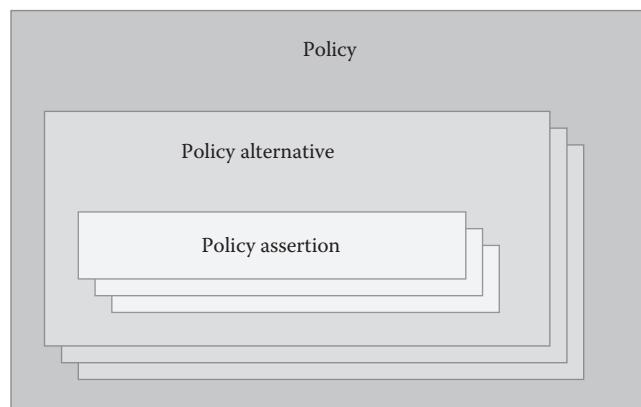

FIGURE 26.6 The structure of a policy as defined by WS-Policy.

These include description of the policy references from WSDL definitions, policy associations with WSDL service instances, and policy associations with UDDI entities.

#### 26.3.4.4 WS-MetadataExchange

The client has received the addresses of targeted services from the device after the discovery process. The next step is to find out more about the Target Services (e.g., their descriptions, requirements, and used data types). This may also be used to find out more about the device itself.

WS-MEX provides a standardized bootstrap mechanism to start the communication with a WS by retrieving the WSDL as well as further information about the WS endpoint such as usage requirements/policies (WS-Policy) and data types (XML Schema) in a well-defined encapsulation format [23]. It defines two request-response operations:

`GetMetadata` is used to retrieve all metadata the WS endpoint provides. It is recommended for a large amount of metadata to provide EPRs (*Metadata references*) or URL (*Metadata Location*) instead of including all metadata in detail in the response. This ensures scalability for service consumers interested only in specific metadata and possibly reduces the network traffic.

`Get` is used to retrieve metadata addressed by a reference. The `Get` operation must be *safe* meaning that the state of requested service must remain unchanged by this operation. It may include a *dialect* characterizing the type of metadata (e.g., metadata defined by WS-Policy), its format, and version. If `Get` is used without a defined dialect and reference for specific metadata, all metadata must be sent in the response.

The default binding of MEX is SOAP 1.1 over HTTP as constrained by the BasicProfile 1.0.

#### 26.3.4.5 WS-Transfer

WS-MEX provides operations to retrieve (metadata) representations of WSs. The resources represented by the WS remain unaffected by that operation. Operations on the WS resources must be defined in a proprietary way and agreed on by both WS interaction partners.

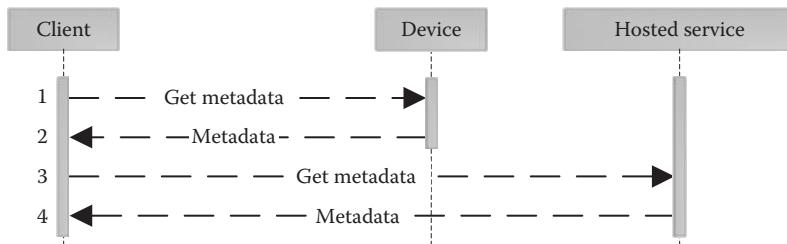

WS-Transfer [24] defines a standardized mechanism supporting *Create, Read, Update, and Delete* (CRUD) operations (called Create, Get, Put, and Delete) on WS resources. A resource is specified as an entity providing an XML representation and being addressable by an EPR. Get, Put, and Delete are operations on resources, while the Create operation is performed by resource factories. The WSs capable of creating new resources are called *resource factories*. WSs implementing a resource must provide the Get operation and may provide Put and Delete operations.

The *Get-operation* is used to retrieve a representation of a resource. A *Put-operation* request allows replacing the representation of a resource by the one sent in the request. If a WS accepts a *Delete-operation*, the corresponding resource must be deleted. The *Create-operation*, as the name suggests, is a request to create a new resource according to the representation in the request.

WS-Transfer is a transport-independent implementation similar to the *Representational State Transfer* approach. The persistence of CRUD operations is not guaranteed because the hosting server is responsible for the state maintenance of a resource.

#### 26.3.4.6 Adaptations to DPWS

The metadata of devices and hosted services are described in a structure conform to WS-MEX. Metadata are considered as static details. Changes to the metadata must include the incrementation of their versions (`wsd:MetadataVersion`) reflected in `Hello`, `ProbeMatch`, and `ResolveMatch` SOAP envelopes sent by corresponding devices and hosted services. The `Get` operation of WS-Transfer is used for retrieving metadata in DPWS. Additionally, other means of retrieval can also be used. Only hosted services possess a WSDL description to foster interoperability with other WSs architectures. It is embedded into the metadata of hosted services.

**FIGURE 26.7** The metadata exchanges of DPWS.

Figure 26.7 shows the metadata exchanges between client, device, and hosted services. As illustrated by the dashed lines, the metadata exchanges are optional because clients might already be aware of the metadata of devices and hosted service. In such case, the clients may use the hosted services directly as defined in their WSDL descriptions. All metadata must be sent in one wsx:Metadata element in the SOAP Envelope Body.

#### 26.3.4.6.1 Description of Devices

The description of a device contains generic characteristics of the device including EPRs to the hosted services. The GetResponse SOAP envelope only includes a wsx:Metadata element that contains all metadata for the device. The metadata of a device has the following structure: device class metadata (*ThisModel*), metadata for the specific device (*ThisDevice*), and metadata for the hosted services (*Relationship*). WS-MEX dialect must be from <http://schemas.xmlsoap.org/ws/2006/02/devprof> for DPWS 1.0 or <http://docs.oasis-open.org/ws-dd/ns/dpws/2009/01> for DPWS 1.1. In the following, only DPWS 1.1 is considered.

*ThisModel* describes the device class metadata containing information about the manufacturer, model name, and optionally manufacturer URL, model number, model URL as well as a presentation URL (a reference to further information). *ThisModel* is described by the metadata section <dpws:*ThisModel* ...>, in which the WS-MEX dialect must be equal to <http://docs.oasis-open.org/ws-dd/ns/dpws/2009/01/ThisModel>.

*ThisDevice* defines the specifics of a certain device of the class *ThisModel*. It is described by the metadata section <dpws:*ThisDevice*...> containing a user-friendly name and optionally the version of firmware and serial number. The WS-MEX dialect must be equal to <http://docs.oasis-open.org/ws-dd/ns/dpws/2009/01/ThisDevice>.

#### 26.3.4.6.2 Relationship

The WS-MEX dialect of this metadata section must be equal to <http://docs.oasis-open.org/ws-dd/ns/dpws/2009/01/Relationship>. The *Relationship* definition identifies the nature and content of the relationship between device/hosting service and hosted services indicated by the type <http://docs.oasis-open.org/ws-dd/ns/dpws/2009/01/host>. It includes optional information about the host and the hosted services. The *host section* (<dpws:*Host*>) contains the EPR of the host, types implemented by the host, and a service ID for the device. The *hosted section* includes the EPR of a hosted service. Therefore, the relationship metadata includes a separate hosted section for each hosted service of the device.

Figure 26.8 presents an excerpt of the SOAP Response message envelope containing the metadata description for a device [8]. The SOAP header elements are specified by WS-Addressing (using the prefix *wsa*). The action (*wsa:Action*) identifies the semantics of the SOAP message—a response message to a Get operation of WS-Transfer. The unique message ID (*wsa:RelatesTo*) relates this response to a certain request message. Furthermore, the message is sent to the address (*wsa:To*) anonymous as defined by DPWS for reply messages. As already described in the messaging subsection,

```

<soap:Envelope ...>
  <soap:Header>
    <wsa:Action>http://schemas.xmlsoap.org/ws/2004/09/transfer/GetResponse</wsa:Action>
    <wsa:RelatesTo>urn:uuid:82204a83-52f6-475c-9708-174fa27659ec</wsa:RelatesTo>
    <wsa:To>http://schemas.xmlsoap.org/ws/2004/08/addressing/role/anonymous</wsa:To>
  </soap:Header>

  <soap:Body>
    <wsx:Metadata>
      <wsx:MetadataSection Dialect="http://docs.oasis-open.org/ws-dd/ns/dpws/2009/01/ThisModel">
        <dpws:ThisModel> ... </dpws:ThisModel>
      </wsx:MetadataSection>

      <wsx:MetadataSection Dialect="http://docs.oasis-open.org/ws-dd/ns/dpws/2009/01/ThisDevice">
        <dpws:ThisDevice> ... </dpws:ThisDevice>
      </wsx:MetadataSection>

      <wsx:MetadataSection Dialect="http://docs.oasis-open.org/ws-dd/ns/dpws/2009/01/Relationship">
        <dpws:Relationship Type="http://docs.oasis-open.org/ws-dd/ns/dpws/2009/01/host">
          <dpws:Host> ... </dpws:Host>

          <dpws:Hosted> ... </dpws:Hosted>
          <dpws:Hosted> ... </dpws:Hosted>
        </dpws:Relationship>
      </wsx:MetadataSection>
    </wsx:Metadata>
  </soap:Body>
</soap:Envelope>

```

**FIGURE 26.8** Example for a SOAP Response message envelope.

this reply address indicates that response has to be sent back right after the SOAP Request message (in the same HTTP session).

The SOAP body in Figure 26.8 contains metadata sections for `ThisModel`, `ThisDevice`, and the `Relationship`. The `Relationship` metadata provides details about the device itself and two hosted services.

#### 26.3.4.6.3 Description of Hosted Services

Now that the client has retrieved the metadata for the device including the EPRs of its hosted service, it may request the WS-MEX description of desired hosted services using the `Get` operation of WS-Transfer. The metadata of a hosted service must contain at least one section providing the WSDL description (metadata dialect equal to `http://schemas.xmlsoap.org/wsdl/`). It must be sent in any `GetResponse` message. The WSDL metadata section may include the WSDL description in line or may provide a link referring to it.

#### 26.3.4.6.4 WSDL Constraints of DPWS

Hosted services must at least support the document/literal encoding style and must include the WSDL Binding for SOAP 1.2 for each `portType` at least. If notifications are supported by the hosted service (e.g., for a publish/subscribe mechanism), it must include the notification and/or solicit-response operation in a `portType` specification. Hosted services are not required to include the WSDL services section in a WSDL description since addressing information is included in the `Relationship` section of the device's metadata.

Hosted services must include the policy assertion `dpws:Profile` in their WSDL indicating that they support DPWS. This may be attached to a `port`, should be attached to a binding, and must not be attached to a `portType`. The policy assertion can also be stated as being optional indicating that the

hosted service supports DPWS but is not restricted to it. Devices have no explicit means to specify the support of DPWS. This must be ascertained by other information.

It should be noted that DPWS does not define a back-reference from hosted services to the device. The only way to find the corresponding device to a certain hosted service is to start a discovery process.

## 26.3.5 Eventing

Some applications might require to get informed about state changes of a specific WS. DPWS provides a publish/subscribe mechanism based on WS-Eventing.

### 26.3.5.1 WS-Eventing

WS-Eventing [25] implements a simple publish/subscribe mechanism sending events from one WS to another. WS-Eventing defines four WS roles: the *subscriber* initiates a subscription by subscribing to an event source. The *event source* is publishing (event) notifications whenever an interesting event occurs (e.g., state change). The notifications are sent to an *event sink*, which processes them in some way. In order to decouple the management of subscription from the event source in highly distributed networks, a *subscription manager* may take over that role. However, event sources are also subscription managers and event sinks are also subscribers in many publish/subscribe systems.

Figure 26.9 provides an overview of roles and message exchanges in a publish/subscribe system using WS-Eventing.

Message 1: A subscriber sends a *Subscribe* message to an event source indicating the address for a *SubscriptionEnd* message, address of event sink, the Delivery Mode, subscription expiration time, and subscription filters. The address for a *SubscriptionEnd* message identifies the WS, which receives such message in case of an unexpected subscription cancellation by the event source (e.g., due to an error). The address of subscriber and event sink is equal to the address for the *SubscriptionEnd* message when the subscriber is also the event sink (as in most applications of WS-Eventing).

The *Delivery Mode* specifies the way a notification is retrieved by the event sink. WS-Eventing specifies an abstract delivery mode allowing the use of any kind of delivery mode. One concrete delivery mode is defined as well. The *Push Mode* is used to send individual, unsolicited, and asynchronous notification messages. As an alternative to push delivery, a mechanism

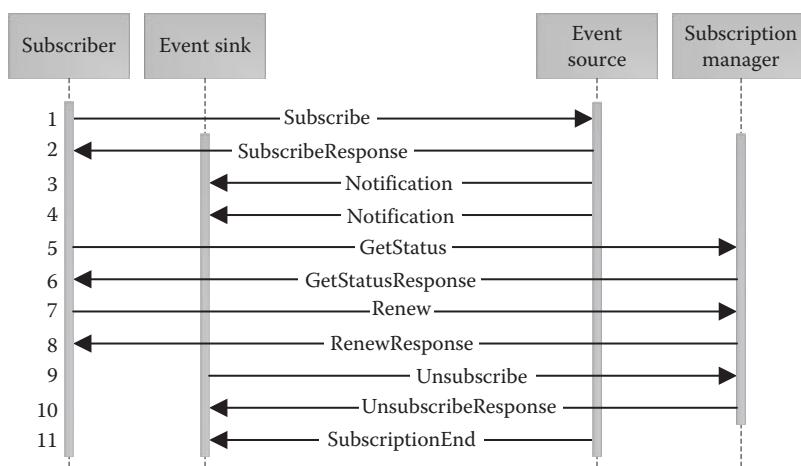

FIGURE 26.9 Roles and message exchanges as defined by WS-Eventing.

for polling notifications could be defined according to the abstract delivery mode (e.g., for applications where the event sink is behind a firewall).

Although subscription can be defined for an unlimited time, WS-Eventing recommends the definition of an absolute expiration time or duration (*subscription expiration time*). This reduces the network load in case of unexpected unavailability of event sinks during a subscription.

*Subscription filters* are defined to only send notifications the event sink is interested in. A Boolean expression in some *filter dialect* (e.g., string or XML fragment) is used to evaluate the notifications. Notifications are sent only when the expression evaluates to `true`. Any kind of filter dialect can be used (e.g., based on XPath).

Message 2: An event source replies with a `SubscribeResponse` message to the subscriber.

When accepting the subscription, the `SubscriptionResponse` contains an EPR of the subscription manager and an expiration time. WS-Addressing MI headers are used to relate a `SubscriptionResponse` to a `subscribe` message. In case the event source is also the subscription manager, the EPR of the subscription manager is one of the event sources.

Messages 3 and 4: *Notification* messages are sent from the event source to the event sink for events defined by the subscription filters. Semantics and syntax of notification messages are not constrained by WS-Eventing as any message can be a notification. However, subscribers may specify `wsa:ReferenceProperties` (WS-Addressing) in the `subscribe` message to request special marked notifications. These reference properties have to be included in each notification message.

Messages 5 and 6: If a subscriber wants to receive information about the expiration time of its subscription, it sends a `GetStatus` message to the subscription manager. The subscription manager includes the expiration time in a `GetStatusResponse`.

Messages 7 and 8: Before the subscription time expires, the subscriber has the chance to renew the subscription by sending a `Renew` message to the subscription manager including the new expiration time. The subscription manager replies with a `RenewResponse` including the new subscription time. If the subscription manager does not want to renew the subscription for any reason, it may reply with a `wse:UnableToRenew` fault in the response message.

Messages 9 and 10: If an event sink wants to terminate the subscription, it should send an `Unsubscribe` message to the subscription manager. If the subscription termination is accepted by the subscription manager, it must reply with an `UnsubscribeResponse` message.

Message 11: If the event source wants to terminate the subscription unexpectedly (e.g., due to an error), it sends a `SubscriptionEnd` message to the event sink. In such case, the event source is required to indicate the error. WS-Eventing specifies the faults `DeliveryFailure` for problems in delivering notifications, `SourceShuttingDown` for indicating a controlled shutdown and for any other fault `SourceCanceling`. Furthermore, the event source may provide an additional textual explanation in the element `wse:Reason`.

Please note that the order the messages exchanged in Figure 26.9 is not representative for all message exchanges in publish/subscribe systems using WS-Eventing.

WS-Eventing additionally defines that WS-MEX should be used to retrieve the event-related information from an event source embedded in the WSDL and optional policies. The services supporting WS-Eventing are marked by a special attribute and their notification, and solicit-response operations generate notifications, which are sent to subscribed event sinks. Solicit-response notifications require a response message from the event sinks. The policy entries specify the Delivery Mode and the filters.

### 26.3.5.2 Adaptations to DPWS

Eventing mechanisms in DPWS are only supported by hosted services (*event sources*) and clients (*event sinks*). Hosting services/devices do not support eventing. Hosted services supporting WS-Eventing must include a `wse:EventSource = 'true'` in corresponding `wsdl:portType` definitions in their

WSDL description (as defined in the WS-Eventing specification). Furthermore, hosted services must at least support the *Push Delivery Mode* as defined by WS-Eventing.

If a notification cannot be delivered to an event sink, the hosted service may terminate the subscription by sending a `SubscriptionEnd` indicating a `DeliveryFailure`.

As the time synchronization of event source and event sink might require additional resources and protocols being implemented, subscription requests and renewal are not required to be based on an absolute time. However, expressions in duration time must be accepted.

DPWS defines a specific dialect for subscription filtering—action filtering—which allows filtering related to specific actions defined in the MI headers of messages sent by the event source. A filter definition contains a white space-delimited set of URIs identifying the events being subscribed to. The event source evaluates the filter definition using the RFC 2396 prefix matching rules. That means all notifications of a `portType` can be received by subscribing to the action property prefix common to all actions of a `portType`.

## 26.3.6 Security

Point-to-point security offered by HTTP through authenticating, encrypting, and signing messages is not enough for complex message exchanges using SOAP. SOAP messages may be sent over intermediary nodes traversing different trusted domains, using heterogeneous transport protocols, and security mechanisms. These issues are addressed by WS-Security.

### 26.3.6.1 Web Services Security: SOAP Message Security 1.0 (WS-Security)

WS-Security [26] provides mechanisms for message integrity and confidentiality to SOAP messaging. It provides a framework to integrate existing security mechanisms into a SOAP message independent of underlying transport technology. WS-Security is based on existing specifications such as XML signatures, XML encryption/decryption, and XML Canonicalization. XML Canonicalization describes the preparation of XML messages for signing and encryption. XML Signature and XML Encryption define mechanisms for signing and encrypting an XML message. Furthermore, WS-Security is based on Kerberos and X.509 for authentication.

WS-Security defines a SOAP header element (`wsse:Security`), which contains security information about used authentication, signature, and encryption mechanisms as well as used security elements (e.g., public encryption keys). WS-Security does not specify which mechanisms should be used but how they are embedded into the security header. The WS-Security header may appear several times in a SOAP message specifying security mechanisms for each intermediary node along the way as well as the ultimate recipient of a SOAP message. A WS-Security header is associated with the corresponding node by using the mandatory `actor` attribute. Two security headers are not allowed to have the same `actor` URI assigned.

In order to sign or encrypt specific parts of a SOAP message, a reference to them is required. Although XPath provides mechanisms to do so, intermediary nodes processing the security headers might not support XPath. Therefore, WS-Security specifies an own mechanism using ID attributes (`wsu:Id`). This makes the processing of security definition easier and faster. An ID has to be unique for the entire SOAP message and is assigned to message elements designated for signing or encrypting. Thereby, it can be simply referred to when defining the parts being encrypted or signed. The ID attribute can also be used to refer to particular security declarations (e.g., public encryption key or signature).

Time often plays an important role in security contexts (e.g., certificates may expire). WS-Security supports this by the attribute `wsu:Timestamp`, which is assigned a security header. It specifies creation time (`wsu:Created`) and/or expiration time (`wsu:Expires`) of a security element.

The attributes `wsu:Id` and `wsu:Timestamp` used to be part of the WS-Security specification. However, they appeared to be useful for a number of WS protocols. Therefore, they have been separately defined in an XML Schema called *Web Services Utility* (indicated by the prefix `wsu`) along with other useful declarations.

### 26.3.6.1.1 Authentication

WS-Security offers two elements to embed authentication information into a SOAP message. The `UsernameToken` specifies a username and password for user authentication. The `BinarySecurityToken` offers the use of any binary authentication token such as a Kerberos ticket or X.509-certificate. It specifies the type of binary security token (e.g., X.809 certificate or Kerberos ticket) and its XML representation (e.g., Base64 encoded). Figure 26.10 illustrates a common authentication procedure using WS-Security [27]:

Message 1: The user requests a security token from an issuing authority. This request may not be WS based. For example, Kerberos protocols could be used to request a Kerberos service ticket.

Message 2: The issuing authority sends the security token (e.g., ticket, certificate, or encryption key) to the WS client, which embeds it into the SOAP message. The client should also sign and encrypt the message.

Messages 3–5: The client sends the (encrypted and signed) SOAP message to the WS. If necessary, the WS can validate the token by contacting the issuing authority. If the token is valid and the message encrypted, the WS replies in a secure SOAP message.

The concrete message interaction depends on the security mechanisms being used. As Kerberos and X.509 are not in the focus of this chapter, please refer to the corresponding specifications for more detail on it.

Authentication information should be signed and encrypted to ensure that it will not be changed or disclosed.

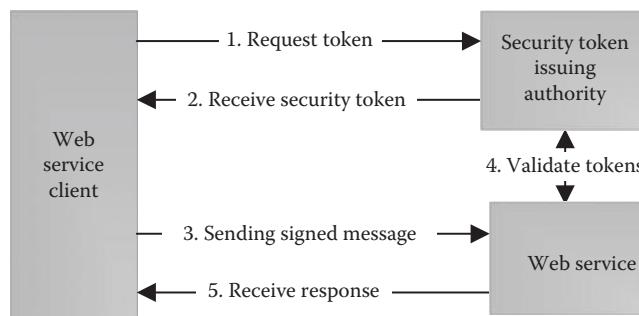

### 26.3.6.1.2 Message Integrity

The signing of a message prevents third parties from manipulating its content but does not exclude them from reading it. WS-Security requires the support of XML Signature for signing message content. The whole SOAP message envelope should not be signed as intermediary nodes might include additional security headers for their own security mechanisms. Such message would fail the manipulation check afterward.

Parts of a SOAP message envelope and also security definitions can be signed using the authentication mechanisms described earlier. Thereby, it is guaranteed that the user identified by the X.509 certificate, the `UsernameToken`, or a Kerberos ticket is the one who has signed the message parts.

### 26.3.6.1.3 Encryption

Encryption prevents third parties from being able to read the content of a message. WS-Security requires the support of XML Encryption. Symmetric or asymmetric encryption mechanism can be used. Symmetric encryption is the use of the same key for encryption and decryption. The key has to be provided to the partners by some other means in order to make sure that the key is not disclosed to untrusted parties. Asymmetric encryption is the use of two keys: a public and a private key. The public key is used for

**FIGURE 26.10** Message exchanges in an authentication procedure using WS-Security.

encrypting a message. As the public key cannot be used for decryption, it can be sent in any message. The private key is used for decryption. It must only be known and belongs to the partner who has to decrypt a certain message or content. X.509 certificates can be used for that.

In summary, WS-Security provides a container to include security definition and elements into a SOAP message. It provides means to include information about user authentication, digital signatures, and encryption mechanisms. Although any kind of security mechanism can be used, WS-Security provides concrete details on using Kerberos tickets and X.509 certificates as well as an own mechanism to include a username and password.

### 26.3.6.2 Adaptations to DPWS

WS-Security requires a lot of overhead in supporting and processing different security protocols and credentials in very heterogeneous networks although it offers enhanced security mechanisms for SOAP messaging over multiple hops and heterogeneous transport protocols. DPWS assumes that clients and devices reside in IP-based networks providing HTTP and HTTPS. Additionally, devices might have constrained resources (e.g., processing power and small storage space). Therefore, DPWS restricts the use of WS-Security to the discovery process, and all other messages are sent using a secure channel. The secure channel is established using existing technologies (HTTPS).

Security is an optional feature of DPWS. It can be omitted in the administrative trusted domain. DPWS security mechanisms have to be used if messages traverse other administrative domains that cannot be trusted.

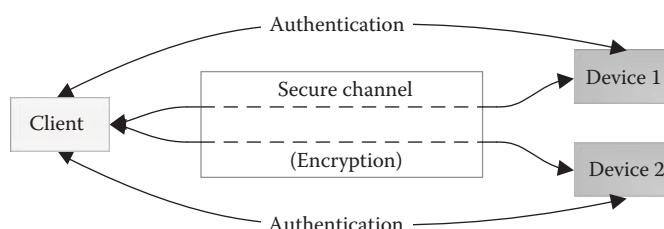

Figure 26.11 provides an overview of the security concept defined for DPWS, which is explained later in detail.

#### 26.3.6.2.1 Authentication

The client specifies the level of security, desired security protocols, and credentials in a policy assertion in the Probe and Resolve message during the discovery. The security policy assertion is included in the metadata section (`wsx:Metadata`) under the SOAP header (`wsa:ReplyTo/wsp:Policy`). The client should also authenticate itself to the device. If several security protocols are proposed by the client, they have to be ordered by decreasing preference. The device selects a protocol for authentication and key establishment from the list and includes it in the corresponding `ProbeMatch` and `ResolveMatch` message. After the security protocols have been negotiated, the client initiates authentication and/or key establishment processes. These processes are out of scope of the DPWS specification and are normally performed using an out-of-band mechanism. If successfully finished, the client establishes a secure channel to the device using Transport Layer Security (TLS)/Secure Socket Layer. The secure channel is also used for communication between client and hosted services.

#### 26.3.6.2.2 Integrity

The integrity of discovery messages of client and devices is ensured by using message-level signatures based on WS-Security. Devices should sign Hello and Bye SOAP message envelopes. If a device has multiple signatures, it must send one message for each of the signatures.

**FIGURE 26.11** Security concept defined for DPWS.

Service must protect the following MI header block of their SOAP messages by signatures: Action field (`wsa:Action`), messageID (`wsa:MessageID`), address of recipient (`wsa:To`), address for response (`wsa:ReplyTo`), and the ID of related request message for responses (`wsa:RelatesTo`). Furthermore, the content portion(s) of the SOAP Body associated with those MI headers must also be signed. The requirements for services are automatically fulfilled if using TLS as proposed by DPWS.

#### 26.3.6.2.3 Confidentiality

Discovery messages are not encrypted, whereas all other messages are encrypted using a secure channel. Services must encrypt their SOAP body.

A secure channel should remain active as long as client, device, and hosted services are interacting. The channel is removed when a device or client leaves the network.

## 26.4 Web Service Orchestration

Although the DPWS is an ideal base to enable connectivity between heterogeneous devices, each client has to be programmed and set up manually for each individual interaction with corresponding devices and services, respectively. This is not a big deal for interactions between one client and several services on devices but involves a huge effort for programming workflows or interaction processes in large networks. WS composition addresses this disadvantage by the definition of process workflows on existing WSSs.

### 26.4.1 Web Service Composition

Service composition is the possibility to combine a number of individual services in such a way that a surplus value is created [2]. Service composition can be divided into two independent aspects: service orchestration and service choreography.

Service orchestration is the execution of a workflow/process of service interactions controlled by a central entity (*service orchestrator*). The central entity plays the role of the initiating client for each individual invocation of services.

Service choreography, by contrast, refers to a decentralized workflow/process that results from each client-service interaction. In other words, each client is aware of its own interactions, but it is not necessarily aware of the interactions between other clients and services. Nevertheless, all client-service interactions form a workflow/process.

Figure 26.12 presents simple examples for service orchestration and choreography. In service orchestration, the service orchestrator (as the central workflow/process coordinator) controls the invocations of three services, their order, and deals with possible failures. In a choreography setup, each participating component is (only) aware of its own interactions. There is no central instance starting and controlling the workflow/processes. The choreography workflow is started by Client 1 when invoking Service 4.

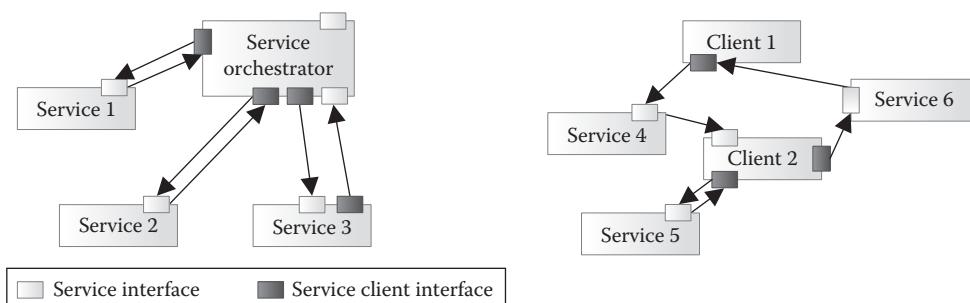

FIGURE 26.12 Service orchestration vs. service choreography.

Another aspect attracting attention while looking at Figure 26.12 is that the individual components do not have clearly assigned roles. Some of them act as both service and service client (illustrated by their interfaces). That is often the case in real-life applications. A strict separation can be done only for a single client–service interaction. For example, the service orchestrator possesses an unconnected service interface. This can be used to start the workflow/process by invoking the service orchestrator. Thereby, services and their functionality can be composed to a single (meta) service. Furthermore, Service 3 might also be a composed service, which takes a long time to finish the execution of its process. Therefore, the service orchestrator provides a callback interface, which will be invoked by Service 3 to deliver the response to its initial invocation (*asynchronous service interaction*). In the meanwhile, the service orchestrator can perform other tasks and does not have to wait for the response of Service 3. Also, the redirection of responses to a third service or client is possible in some SOA implementations as shown in the interaction between Service 4 and Client 2.

It is obvious that the process designer has more influence on aspects such as selection of participating, fault tolerance, compensation of occurring errors, and handling of events by using service orchestration instead of service choreography. Service choreography is useful if some internal aspects of interaction processes are not known (e.g., when involving components from other companies that themselves are interacting somehow).

The orchestration of services to workflow processes falls into the category of business process management (BPM). Although process management originates from the business sector, its concepts can be adapted to the automation of technical processes, which is just the intention of this chapter.

BPM takes care of the planning, modeling, executing, and controlling of processes and workflows, respectively [28]. It bridges the gap between business and IT by offering an outside view that is oriented on the interaction process of components rather than the performance of participating components. Participating components are *black boxes* for the process designer. BPM reacts on the adaptability requirements of constantly changing environments and requires a standardized communication and interface to involved components. Process definitions in the area of IT have to be machine readable to enable automation. Among the WS protocols, the WS-BPEL standard combines all aspects of BPM with the advantages of SOAs represented by WSs.

## 26.4.2 Web Services Business Process Execution Language

The Web Services Business Process Execution Language (WS-BPEL) is an XML format, which is based on WS standards [29], to describe machine-readable processes. WS-BPEL processes can be designed using graphical tools and can be directly executed by a WS-BPEL engine/orchestrator. WS-BPEL provides several concepts in order to support flexible processes:

- WSs interaction. A WS-BPEL engine provides a WS interface to each WS-BPEL process. Thereby, WS-BPEL processes are started when their corresponding WS interface is invoked. Synchronous and asynchronous interactions with other WSs are supported by WS-BPEL. Synchronous interaction is the immediate response of a WS to its invocation. Asynchronous interaction is the delayed response of a WS by invoking the corresponding callback interface provided by the WS-BPEL process.
- Structuring of processes. WS-BPEL offers validity scopes to distinguish between local and global contexts. Processes can define loops, condition statements, and sequential and parallel execution. Dependencies between process threads can also be defined.
- Manipulation of data. WS-BPEL allows the use of variables for the internal process execution. Data can be extracted from messages, validated, manipulated, and assigned to other variables or messages.
- Correlation. In order to relate a certain message to a specific instance, WS-BPEL introduces the concept of correlation. It allows the identification of a certain context common to all messages of one instance.

- Event handling. Events can be handled in parallel to the process execution. They may be triggered either by the reception of a certain message or by a time-out.
- Fault handling. WS-BPEL also supports mechanisms for exception handling if a fault is thrown.
- Compensation handling. As the execution of a process is not an atomic operation, successfully completed WS interactions have to be possibly undone or compensated in case of a fault. For example, the payment of a flight ticket is not successful, but the seats are already reserved. Then, the reservation has to be compensated, which is facilitated by the WS-BPEL compensation handling.
- Extensibility. WS-BPEL provides means for adding new activities and data assignment operations.

WS-BPEL resides on top of the WS protocols. It supports the Basic Profile for WSs [30], which provides interoperability guidance for the WS core specifications such as WS communication protocols, description, and the service registry. DPWS is not supported by WS-BPEL.

#### **26.4.2.1 WS-BPEL Extension for People (BPEL4 People)**

The BPEL4 People enables the involvement of people in the process design (e.g., monitoring by people or realizing manual input to processes) [31]. Process designers can define human interactions and specify their contexts such as individual tasks, roles, and administrative groups of people.

Human tasks can be separated from the process definition. This is specified by Web Services Human Task (WS-HumanTask) [32]. A human task can be exposed as WS and thereby used in a process.

BPEL4 People and WS-HumanTask are OASIS standards since 2010.

---

## **26.5 Software Development Toolkits and Platforms**

There are currently several initiatives developing software stacks, toolkits, and enhancements to DPWS.

### **26.5.1 WS4D, SOA4D**

The *Web Services for Devices (WS4D) initiative* [33] was started from German partners (University of Rostock, Technical University of Dortmund, and Materna GmbH) of the European ITEAR&D project service infrastructure for real-time embedded networked application (SIRENA). Currently, four DPWS software development kits are available and released as open source. The *Java Multi Edition DPWS stack* is based on the Connected Limited Device Configuration profile enabling DPWS on very resource-constrained devices. The *gSOAP DPWS stack* is based on the gSOAP code generator and SOAP engine and is especially designed for embedded devices. The *Axis2 DPWS stack* is based on the Apache Axis2 WSs engine and focuses on enterprise applications. The *uDPWS stack* is developed for device with extreme constrained resources such as sensor nodes. All four stacks and their toolkits are available as open-source software.

The *Service-Oriented Architecture for Devices (SOA4D) initiative* [34] originates from the European ITEA R&D project service-oriented device architecture, which is the succeeding project of SIRENA. SOA4D aims at fostering an ecosystem for the development of service-oriented software components adapted to the specific constraints of embedded devices. SOA4D provides two open-source stacks and corresponding toolkits. The *DPWS Core stack* provides an embeddable C WSs stack based on gSOAP. The *DPWS4J Core stack* provides a Java WSs stack for the J2ME CDC platform.

Both initiatives work closely together to ensure the interoperability between their stacks.

### **26.5.2 DPWS in Microsoft Windows**

UPnP and DPWS (here called WSs on Devices WSD) are part of Windows Rally facilitating the integration of network-connected devices in a plug-and-play manner.

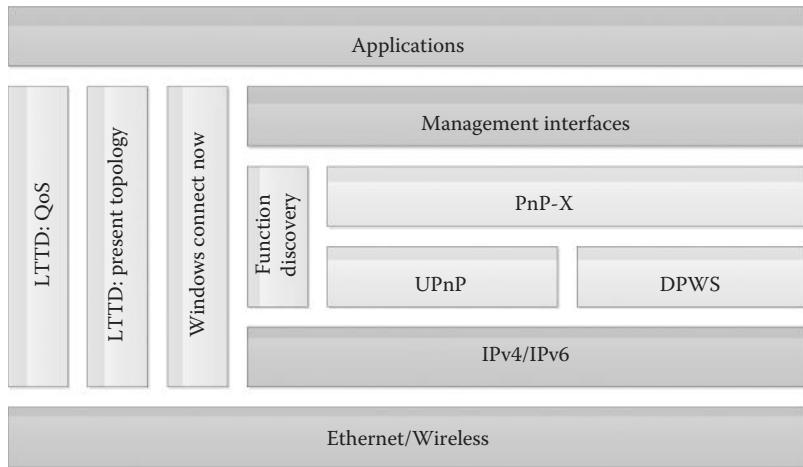

FIGURE 26.13 Windows Rally.

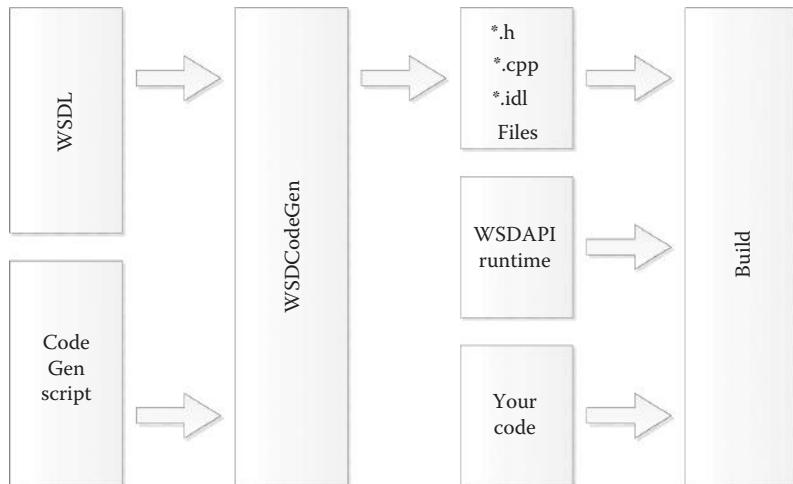

FIGURE 26.14 DPWS Code Generator.

Figure 26.13 presents an overview of Windows Rally and used technologies [35]. The *Link Layer Topology Discovery* enables the discovery of devices using the data-link layer (Layer 2). It can be used to determine the topology of a network, and it provides QoS extensions that enable stream prioritization and quality media streaming experiences. Windows Connect Now is a part of Rally and aims at simpler wireless device configuration. Function discovery is a generic middleware and can be used to execute common discovery enabling the searching for UPnP and DPWS devices.

*Web Services on devices API* (WSDAPI) is an implementation of the DPWS 1.0 in Microsoft Windows since Windows Vista. The API supports discovery, metadata, control, eventing, and binary attachments to messages. In addition to that, it supports XML schema extensibility. As part of WSDAPI, a code generation tool WSDCodeGen converts WSDLs to COM objects (Figure 26.14) [36].

## 26.6 DPWS in Use

---

This section describes applications making use of DPWS.

### 26.6.1 Automation Scenarios

#### 26.6.1.1 Smart Metering

The actual situation in smart metering is characterized by a coexistence of a large number of proprietary and open standards for wired as well as wireless communication. These standards show low or no interoperability to each other. Therefore, it is very difficult to integrate multi-vendor solutions using one sustainable holistic approach. In [37], proposed approach is to use WS technology as an open wide-spread Internet standard for the creation of a heterogeneous network for smart metering devices.

In the proposed work, the smart meter profile for WS based on Smart Message Language and DPWS was introduced. It was demonstrated that using DPWS-enabled smart meters, a heterogeneous meter network can be built using existing open standards. From a technical perspective, the suggested WS-based solution is not bound to any physical layer technology so that any possible technology supporting IP can be used. This eases the setup of heterogeneous and vendor-independent meter networks. Due to the sensitivity of meter data, energy profiles, and controlling capabilities, special security requirements have to be satisfied. Authorization, encryption, and signature are common security measures. They are already integrated in DPWS, thereby providing required privacy and security for automated meter reading. In order to reduce communication overhead, CoAP is used for HTTP and Efficient XML Interchange (EXI) for XML binary encoding. Thus, traffic overhead is reduced by over 90%. The suggested approach can be easily applied to nearly all smart metering protocols.

The works in [37,38] break the myth that WSs require high computation power and produce high communication overhead. The uDPWS stack requires ca. 46 KB ROM and 7 KB RAM. The compression through CoAP and EXI do not produce additional CPU or memory load. Nevertheless, the compression rate is over 90%.

## 26.7 Conclusion

---

The DPWS solves important requirements of embedded systems and hardware components. It provides an SOA for hardware components by enabling WS capabilities on resource-constraint devices. In particular, DPWS addresses the announcement and discovery of devices and their services, eventing as a publish/subscribe mechanism, and secure connectivity between devices.

Although DPWS is still a quite young technology, it can be expected that it will soon play an important role in building a bridge between device automation and enterprise networks. This results also from the fact that Microsoft and printer manufacturer support it in their products, and a lot of research and development is currently performed with respect to DPWS. A process management standard such as WS-BPEL will reveal the full potential of DPWS and simply the development and controlling of complex automation systems.

### **27.1 Why Do We Need Functional Safety in Automation?**

---

Any active industrial process is more or less associated with the risk of

- Injuring or killing people
- Destroying nature
- Damaging investments

With most of the processes, it is quite easy to avoid risk without special requirements imposed on automation systems. However, there are typical applications associated with high risk, for example, presses, saws, tooling machines, robots, conveying and packing systems, chemical processes, high-pressure operations, off-shore technology, fire and gas sensing, burners, and cable cars. Those applications need special care and technology.

Over time, the market balances out the reliability and the availability of the *standard* automation technology against a certain economic cost level. That means the failure, or error rate, of the standard

automation technology under normal circumstances is acceptable for normal modes of operations, but not sufficient for the safety critical applications, mentioned earlier.

The situation may be compared with the public mail system. While normal letter expedition is expected to be as affordable as possible at certain delivery uncertainty, everybody will use special mail for important messages.

## 27.2 Dichotomy of Standard and Functional Safety Automation

---

In the past decades, microcontrollers, software, personal computers, and communication networks have dramatically influenced the automation area, leading to cost reduction, higher flexibility, and availability. In respect to safety, standards and regulations of the day were prohibiting any usage of existing solutions. Safety automation had to be *hard-wired* and based on *relay* technology. This dichotomy, or gap, is quite natural due to the fact that safety relies on trusted technology, trust in experience, and experience accumulated over long time. But adding *classical* safety to modern automation solutions leads to increased cost due to additional wiring and need for engineering, to less flexibility and availability than expected, and to other disadvantages. Recently, the situation has changed significantly. Microcontrollers and software have been in a widespread use in diverse industrial automation applications. The preconditions for their use in safety applications were introduced in the international standard IEC 61508, with its different safety integrity levels, from SIL1 to SIL4 [1].

## 27.3 Motivation and Objectives for PROFIBUS and PROFINET

---

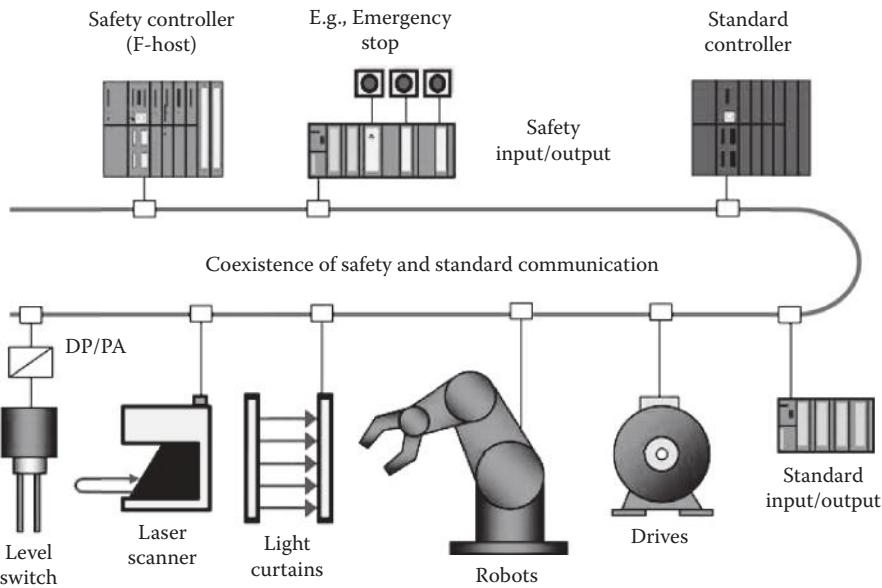

Over its lifetime, since 1989, PROFIBUS has emerged to one of the most important fieldbus systems in the world with more than 50 million nodes. PROFINET IO, the Ethernet-based companion, follows the success story since its introduction in 2005. Both are standardized within IEC 61158 and IEC 61784 [2], respectively, and enable decentralized applications in factory and process automation (PA) with a variety of appropriate transmission technologies such as Ethernet, RS485, MBP-IS,\* fiber optics, and wireless. It was, thus, merely a matter of time to introduce, in a seamless manner, the necessary means for safety applications on PROFIBUS DP & PROFINET IO and to provide a similar flexibility and availability also for powerful functional safety devices like remote I/O, laser scanners, light curtains, level switches, shutdown valves, drives, robots, and alike.

Back in 1998, when the PROFIBUS organization started its project “functional safe communication across PROFIBUS DP,” more than 25 companies, renowned for their involvement in the functional safety area, decided to connect the above-mentioned safety devices to the same transmission line, as the standard devices, and let them communicate with an additional programmable safety-related controller (F-Host in Figure 27.1). The requirement was that neither cables, ASICs, and layer stack software nor other communication devices such as repeaters, links, and couplers should be changed. Configuration, parameterization, programming, and diagnostic means should be as familiar to the user as possible in order to simplify the deployment of the safety option: *what he/she is using, he/she will not be losing*. Fortunately, the working group was able to base its design and development efforts on the new IEC 61508 and on the groundwork of the *railway standard* IEC 62280-1 [3]. PROFIBUS DP and PROFINET IO fall in the category of the so-called *defined transmission systems*, with configured and well-known participants and transmission properties, the preconditions of functionally safe communication. The public phone system or the Internet, for example, falls in the category of the *open transmission systems*.

From the very beginning, it was clear that the transmission of safety messages via the standard PROFIBUS DP (including the PROFIBUS PA), and some years later PROFINET IO, cable would not

---

\* MBP-IS = “Manchester Coded-Bus Powered and Intrinsically safe” replaces the previously used name “IEC 1158-2.” Further development has listed additional procedures in the corresponding IEC standard, so that creating an unambiguous designation had become necessary.

**FIGURE 27.1** The PROFIsafe vision.

prove sufficient for the new generation of safety devices that had to be connected to it. What sense would it make, if merely the shutdown signals could be transported via the bus, while parameter value assignment, or diagnostic messages, in the event of a failure still require a time-consuming on-site PC connection via a proprietary interface?

There was a need for the device manufacturers to support rapid device replacement and integration of the device commissioning and diagnostic software with the engineering software of the system developers in order to improve production flexibility (e.g., program-controlled parameter value assignment) and to increase availability of the manufacturing assets (intelligent diagnosis and preventive maintenance).

Safe communication could be achieved by using redundant transmission lines and cross-checking as a basis for safety functions. However, the working group opted for a *single-channel* solution. The redundancy can still be added to the system as an option to provide additional higher availability/reliability for the operational functions (Table 27.1).

**TABLE 27.1** Safety and Redundancy Options

	PROFIBUS DP PROFINET IO	PROFIsafe	Redundancy	PROFIsafe and Redundancy

<i>Functional safety</i>	—	Prevent hazards through safety functions (required by laws or insurances)	Redundancy by itself does not provide functional safety	Prevent hazards through safety functions (required by laws or insurances)

## 27.4 PROFIsafe, the Solution

### 27.4.1 Concept

PROFIBUS DP and PROFINET IO, like most of the fieldbus systems, employ only the layers 1, 2, and 7 of the ISO/OSI model [4], only for real-time applications. In order to avoid any changes to any of these layers, the safety measures were added as a safety layer on top of layer 7, thus increasing the size of the OSI application layer by some kilobytes. Since the safety layer is only responsible for the *transport* of safety-related *user*, or process data, it takes the remaining parts of the (safety and) application layer to acquire and process these data. The technology firmware in a safety-related device (e.g., light curtain) can incorporate these layers; in case of SIL3, this is typically a redundant hardware/software structure (Figure 27.18). Similarly to the *non-safety* mode, the process data (signals and/or process values) are packed in the protocol data unit (PDU) of a PROFIBUS DP, or PROFINET IO, message frame. In case of PROFIsafe, the raw process data are supplemented by additional information, discussed in the next sections. The safety-augmented process data are called a *PROFIsafe PDU*. Ideally, a *PROFIsafe PDU* shall be passed as a whole, and completely unmodified, from a (safety) sender to a (safety) receiver no matter what kind of transmission system both are using. Thus, the safety measures are *encapsulated* in the communicating end devices.

### 27.4.2 Black Channel

Such a transmission system from one safety node to another is called a *black channel*, an analogy to a *black box* (see Figure 27.3). The chosen communication technology does not matter except for a few basic constraints to be discussed later on in this chapter. Another implication is that none of the error detection mechanisms of the chosen communication technology is employed to guarantee the integrity of the transferred process data. Basically, there are no restrictions with respect to transmission rate, number of bus devices, or transmission technology—as long as its parameters are acceptable by the required reaction times of the safety applications. The example in Figure 27.2 demonstrates that PROFIsafe also employs the *black channel* principle for complex PROFIBUS DP and PROFINET IO structures.

Safety-related sensor signals from an F-DI module of a PROFINET IO remote I/O device that can be equipped with other safety-related and non-safety-related modules with input/output channels are routed via the PROFINET IO device node to the PN IO controller. From here, they go via a local backbone bus to the F-Host equipped with a programmable safety-related system (e.g., Safety-PLC). After the safe logic operation, a corresponding output signal is routed via the local bus back to the PN IO controller, and, then, via a PN IO/DP Link to a PROFIBUS DP segment, and from there to its final destination, a drive with integrated safety. In case of explosion-proof areas requiring intrinsic safety, signals are passing a DP-PA Link. The transmission rate is reduced there, and the intrinsically safe transmission technology (MBP-IS) is employed for routing a signal to the safety-related PA slave. At no point on its communication path, the signal has employed a redundant communication path. In other words, this is a *single-channel* transfer.

Up to now, we simply dealt with the communication paths for safety-related messages. Thus, it is still open who is responsible for the transfer and when the transfer takes place. Here, too, PROFINET IO and PROFIBUS DP standard mechanisms are used—the Controller–Device or Master–Slave operation, respectively. Controllers, or Masters, which may be assigned to an F-Host, *cyclically* exchange messages with all their configured Devices, or Slaves. This means that there is always a 1:1 *relationship* between Controller–Master and Device–Slave. The polling operation has the advantage that any failed device will be detected immediately—one of the basic principles of safety technology. Now, we are able to identify the basic constraints for the *black channel* for PROFIsafe operations: the polling principle and the 1:1 relationship.

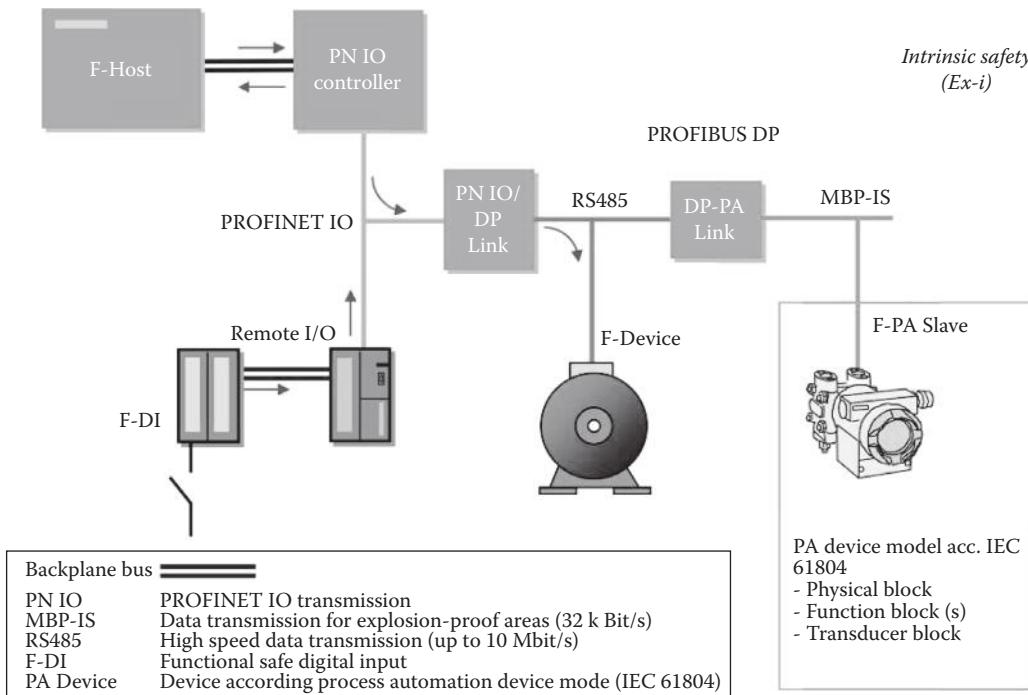

FIGURE 27.2 Complete communication paths for PROFIsafe PDUs.

### 27.4.3 Possible Transmission Errors and Their Remedies

Various errors may occur when messages are transferred in network topologies of the described complexity, be it due to hardware failures, extraordinary electromagnetic interference (EMI), or other influences. A message of a logical connection between two PROFIsafe safety nodes can be lost, occur repeatedly, or mirrored (loopback), be inserted from somewhere else, appear delayed, in an incorrect sequence, out-of-sequence due to storage elements in the network and/or show corrupted data. In case of safety-related communication, there may also be misrouting due to incorrect addressing, which means that a standard or safety-related message erroneously appears at a safety, or wrong, device and pretends to be an expected safety message. Figure 27.3 shows the black channel for such a logical connection and the possible communication error types.

Out of the numerous remedies known from literature, PROFIsafe focuses on those presented in the matrix shown in Table 27.2.

These include the following:

- The numbering of the PROFIsafe PDUs (*sign-of-life*)
- A time expectation with acknowledgment (*watchdog*)
- A Codename between sender and receiver for each direction (*password*)
- Data integrity checks (cyclic redundancy check [CRC])

Using the numbering, a receiver can see whether it received all of the PROFIsafe PDUs and within the correct sequence. The receiver returns to the sender a PROFIsafe PDU with the correct number as an acknowledgment. Basically, a simple *toggle bit* would have proven sufficient. However, due to possible storing network elements such as routers or switches, a large series of numbers has been selected for PROFIsafe.

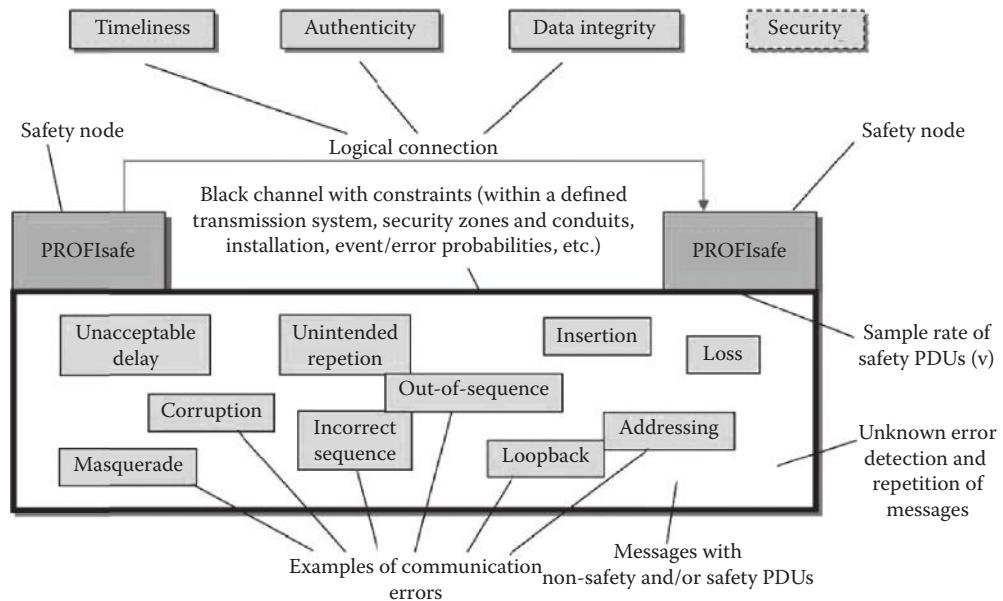

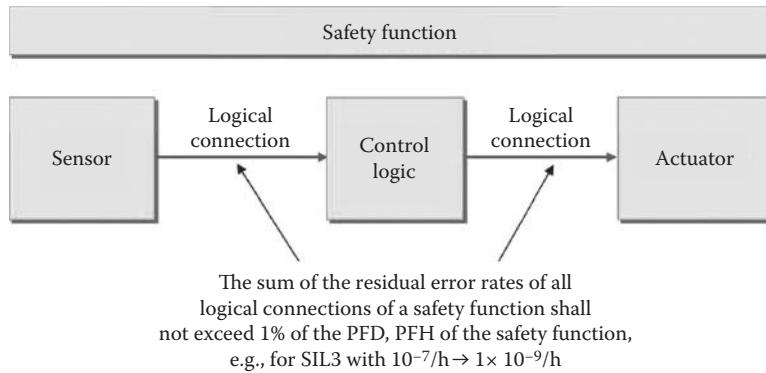

FIGURE 27.3 Black channel and PROFIsafe properties of logical connections.

TABLE 27.2 Black Channel Error Types and Safety Measures of PROFIsafe

Safety Measures				
Communication Errors	Monitoring Number (Virtual)	Timeout with Receipt	Codename for Sender and Receiver	Data Integrity Check
Corruption				X
Unintended repetition		X		
Incorrect sequence	X			
Loss	X	X		
Unacceptable delay		X		
Insertion	X		X	
Masquerade			X	
Addressing			X	
Out-of-sequence	X			
Loopback of messages			X	

In the functional safety technology, it matters not only that a message transmits the correct process signals or values. The up-to-date values must arrive within a process fault tolerance time, thus enabling the respective device to automatically initiate on-site a safe state, if necessary (e.g., stop of movement). For this purpose, the devices use a watchdog timer that is restarted whenever new PROFIsafe PDUs with incremented numbers have arrived. Numbering and watchdog timer together provide the basis for an important property of functional safety communication, namely, the *Timeliness* (see Figure 27.3). The procedures and sizes of the chosen safety measures for *Timeliness* must meet the quantitative requirements of IEC 61508.

The 1:1 communication relationship (logical connection) between the Controller-Master and a Device-Slave facilitates the detection of misrouted messages. Each and every safety logical connection must have a unique identification (called Codename) inside the defined network, and this Codename can be used to verify the Authenticity of a PROFIsafe PDU. Authenticity is another property of functional safety communication (see Figure 27.3). Again, the procedures and sizes of the chosen safety measures for *Authenticity* must meet the quantitative requirements of IEC 61508.

**FIGURE 27.4** Safety function acc. IEC 61508 and the 1% rule.

Data Integrity is the third property of functional safety communication (see Figure 27.3). Detecting corrupted data bits through an additional CRC plays a key role. The procedures and sizes for *Data Integrity* must meet the quantitative requirements of IEC 61508.

The necessary probabilistic examinations for all three properties can benefit from the definitions within the IEC 61508 that considers the probability of failure of entire safety functions. PROFIsafe is following this approach (Figure 27.4).

Accordingly, a safety circuit includes all sensors, actuators, communication elements, and logic processes that are involved in a safety function. IEC 61508 defines overall values for the average probability of failures for different SILs. For SIL3, for example, this is an average probability of failures per hour (PFH) of  $10^{-7}/h$ . For the transmission, PROFIsafe takes up only 1%. This means that the permissible PFH for the sum of the PROFIsafe properties *Timeliness*, *Authenticity*, and *Data Integrity* is  $10^{-9}/h$ .

The major steps of the PROFIsafe protocol development are outlined in the following.

First, suitable CRC generator polynomials had to be determined for a reasonable PROFIsafe PDU length.

The following so-called *proper* polynomials are chosen for the usage with PROFIsafe ( $r$  = length of the CRC signature):

$r = 16$  Bit: 0x4EAB

$r = 24$  Bit: 0x5D6DCB

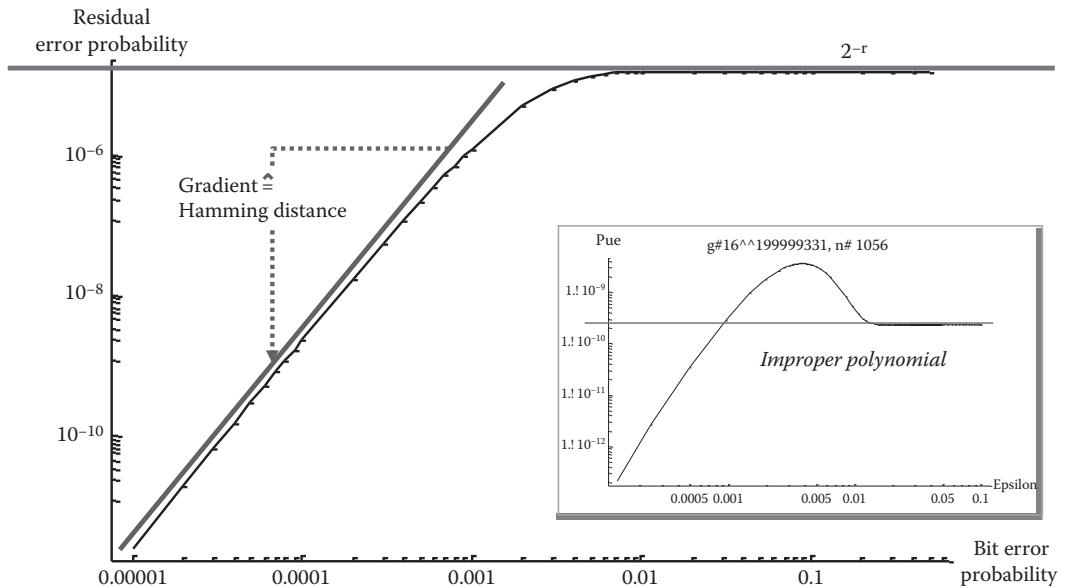

$r = 32$  Bit: 0xF4ACFB13

A polynomial is called *proper* when the residual error probability over an increasing bit error probability never crosses the limit  $2^{-r}$  (e.g., when the curve rises continuously monotonic). Figure 27.5 shows examples of a *proper* and an *improper* polynomial.

The residual error probability (y axis) becomes critical with a high bit error probability. The more bits are corrupted within a PROFIsafe PDU, the higher the probability of a residual error. Usually, EMIs in the form of burst disturbances cause the corruption of a series of adjacent bits within a message. As long as the burst interference is shorter than the bits of the CRC signature, any corruption will be detected. In order to reduce risk further, PROFIsafe uses a patented procedure—the SIL monitor.

#### 27.4.4 SIL Monitor

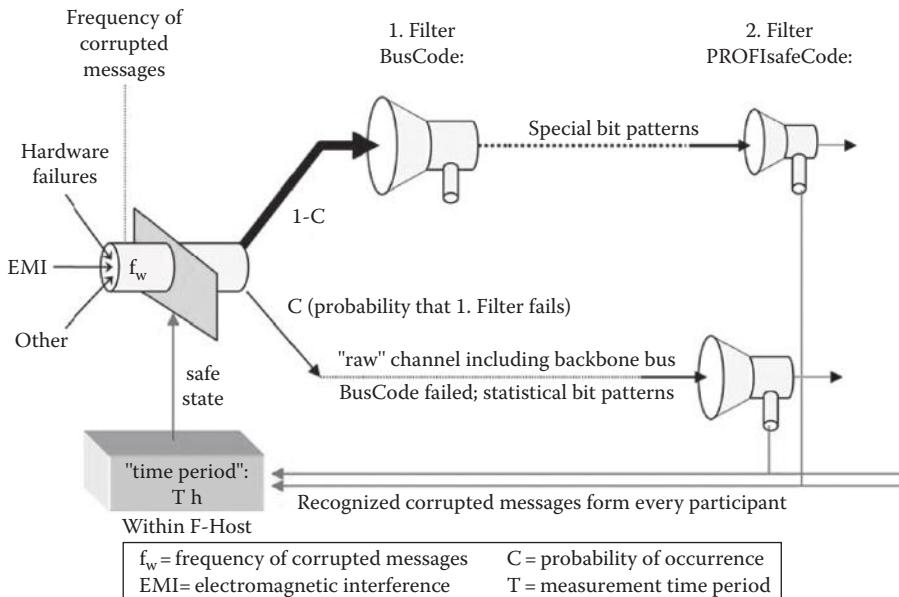

As mentioned before, PROFIsafe is not relying on the basic data integrity checks of PROFIBUS DP (see Figure 27.7), or PROFINET IO (see Figure 27.8), or other transmission mechanisms. The entire error detection necessary to attain the required SIL (in factory automation usually SIL3 as the maximum) is advantageously only implemented in the superimposed PROFIsafe protocol. Being dependent on the

**FIGURE 27.5** Examples of proper and improper generator polynomials.

detection mechanisms of the basic transmission systems would require complex verifications for all possible communication configurations (the so-called white channel approach). Thus, a mechanism was created that guarantees the compliance with SIL levels over the service life of a distributed safety-related automation solution, irrespective of the employed components and the configuration (see Figure 27.6).

Here, all influences that may corrupt the PROFIsafe PDUs are looked at as a frequency  $f_w$ , whatever the causes of the corruption may be: hardware failures, EMI, etc. For each safety function, the F-Host monitors detected corrupted PROFIsafe PDUs from the associated F-Devices–Slaves via the Status Byte

**FIGURE 27.6** The SIL monitor.

(see Figure 27.9). It also monitors received detected corrupted PROFIsafe PDUs on its side. Once the frequency of the corrupted PROFIsafe PDUs exceeds a certain limit, the F-Host causes the safe state in the safety function to be activated. The SIL monitor is not a separate component. It is implemented as a part of the PROFIsafe protocol software within the F-Host.

### 27.4.5 Messages with PROFIsafe PDUs

Up to now, we discussed the mechanisms PROFIsafe employs for safely transporting the PROFIsafe PDUs. This section now deals with the concrete mapping onto the PROFIBUS DP and PROFINET IO communication. Figure 27.7 shows the structure of a PROFIBUS DP message frame.

In this case, PROFIBUS DP achieves data integrity via the parity bit (PB) and the frame checking sequence. Figure 27.8 shows the structure of a PROFINET IO message frame. In this case, PROFINET IO achieves data integrity via a 32-bit CRC signature.

### 27.4.6 PROFIsafe Parameters

The configuration part of an engineering tool uses the electronic General Station Description (GSD) of a particular F-Device–Slave to arrange for the format of the standard process data to be transferred within the PDU of a message between a PROFINET IO controller–PROFIBUS DP master and its PROFINET IO device–PROFIBUS DP slave. The same happens in case of PROFIsafe PDUs.

There are two groups of safety-related parameters. The *F* parameters (*F*-Parameter) are associated with the PROFIsafe protocol layer and the *i* (= individual) parameters (*i*Parameter) with the individual safety-related technology firmware of a safety device. The earlier-mentioned CRC signature protection is used not only for cyclically ensuring the data integrity of the process signals and process values but also for ensuring the data integrity of the *F*-Parameter (such as Codename, watchdog time, and protocol version) and the *i*Parameter stored in the individual slaves. For this purpose, a separate CRC signature value (CRC\_FPs+) of these parameters is generated and used at start-up and in case of a communication restart after an error.

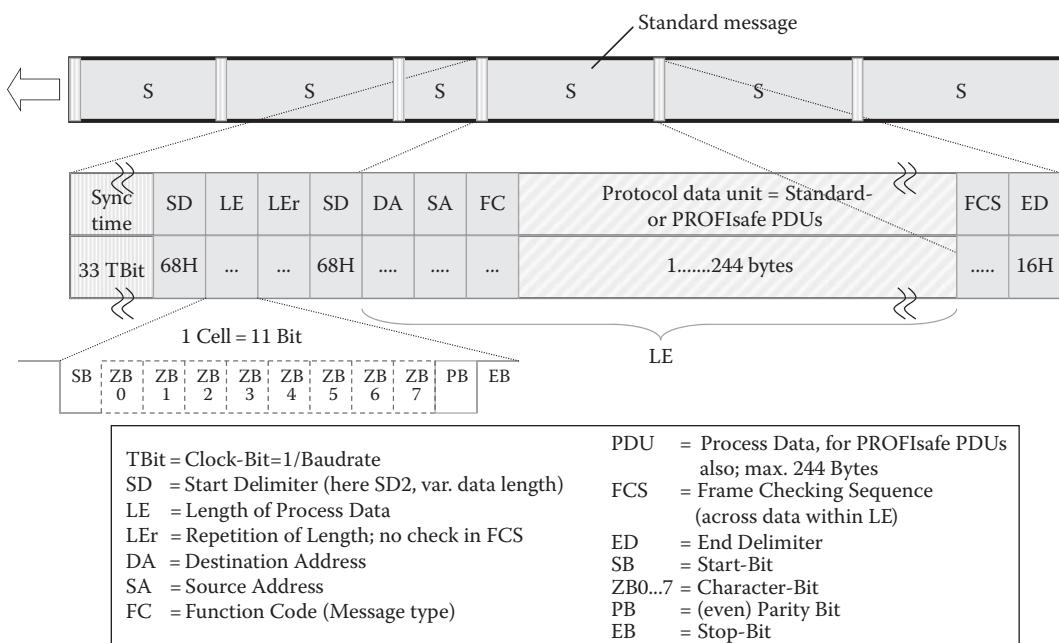

FIGURE 27.7 PROFIBUS DP message structure.

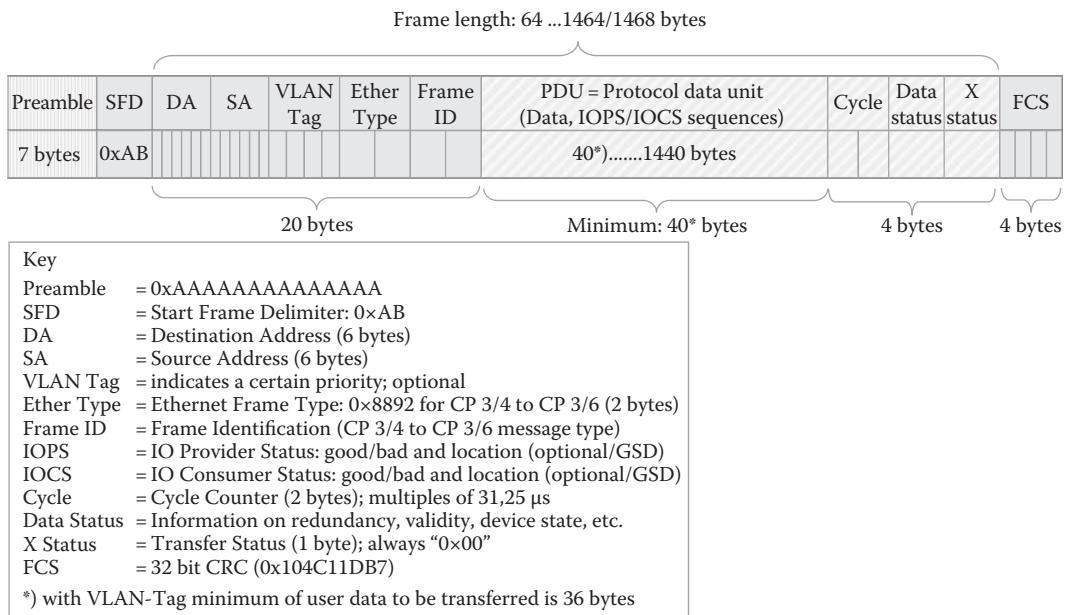

FIGURE 27.8 PROFINET IO message structure.

### 27.4.7 Structure of PROFIsafe PDUs

The PROFIsafe protocol is located on top of the fieldbus application layer, as shown in Figure 27.3, and realized in the form of state machines on the sender (F-Host\*) as well as on the receiver side (F-Device) to cover start-up, regular, and error behavior. In order to synchronize both state machines, the F-Host uses a Control Byte to send commands, and the F-Device a Status Byte to return acknowledgments and additional information for the SIL-Monitor, for example, in case of corrupted PROFIsafe PDUs. The structures of the PROFIsafe PDUs from F-Host and F-Device are

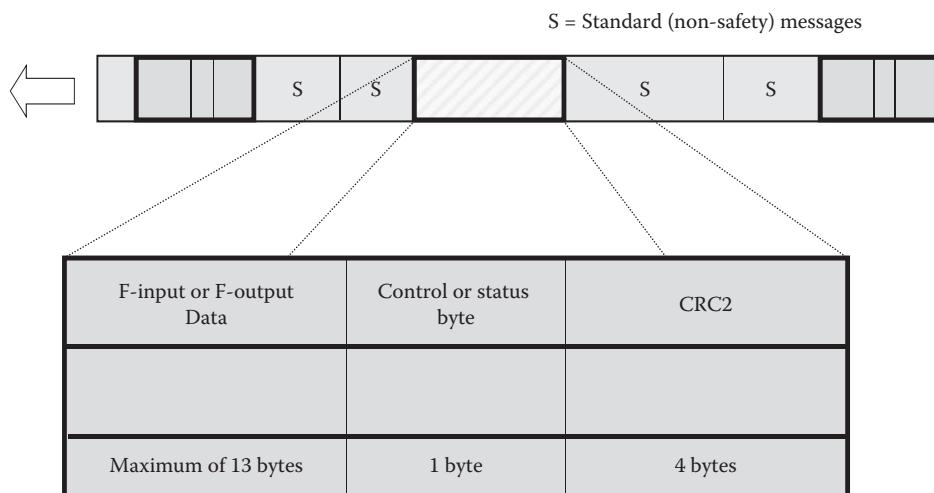

FIGURE 27.9 PROFIsafe PDU structure.

\* For simplicity, *F-Host* and *F-Device* are used for both PROFIBUS DP and PROFINET IO.

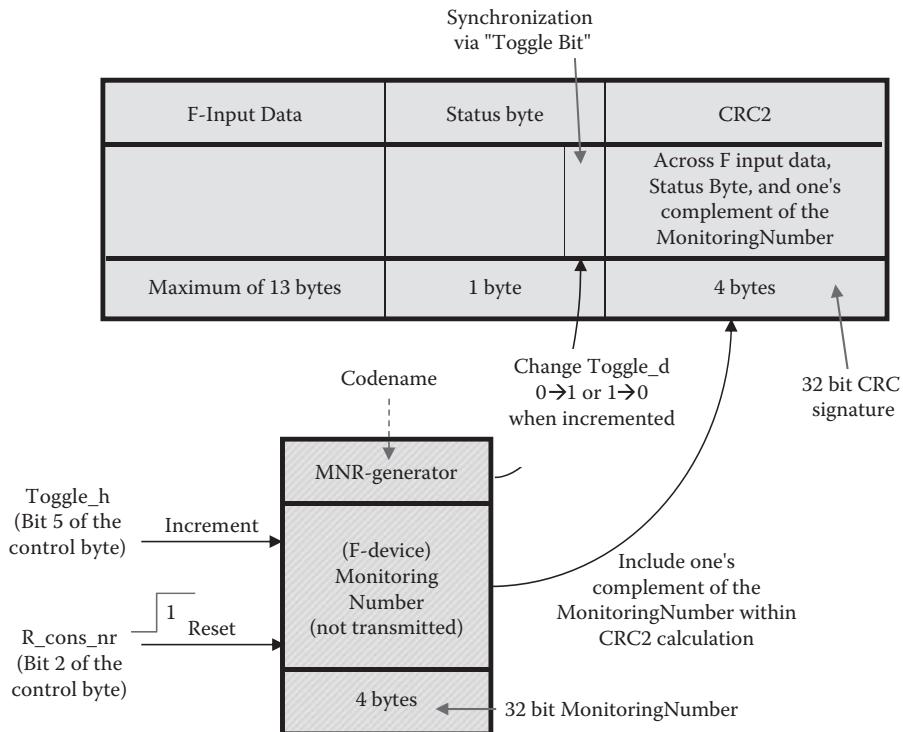

FIGURE 27.10 Implicit method of PROFIsafe via MonitoringNumber (F-Device).

symmetrical as shown in Figure 27.9. The F-Host sends F-Output data (in case of actuators) and the F-Device returns F-Input data (in case of sensors). The maximum length in both cases is 13 bytes. Figure 27.9 also shows 4 bytes of CRC signature to ensure the *Data Integrity*. But obviously, something is missing, isn't it?

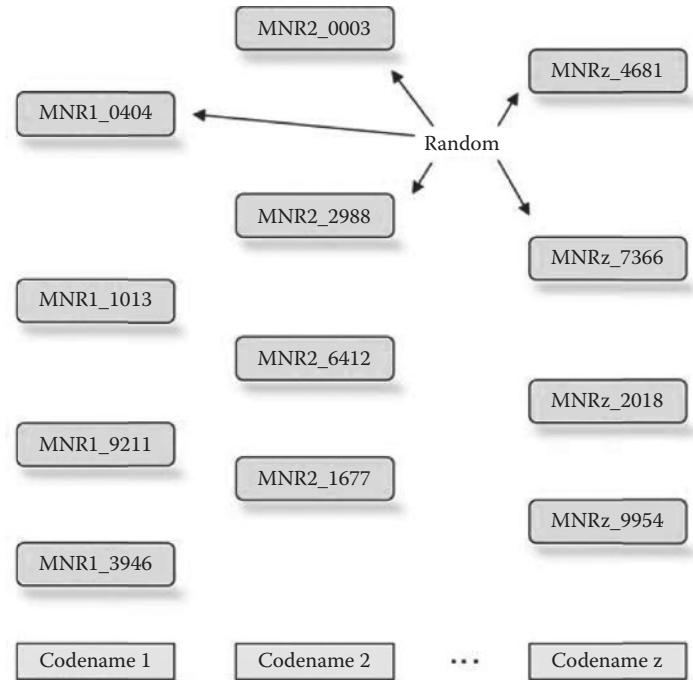

As mentioned already, PROFIsafe uses numbering of PROFIsafe PDUs together with a watchdog timer to check *Timeliness* and Codenames to check *Authenticity* of the transmitted safety process data. Researches have shown that both numbering and Codename require each 32 bits. If both would have had to be transmitted in an *explicit* manner, PROFIsafe would have turned out to be very inefficient with a *trailer* of 13 bytes in total for a few F-I/O bits or bytes! Thus, PROFIsafe uses an implicit manner and includes both the numbering and the Codename in the CRC signature (CRC2) calculation. This does not only save bytes, it also prevents this information from being corrupted during transmission. However, since any CRC securing comes with a certain loss of information, a special method is used as shown in Figure 27.10.

A special procedure, called *MNR-Generator*, creates 64-bit-long elements of an exclusive number sequence based on the individual Codename of the particular F-Device and a pseudo random number generator. The initial elements of the sequence are built as follows:

$$\begin{aligned} \text{CNNR\_64[1]} &= f(\text{constant}, \text{Codename}) \\ \text{CNNR\_64[2]} &= \text{CNNR\_64[1]} \times \text{constant} \end{aligned}$$

The cyclically used elements are built as follows (similar to a Fibonacci sequence):

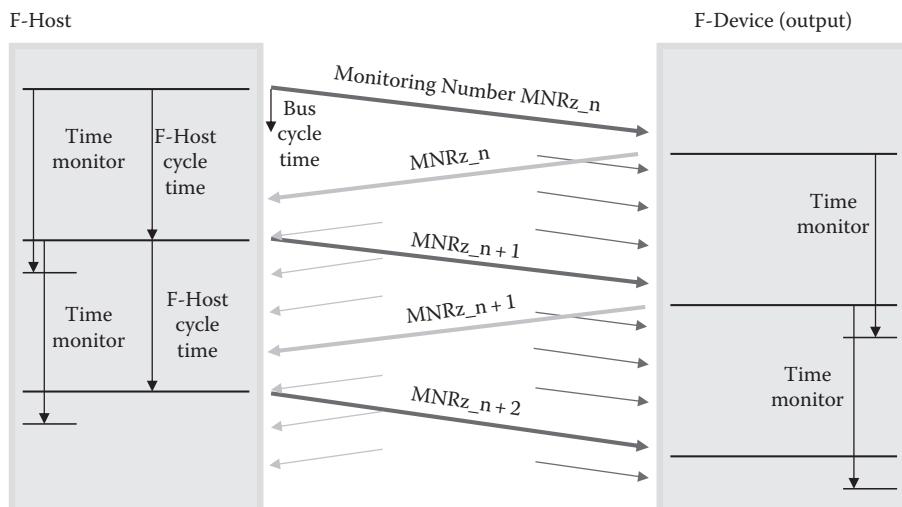

$$\begin{aligned} \text{CNNR\_64[0]} &= \text{CNNR\_64[1]} + \text{CNNR\_64[2]} \\ \text{CNNR\_64[2]} &= \text{CNNR\_64[1]} \\ \text{CNNR\_64[1]} &= \text{CNNR\_64[0]} \end{aligned}$$

**FIGURE 27.11** Principle of the disjoint and random MonitoringNumbers.

The finally used MonitoringNumber (MNR) is built from the 32 most significant bits of CNNR\_64[0]. Details of the procedure are specified in [5]. Figure 27.11 shows the principle of the disjoint MNRs.

The MNR enables the receiver to monitor the vitality of sender and communication link, the *Timeliness* of the safety process data, and the *Authenticity* of the sender in one step. Via the acknowledgment mechanism, it is also monitoring the propagation times between sender and receiver (see Figure 27.12).

**FIGURE 27.12** Mastering propagation times.

## 27.4.8 Synchronization Means (Finite-State Machines)

In distributed systems, a potential failure of the supply voltage of the devices and their subsequent restart is of particular importance. This hazard potential has been investigated and covered using detailed state and interaction diagrams in the PROFIsafe specification [5].

# 27.5 Beyond Functional Safety Communication

## 27.5.1 Safety-Related Programmable Control Logic

PROFIsafe specifies how to connect any type of F-Host to PROFIsafe communications. But it does not dictate how safety-related signals and process values are to be processed within an F-Host. It turned out, however, that programming safety circuits in graphic languages, such as ladder diagram, or function block (FB) diagram according IEC 61131-3, are preferred to any textual language. In the PA world, the representation in the Continuous Function Chart is well accepted. Approved relay-based safety circuits now can be offered as a standard certified software library [6].

There are manufacturers offering the option of retrofitting safety-related user programs for some of their programmable logic controllers (PLCs) with the necessary hardware redundancy (see Figure 27.13).

The functional safety application software has a time diversity structure; it executes in protected areas where it cannot be influenced by the standard application program. Special functional safety I/O modules can supplement the associated standard remote I/O field devices. CNC control systems, too, provide the connection for PROFIsafe field devices.

## 27.5.2 Commissioning and Repair

In order to be able to *address* the individual signals and/or process values during programming, the fieldbus must be *configured* using an engineering tool. During this configuration, the fieldbus participants arrange for their network address, the input/output signal data structures and types, the transmission rate, etc. In case of F-Devices, additional steps are required supplying the F-Parameters to the PROFIsafe layer: Codename, watchdog time, etc. During start-up of the fieldbus network, the F-Host with its associated PROFINET IO controller or PROFIBUS DP master sequentially provides all devices with the necessary parameters including F-Parameters before it starts cyclic operation [7].

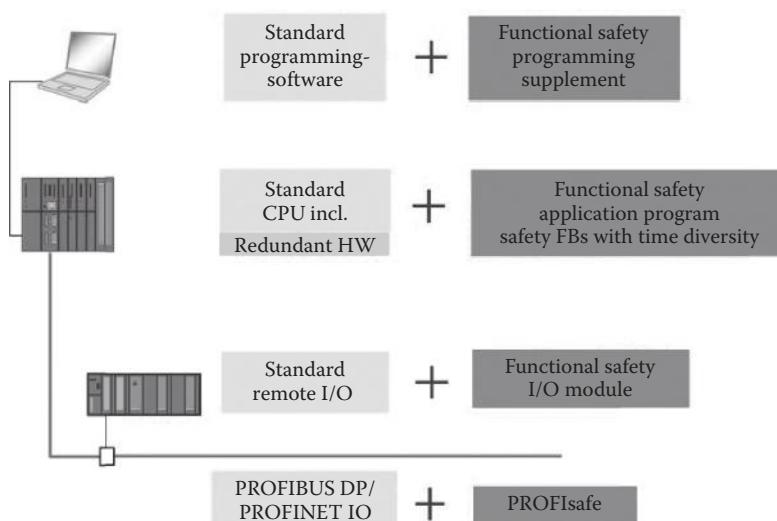

FIGURE 27.13 Possible retrofit options with PROFIsafe.

Caused by the wide acceptance of microcontrollers, various novel devices such as laser scanners and light curtains have turned up in the past even for safety applications that feature a certain complexity and require system support to be able to develop their full functionality. These are, for example, teach-in, rapid device replacement in the event of a malfunction, predictive diagnostics, self-testing and trend analysis, and more.

PROFIsafe has shown ways for mastering these tasks—the so-called three-component model that separates the responsibilities of device manufacturers and system manufacturers by using suitable interfaces. In the simplest case of an F-Device that does not require any technology-related iParameter, a PROFIsafe connection and a corresponding electronic data sheet (GSD file) prove sufficient. A possible example is a level switch. Slightly more effort is required in the case of a safety device with iParameter. It can be connected to a laptop via a separate RS-232, USB, wireless, or other interface. In order to perform diagnostics, it uses a proprietary parameterization and diagnostics program. The program could also be routed to the F-Device using acyclic services of PROFINET IO or PROFIBUS DP that are accessible via the *Tool Calling Interface* [8] or *FDT/DTM* interface technology [9]. Typical representatives of such devices are laser scanner that can be used to protect the entrance to a manufacturing cell. A device manufacturer would have to provide the safety device, a GSD file, and a parameterization and diagnosis program with the appropriate interfaces.

An important customer requirement is the possibility of device replacement without tools in case of faults. PROFIsafe specifies the so-called iPar-Server technology. Figure 27.14 demonstrates the principle steps of the iPar-Server mechanism via an example.

Together with the network configuration and F-Parameterization of an F-Slave/F-Device with the help of the engineering tool, an associated iPar-Server function is instantiated (step 1). The assigned parameterization and diagnosis tool at installation can be launched via an appropriate interface (step 2) from the engineering tool propagating at least the node address of the configured device. Parameterization, commissioning, test, etc., can be executed with the help of the tool (step 3). After finalization, a CRC signature across the iParameter is being calculated and displayed for copy and paste into the entry field of a special F-Parameter (“F\_iPar\_CRC”) within the configuration part of the engineering tool (step 4).

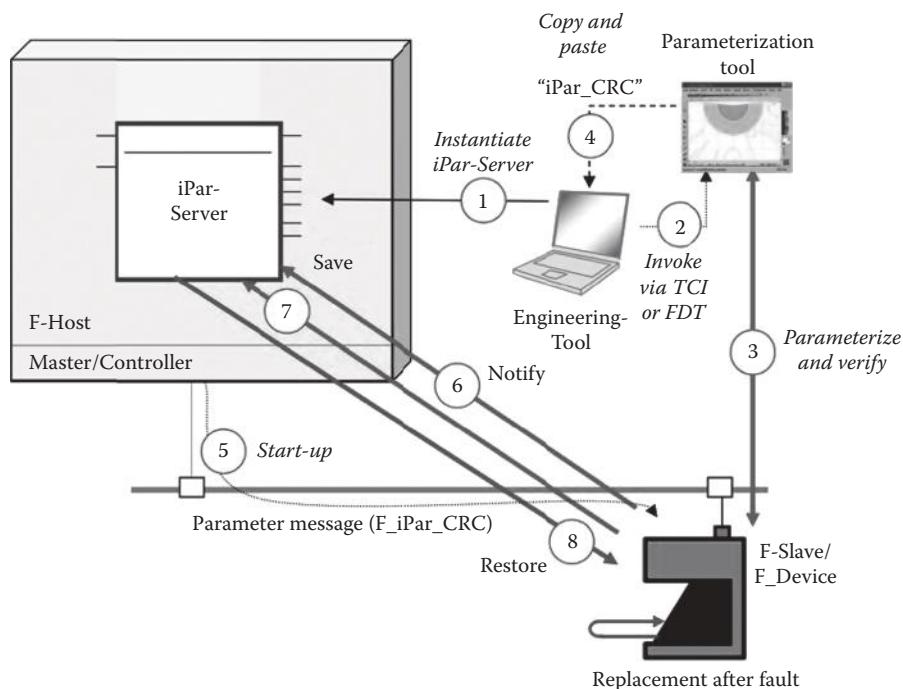

FIGURE 27.14 The iPar-Server for fast device replacement.

A restart of the F-Slave/F-Device is necessary to transfer the “F\_iPar\_CRC” parameter into the F-Slave/F-Device (step 5). After final verification and release, the F-Slave/F-Device is enabled to initiate an upload notification (step 6) to its iPar-Server instance. The iPar-Server is polling the diagnosis information to interpret the request and to establish the upload process (step 7), which stores the iParameters as instance data within the iPar-Server.

In case of the replacement of a defect F-Slave/F-Device, it receives again its F-Parameters including the “F\_iPar\_CRC” (same as in step 5) at the start-up. As iParameters normally are missing in a replacement or nonremanent F-Slave/F-Device, it initiates a download notification (step 7) to its iPar-Server instance. The iPar-Server is polling the notification to interpret the request and to establish the download process (step 8). Through this transfer, the F-Slave/F-Device is enabled to provide the original functionality without further software tools.

The most demanding devices are the ones that require user-program-controlled parameter value assignment during production, in addition to the features mentioned earlier. This requires an additional so-called proxy FB in the controller (e.g., F-Host).

### 27.5.3 Availability

The availability plays a significant role in safety technology. It is a precondition. There is too much of a risk that a frequent—and apparently groundless—*trip* of the safety devices causes the system to shut down (*Bhopal* effect) [10]. There are mainly five areas that influence the availability of a system:

1. Design-assembly of the devices
2. Facility layout and installation
3. Operating conditions
4. Reliability of the components (bathtub curve)
5. Requirements for operator actions

In recent years, most standard automation devices and systems on the market have reached a design and assembly quality standard that ensures high reliability (high meantime between failures). Among the reasons for that are standards, test laboratories, and certifications. However, the availability (up-time in relation to down-time plus up-time) may deteriorate in safety systems that are based on standard systems. Redundant standard components (e.g., two or three controllers) that require synchronization can be the cause. The safety device trips if one component takes longer to execute than the other one due to an external event. This risk exists also in the redundant implementation of sensors whose measured values diverge briefly (discrepancy). PROFIsafe therefore endeavors to support certified (functional safety) F-Devices that take the risk away from the user as much as possible. Standard fieldbus systems, even proven-in-use, without additional mechanisms like PROFIsafe and risk assessments of devices, and the safety functions according to safety standards may not be considered functional safe.

In order to prevent EMI from affecting the operation of a system, the PROFIBUS User Organization have published installation guidelines [11] whose utilization in bidding procedures is recommended, thus creating a clear situation right from the outset. They specify aspects like grounding, shielding, and lightning protection. PROFIsafe makes the satisfaction of these installation guidelines a prerequisite for the operation.

The operating conditions of a system have a strong influence on the reliability–availability. As we all know, a temperature rise of 10 K reduces the service life of an electronic device by 50%. Here, PROFIsafe can merely give recommendations. Devices should be designed for the usage in one of the following zones: office environment, enclosed-type operation within racks, and process participation inside and outside a building.

The means of the *predictive diagnosis* is used in order to avoid unexpected failures toward the end of the service life of a field device. The so-called proxy FBs are provided in the PROFIsafe concept. They can execute, automatically and periodically, test programs in the field device in order to determine its states and the trend (e.g., in electronic shutdown valves that are demanded very seldom). This enables risky units to be replaced at a time when the process is stopped anyway.

The availability of a system is also reduced if the user is unable to handle it properly due to complexity or variety. Solutions with PROFIsafe perfectly fit into the paradigm of fieldbus-based automation systems and thus offer a tremendous risk reduction and increase in flexibility compared to previous solutions. Additional activities on standardization of software user interfaces are complementing the advantages [12].

#### 27.5.4 Status of PROFIsafe-Related Specifications and Guidelines

At Hanover Fair in 1999, the PROFIBUS User Organization had published version 1.0 of the PROFIsafe specification for PROFIBUS DP, followed by version 2.0 in September 2005 incorporating PROFINET IO. Current version 2.6 covers research results on quantitative considerations for the properties of *Timeliness*, *Authenticity*, *Data Integrity*, and CRC behavior in case of the implicit transmission as described in this publication.

All versions have been confirmed by positive reports from the Institute for Occupational Safety and Health of the German Social Accident Insurance (IFA) and the worldwide operating Safety-Assessment Organization (TÜV). Associated guidelines and specifications are described in detail later in this publication. They can be found on the Internet under <http://www.profibus.com> ([14,16,18,20]).

PROFIsafe was internationally standardized in IEC 61784-3-3.

#### 27.5.5 Standards Catching Up

Figure 27.15 shows an overview of the fieldbus and safety-related standards within the context of PROFIsafe.

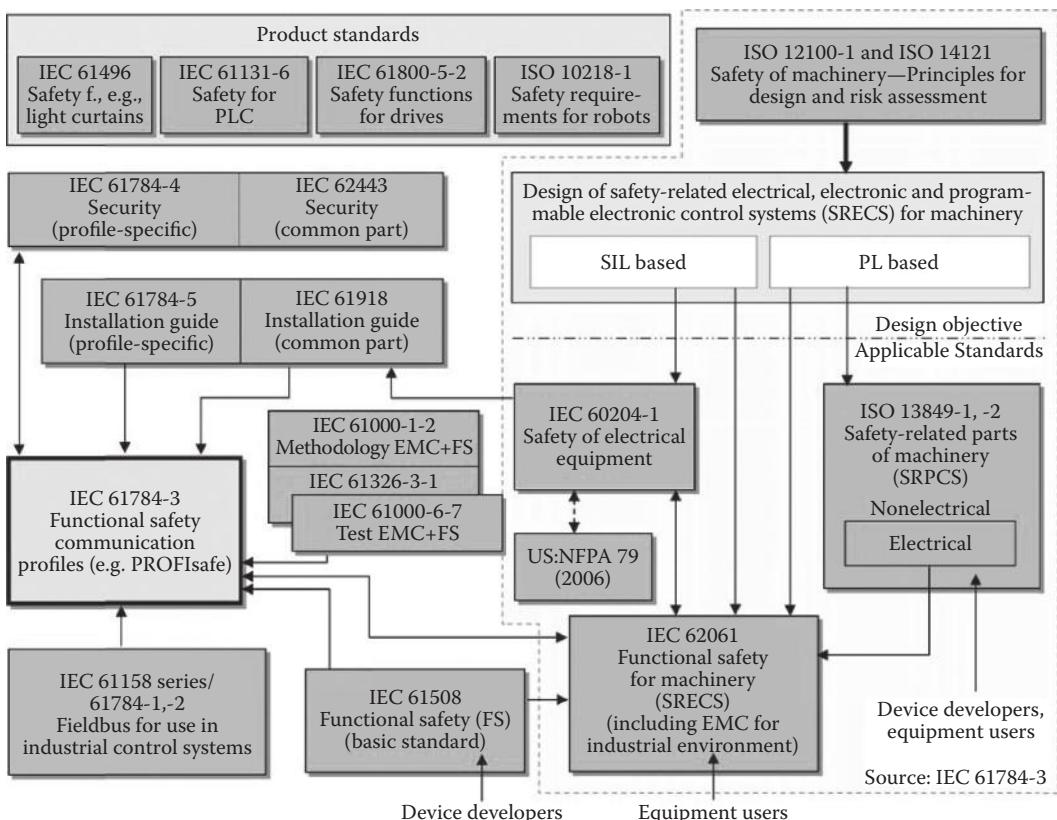

FIGURE 27.15 Relationship between relevant standards for machinery.

The development of PROFIsafe is based on IEC 61508, which focuses on safety functions, on quantitative SILs as opposed to qualitative levels in previous safety standards, and on software development procedures and communication. In order to facilitate the application of the new technology, an IEC 62061 has been created for equipment users, supplemented by IEC 60204-1. The ISO 13849-1 follows the tradition of EN 954. However, it extends its categories by quantitative considerations and introduces performance levels (a–e) instead. It also covers nonelectrical parts of machinery. Recent standards such as IEC 61000-1-2, IEC 61326-3-1, and IEC 61000-6-7 specify the EMC testing procedures and levels. More and more product standards are based on IEC 61508 or ISO 13849-1.

## 27.5.6 Peculiarities for Different Industries

After 15 years and more, PROFIsafe is very well accepted within factory automation. The discussions about the need of using a separate safety bus in addition to the standard fieldbus for the implementation of distributed safety technology are gone in favor of a single cable solution. Many users are following a migration strategy. First, within existing facilities, the new PROFIsafe technology replaces the relay-based safety technology via a second fieldbus segment. At the next opportunity and after some experience, they switch to the combined solution due to the obvious many advantages such as uniform engineering and diagnosis.

Safety applications in process engineering require a consideration that exceeds the functional safety. Pressure and temperature in a process, for example, cannot always be *monitored* independently of each other. A high availability of sensor functions requires a large degree of design skill and experience. To a large degree, the topic of *proven-in-use* plays a large role.

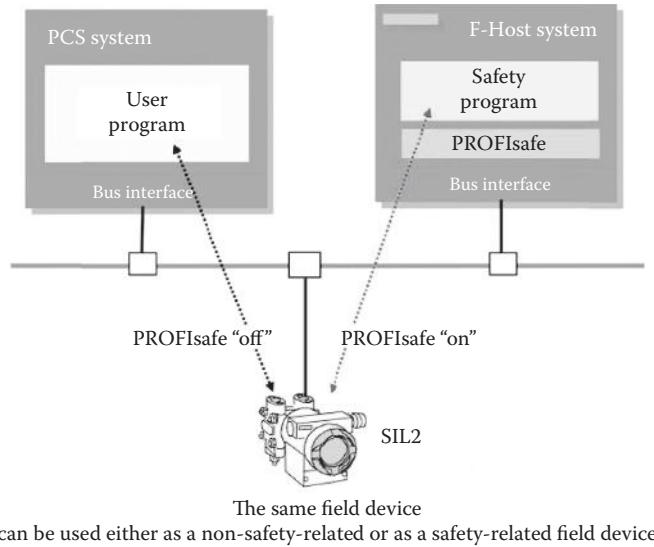

Up to now, the part of the protection equipment—which mostly represents cases similar to SIL2—has been solved with standard field devices and 4–20-mA transmission technique. Communication faults, such as line interruptions or short circuit, were recognizable, the devices were proven-in-use, and safety monitoring was performed in the F-Host system by interpreting redundant signals and voters. In the case of microprocessor-equipped equipment, guidelines like the NAMUR recommendation NE79 defined the necessary prerequisites. These include the proof that the software–firmware has been developed according to generally recognized quality standards. Furthermore, the user expects facilities such as watchdog timer, memory test, and protection against inadvertent parameter changes. The new recommendation NE97, which NAMUR published at the end of 2002, deals with the subject *Fieldbus for Safety Tasks*. Among other things, this recommendation shows two possible solutions that can easily be implemented with PROFIsafe.

A proven-in-use field device, developed according to NE79, connected to PROFIBUS could actually be used for applications up to SIL2, if the possible communication faults that are known in bus operation, such as address corruption, loss, and delay, could be eliminated. As we already know, this is possible, if we employ a PROFIsafe protocol that is implemented in a single-channel manner. In future, this solution permits proven-in-use standard PROFIBUS field devices to be operated in the standard operation mode, or optionally in the safety mode, just by changing a single parameter. The user is at liberty to employ certified products (see Figure 27.16).

In many systems, the installed proven-in-use field devices are retained, and an additional fieldbus wiring is installed via a so-called remote I/O. For this operating mode, too, NE97 provides for a solution.

The PA field devices are usually subject to a strong standardization of device model and device parameters. Parameter value assignment, too, is expected to be as uniform and consistent as possible. To take this into account, PROFIsafe communication has been specified compatibly into the existing *PA device model* [13]. The related specification [14] especially deals with the following topics:

- Switching between standard and safety modes
- Preparation and commissioning phases
- New parameters in the Physical Block of the PA device model
- Safety-related data structures for the cyclic data exchange
- Configuration data

**FIGURE 27.16** PROFIsafe in field devices for process automation.

As already mentioned, the field devices should be usable in the standard mode and in the safety mode. It is planned to achieve this switch by corresponding parameter settings in the related GSD file, and thus during the start-up of the field device.

Due to the contingency that parameters have to be edited during operation, particular commissioning phases have been designed that permit existing parameter assignment tools based on Electronic Device Descriptions to be used [15]. In this case, the parameter assignment usually is performed offline, and the device is sealed by soldering or similar procedures.

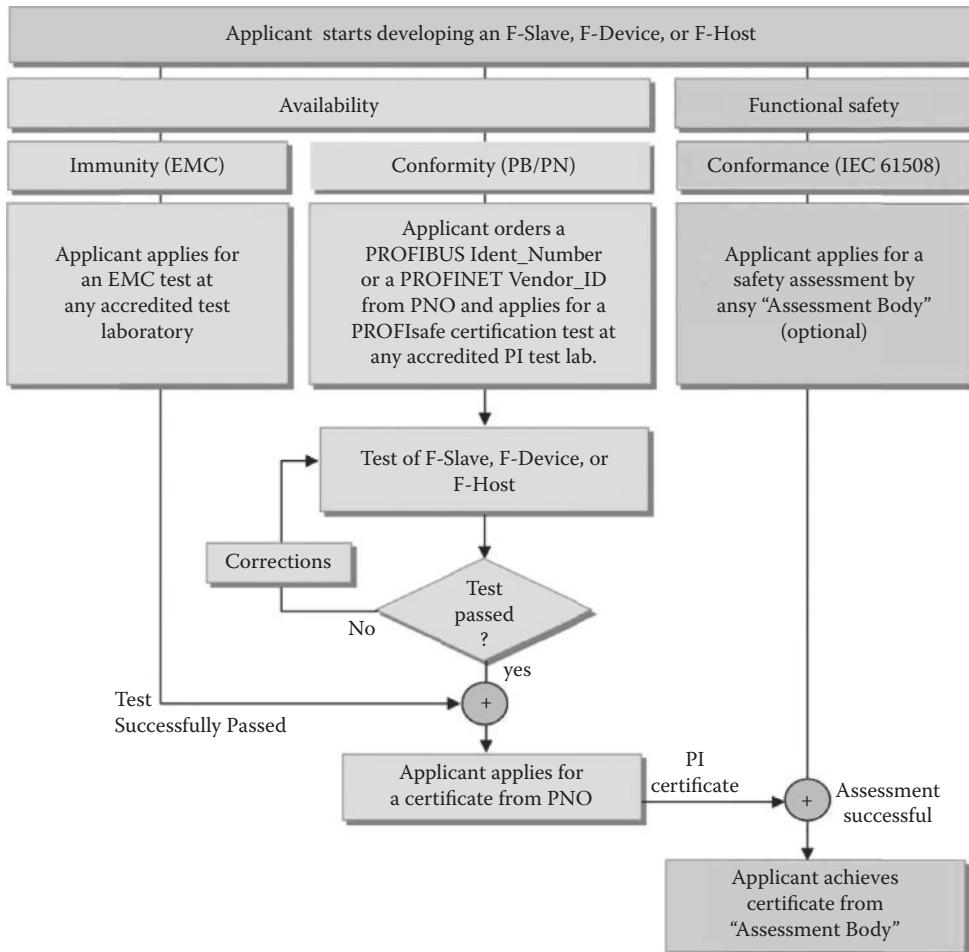

Additional data formats for the PROFIsafe PDU supplement the standardized data formats for the PA device model for cyclic data exchanges.

### 27.5.7 Environmental Conditions

In the meantime, further specifications have been published since most safety standards still ignore field-bus operations. One of these is defining the boundary conditions for safety communications [16]. It deals with the topics of installation guidelines, electrical safety (overvoltage shock protection—SELV–PELV), power supply units, and immunity to EMI. The other is describing a policy for all PROFIBUS member companies and providers of safety-related devices dealing with responsibilities and the quality of products and services [17].

### 27.5.8 Test and Certification

The PROFIsafe mechanisms are based on finite-state machines. Thus, it was possible via a validation tool for finite-state machines to mathematically prove that PROFIsafe is working correctly even in cases where more than two independent errors or failures may occur. This was systematically achieved by generating all possible cases for *test-to-pass* and *test-to-fail* situations. They have been extracted as test cases for a fully automated PROFIsafe layer tester, which is used to check the PROFIsafe conformance of safety-related devices. It is part of a three-step procedure within the overall certification process (see Figure 27.17) [18].

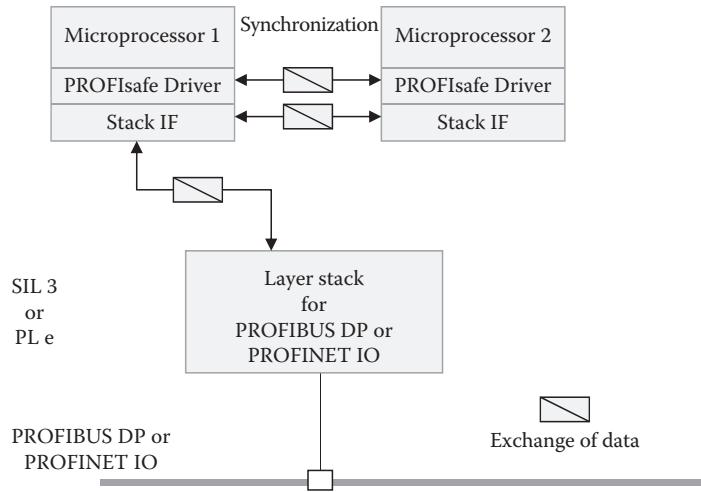

**FIGURE 27.17** The PROFIsafe certification procedure.

### 27.5.9 Development Tools and Support

Using PROFIsafe in factory automation with short reaction times, and—on the other hand—in hazardous areas in PA with lowest power dissipation, places contradictory tasks. Since most modern devices use microprocessors, implementing the PROFIsafe procedure in software is an obvious solution. The operating conditions determine the selection of the microprocessor with respect to high performance or low power dissipation. PROFIsafe, ideally, requires only some kilobytes of free memory: no additional power supply and no additional space in the confined enclosures. PROFIsafe becomes a part or the device-specific safety software.

Immediately after completion of the first specification, the company consortium started a joint development of the *generic PROFIsafe driver software* for F-Devices. Generic in this context means that the driver has been implemented in ANSI-C and according to the encoding rules for safety technology for different microprocessors and C compilers. Although it should preferably be used in dual-channel mode (see Figure 27.18), it may also be used in single-channel mode (see Figure 27.16). A complete development kit (PROFIsafe Starterkit) is available for F-Devices. Upon application for the test at accredited PROFIsafe test laboratories, the F-Device tester software is available for early testing in the development phase.

**FIGURE 27.18** Generic PROFIsafe driver for F-Slaves and F-Devices.

### 27.5.10 Products

A large number of PROFIsafe products are currently available such as safety-related PLCs from more than five renowned manufacturers as well as numerical controllers, remote-I/O for IP20 and IP67, laser scanners, light curtains, door locks, pressure transmitters, motor starters, drives with integrated safety, robots, gas and fire sensors, etc. Worldwide, there are more than 2.5 million PROFIsafe nodes installed.

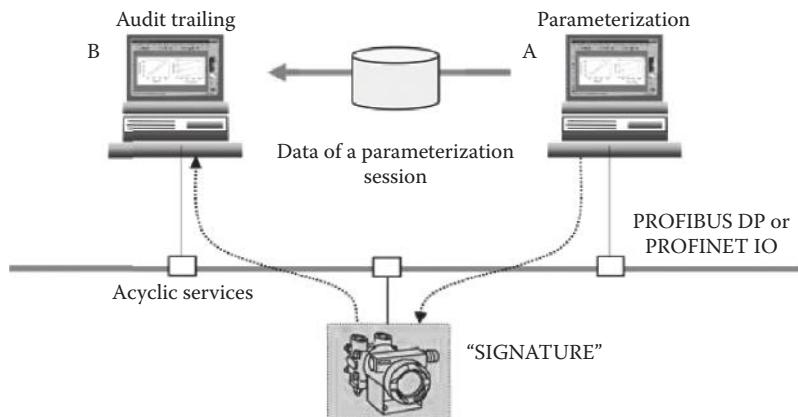

For further actual details, please see [www.profibus.com](http://www.profibus.com) and [www.profisafe.net](http://www.profisafe.net).

### 27.5.11 Prospects

The sophisticated safety-related devices mentioned in this publication with its many possibilities to use iParameters to adapt to all kinds of safety applications in a flexible manner are causing the requirement for continuous automatic monitoring of security, safety, and data integrity. Thus, regulations like 21 CFR 11 [19] defined “rules for the use of secure, computer-generated, time-stamped audit trails to independently record the date and time of operator entries and actions that create, modify, or delete electronic records. Record changes shall not obscure previously recorded information. Such audit trail documentation shall be retained for a period at least as long as that required for the subject electronic records and shall be available for agency review and copying.”

The device-independent Profile Guideline, Part1 “Identification & Maintenance Functions” [20], suggests using asset identification parameters and the parameter SIGNATURE to allow parameterization tools to store a *security* code as a reference for a particular parameterization session. Audit trailing tools can acyclically retrieve the code for integrity checks at any time via the fieldbus (see Figure 27.19). Together with the *asset identification parameters* consisting of MANUFACTURER\_ID, ORDER\_ID, and SERIAL\_NUMBER, the SIGNATURE parameter allows unambiguousness of the session data.

PROFINET IO is gaining recognition on the market. Many car manufacturers are standardizing on PROFINET and PROFIsafe. Due to its *black channel* approach, the PROFIsafe technology can be used on both PROFIBUS DP and PROFINET IO without changes. No matter which one a manufacturer decides to use as the basis, with PROFIsafe, he is on the safe side.

**FIGURE 27.19** Audit trailing for secured safety parameters.

## Abbreviations

CRC	Cyclic redundancy check
DP	De-centralized peripherals
DTM	Device type manager
EMC	Electromagnetic compatibility
EN, prEN	European standard, preliminary...
F, FS	Failsafe or functional safety
FB	Function block
FDT	Field device tool
GSD	General Station Description (electronically readable data sheet)
HW	Hardware
IEC	International Electrotechnical Commission
IF	Interface
IFA	Institute for Occupational Safety and Health of the German Social Accident Insurance
I/O	Input/output
IP	Ingress protection, e.g., IP20
ISO/OSI	International Standards Organization/Open Systems Interconnection (Reference Model)
NAMUR	Association of users of process control technology
PA	Process automation
PB	PROFIBUS DP or parity bit
PDU	Protocol data unit
PI	PROFIBUS and PROFINET International (user organization)
PL	Performance level (ISO 13849-1)
PLC	Programmable logic controller
PN	PROFINET IO
SIL	Safety integrity level (IEC 61508)
SW	Software
TÜV	Safety Assessment Organization

### 28.1 Introduction

SafetyNET p [1] is a communication protocol developed by Pilz GmbH & Co. KG, which allows the construction of industrial Ethernet-based networks and is suitable for both real-time communications and safety-oriented applications. The protocol enables the transmission of safety-related data on the same cable used for the transfer of control or process data. In fact, SafetyNET p makes available a logical safe channel that is certified in accordance with the safety integrity level 3 (SIL 3) of IEC 61508 [2] and can be used to transfer safety data without the need of a physical dedicated communication line.

Combining safe and nonsafe communications over the same medium has several advantages: first of all, the reduced amount of cables needed to connect the network elements makes the wiring of components simpler, thus reducing costs for setup and maintenance. Moreover, the ability of connecting safe and nonsafe devices to the same network makes a number of non-safety-related functions (e.g., remote diagnostic, data logging) available for safe devices and at the same time allows standard devices to access safety data for further non-safety-related processing tasks.

SafetyNET p is a multimaster bus system where all devices are given the same rights, and therefore, it does not require a centralized controller. It has been designed to operate according to a publisher-subscriber model, where each device publishes its relevant data and can subscribe, at the same time, the reception of data needed to carry out its tasks, which are produced by other entities in the network.

SafetyNET p implements two communication models, known as real-time frame line (RTFL) and real-time frame network (RTFN).

RTFL has been designed for fast intracell communications, where real-time performance is of primary importance. It is based on a linear topology, and the transport of data is supported through standard Ethernet (OSI layer 2) frames. This communication model enables a minimum bus scan time of 62.5 µs and limits jitters to 100 ns or less, making the protocol suitable for highly demanding control applications. Low jitter is achieved by means of a specialized synchronization mechanism,

the so-called precise clock synchronization (PCS), which makes the protocol suitable for distributed processing that requires a high level of simultaneity.

When real-time requirements are not so tight and a cycle time over 1 ms is sufficient, the RTFN communication model can be used to obtain the maximum degree of flexibility and integration with other standard Ethernet-based protocols likely adopted at higher levels of the factory hierarchy. In fact, RTFN can use the standard UDP/IP protocol to transport data, allowing both the routing of frames among different networks and the integration with the existing communication infrastructures. RTFN is usually used for communication from cell to cell and for the connection of cells to the office network by implementing star or tree network topologies. Synchronization of RTFN devices and RTFL networks is made possible by means of the precision time protocol (PTP) [3] with the advantage that it is supported by many standard Ethernet components such as switches.

Regardless of the communication model used to transport data, SafetyNET p supports two distinct logical channels: [4,5] the cyclic data channel (CDC) and the message channel (MSC). When devices are actually in operation, most data are transmitted at regular time intervals or, in other words, their transmission is cyclic. CDC is dedicated to this type of information.

MSC is used to transmit acyclic data such as initialization parameters, diagnostic information, and device programming instructions. The interface of applications to the communication system [6,7] is based on the popular CANopen application layer [8].

Since safety data are cyclic in their nature, the safety application layer [9,10] is built on the top of CDC and relies on the black channel concept: the protocol implements a set of safety-related transmission functions and also monitors the integrity of the safe communication channel, so as to ensure that even the tight requirements of SIL 3 are satisfied. With the exception of the actual safe subscribers, for example, safe sensors, safe PLCs, and safe actuators, all other network components such as switches and cables are regarded as non-safety-related and can be standard devices. Such an idea was introduced in IEC 62280-1 [11,12] and basically originates from the railway signaling technology.

Due to its flexibility and completeness, the protocol is suitable for a wide range of applications that span from factory and safe automation to remote control and protection of railway networks.

## **28.2 SafetyNET p Physical Layer**

---

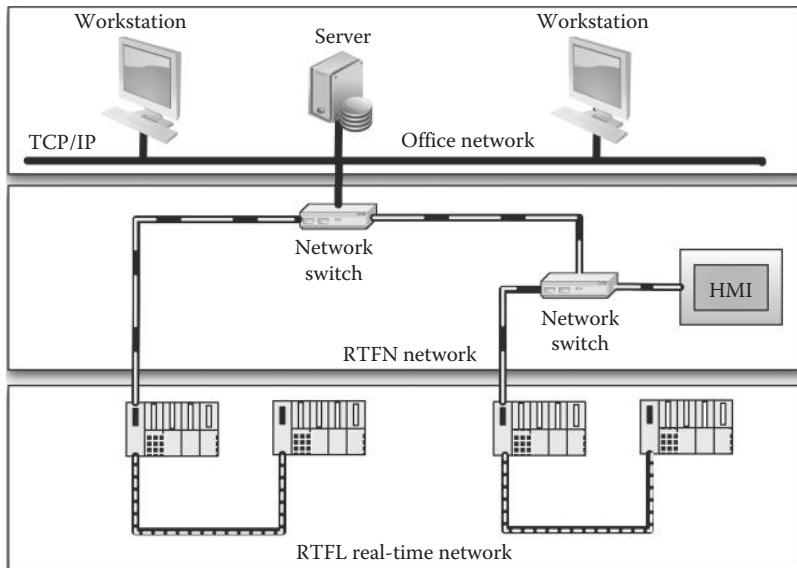

As mentioned before, SafetyNET p specifies two communication variants: RTFL for fast intramachine communications and RTFN for the interconnection of different machines and communications with the office networks. A typical structure of a SafetyNET p network is shown in Figure 28.1.

Both SafetyNET p communication variants are based on the well-known Standard Ethernet IEEE 802.3 technology [13]. Since its invention, Ethernet has been evolving to meet the ever-increasing demand for flexibility and transmission bandwidth. According to the IEEE 802.3 specification, standard Ethernet foresees many possible variants. SafetyNET p relies on 100 BASE-TX, which is the most common 100 Mb/s implementation. This allows the use of standard components and makes compatibility easier (one of the most important reasons for Ethernet-based field communications).

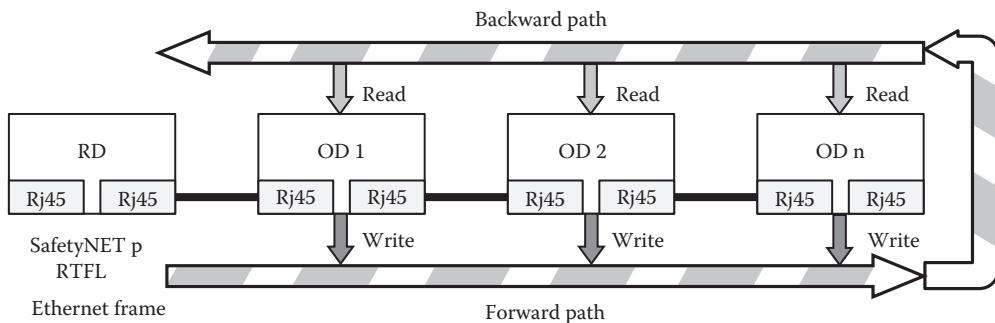

### **28.2.1 RTFL Topology**

For highly synchronized communications with fast process data rates, the use of standard Ethernet hardware is not sufficient. SafetyNET p meets these requirements by using special active components that allow on-the-fly processing of 100 BASE-TX frames. Every RTFL device includes one special component and is equipped with two Ethernet ports that can be arranged in a preferred line topology as depicted in Figure 28.2. Each RTFL device is addressed individually by its predecessor in the line using the MAC address, which is modified on the fly while a frame is being processed.

The basic communication is initiated by a special device called root device (RD). At each communication cycle, RD creates an RTFL Ethernet frame and sends it along the line. All the cascading devices,

**FIGURE 28.1** Typical structure of a SafetyNET p network.

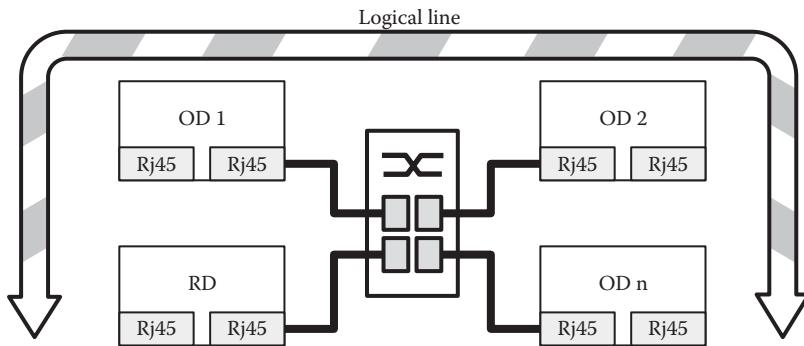

**FIGURE 28.2** RTFL physical line.

also known as ordinary devices (ODs), append their data to the frame. When the frame reaches the end of the line (last device), it is forwarded on the way back to RD. While traveling in this direction, relevant data are then read by the different ODs. Each RTFL network requires just one RD.

Ordinary switches store each frame for the time needed to decide which port has to be used for forwarding. This is necessary in order to avoid collisions when frames, which arrive to the switch at the same time, have to be sent out through the same port. In a linear topology, however, this event cannot occur, and cut-through switches can be adopted without causing problems. By contrast, if a star topology is needed for an RTFL system, store-and-forward switches are required, which introduce additional latencies and jitters. It is worth noting that even if the physical topology is a star as depicted in Figure 28.3, the logical topology is a line also in this case. In fact, each device is enabled to forward the frame only to either its logical successor or logical predecessor, depending on whether the frame is traveling on the forward or backward path, respectively.

During start-up, management frames are exchanged between the bus master and the ODs. After entering the steady-state operating cycle, frames are always sent along the (physical) linear structure, with point-to-point transmissions between any two adjacent devices, but virtually emulating broadcast transmissions where all devices are enabled to access the content of the same frame.

**FIGURE 28.3** RTFL logical line.

The communication efficiency of Ethernet depends on the size of the transmitted frames. For small data, the ratio between the frame header and the payload size is not optimal. SafetyNET p RTFL is designed to minimize the overhead by using frames as common containers for data from all devices. This means, for instance, that a single Ethernet frame (which is processed cut-through with only a small delay) can carry all process data needed by devices. Minimizing header overheads is important to reach cycle times as short as 62.5 µs, which are needed especially in motion control applications.

### 28.2.2 RTFN Topology

RTFN allows SafetyNET p to be used within standard Ethernet networks without the adoption of special hardware. Communication occurs on the top of layers 2 (MAC) and 4 (UDP) and is therefore independent from the physical media.

Standard Ethernet topologies can be used for RTFN as long as they meet the real-time requirements of the application. A typical RTFN use is granting the connection between the factory network and the RTFL subsystems. Devices are then connected to switches or even routers if the communication is UDP-based.

### 28.2.3 Cables and Connectors

The ability to control the connection technology in an industrial environment is a key criterion in gaining acceptance for an industrial communication system among users. Ethernet connectors commonly used in offices can also be suitable in this case. Essentially, three types of connectors are specified for SafetyNET p, but others may be adopted to fit in well with specific application needs.

#### 28.2.3.1 IP20 Connector

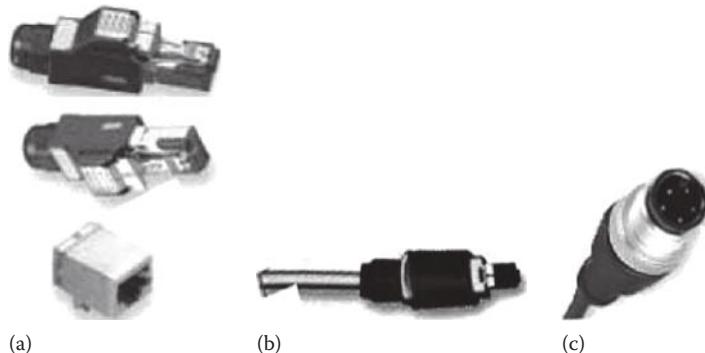

The RJ45 mating interface, which is popular in the office environments (Figure 28.4a), is used in the control cabinets, with a version that has been optimized for the field level. This connector is more robust and easier to install in the field than its office counterpart.

#### 28.2.3.2 IP67 Connector

Two types of connectors are certified for use outside the control cabinet in an IP6x environment, that is,

1. Push-pull connectors with RJ45 mating interface (Figure 28.4b)
2. M12 round connectors, D-coded (Figure 28.4c)

For Gigabit Ethernet also, M12 round connectors X-coded can be used with SafetyNET p.

**FIGURE 28.4** Connectors for SafetyNET p. (a) RJ45 connector, (b) RJ45 push-pull connector, and (c) M12 D-coded.

### 28.2.3.3 Cabling

Cabling of SafetyNET p devices is based on the guidelines published in the IAONA “Industrial Ethernet Planning and Installation Guide” document [14]. IAONA created this guide because the Ethernet cabling strategies, originally conceived for building installations, were unsuitable for production environments. SafetyNET p uses Industrial Ethernet cables, which conform to CAT 5 as a minimum, with an AWG22/7 cable cross section. In this way, it is possible to achieve a maximum cable run of 100 m between any two SafetyNET p devices.

## 28.3 Communication Model

Protocols for RTFL and RTFN have been designed to offer the same set of services for both cyclic data exchanges and acyclic communications [4,5].

For both communication models, two logical channels for data exchange are specified: a CDC to transfer cyclic process data and an MSC to transfer nontime-critical data such as diagnostic information and configuration parameters. Message transmissions on the CDC are not confirmed, while transfers on the MSC can be invoked by means of both confirmed and unconfirmed services.

Logical channels are implemented at the frame level: every SafetyNET p frame is characterized by a 2-byte header field that univocally identifies the logical channel used in the communication. Even if all the frames are transmitted on the same physical line, SafetyNET p devices have the illusion to communicate on two distinct channels.

In addition, SafetyNET p specifies two further acyclic services: a communication management service (CMS) to perform the initialization of a SafetyNET p network and a time synchronization service (TSS) for node synchronization. TSS relies on MSC to carry out its functions and is available only for RTFL-based communications.

Besides differences at the physical layer, as pointed out in Section 28.2, the two SafetyNET p communication techniques mainly differ for both the interaction models adopted in cyclic communications and the way frames are transported.

RTFL is based on a producer-consumer paradigm, where producers make data available to zero or more consumers. In this case, SafetyNET p protocol data units (PDUs) are transported directly in the payload field of standard Ethernet frames as depicted in Figure 28.5. SafetyNET p PDUs carried by Ethernet frames are identified by the value 0x9C40 encoded in the EtherType field. This number, in fact, is the unique identifier that has been assigned to SafetyNET p telegrams by the IEEE EtherType Field Registration Authority [15].

OSI	Layer	Internet	File transfer	E-mail	Precision time protocol	Domain name system	SafetyNET p RTFN	SafetyNET p RTFL
7	Application	HTTP						
6	Presentation		FTP					
5	Session			SMTP				
4	Transport		TCP		UDP			
3	Network				IP			
2	Data link					MAC		
1	Physical					PHY		

FIGURE 28.5 Mapping of SafetyNET p on the OSI model.

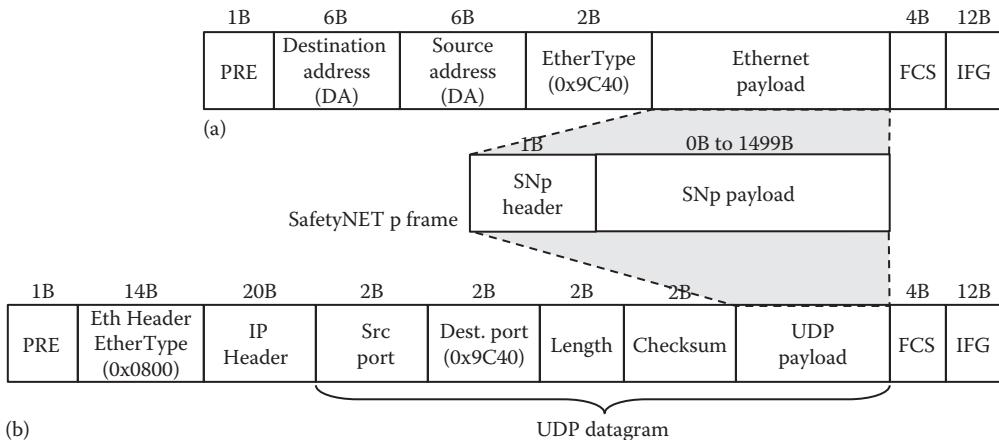

At every communication cycle, RD initiates the data transmission by generating an RTFL Ethernet frame and by sending it to the first OD in the line. Each OD receives the frame from its predecessor, writes its data into the frame, and forwards the frame itself to the next (downstream) OD. Each device knows the MAC addresses of its predecessor and successor in the line and uses this information to correctly forward the Ethernet frame. The last OD device in the line, after writing its data, reads its relevant data (if any) already inserted in the frame by its predecessors and starts the transmission of the frame in the backward direction. On the backward path, each OD reads the relevant data that have been published by other devices and forwards the frame to its predecessor, until RD is reached. In this way, data can be produced and consumed in the same communication cycle. Each communication cycle consists of one MSC PDU followed by one or more CDC PDUs.

RTFN, instead, adopts a publisher–subscriber interaction model for cyclic data exchange, where each publisher makes data available to a group of one or more subscribers. The model relies on CMS to set up the direct links between publisher and subscribers. Subscribers use the CMS *subscribe request* message to join the publication of data of their interest. Publishers confirm any request with the CMS *subscribe acknowledgment* message. Once the direct links have been created, publishers make cyclic data available to subscribers by sending CDC packets (one for each subscriber).

In RTFN, cyclic PDUs can be transported by either standard Ethernet telegrams or by a higher-level protocol such as UDP/IP as depicted in Figure 28.5. SafetyNET p PDUs carried by UDP frames have to be addressed to port 0x9C40, which is the unique port number assigned to SafetyNET p by the Internet Assigned Numbers Authority [16]. The direct MAC frame transport mechanism reduces frame-processing delays, while the transport mechanism based on the UDP/IP protocol has the advantage of allowing communications among different subnetworks even if segmentation is performed by routers. MSC PDUs are transferred only by means of UDP/IP datagrams.

### 28.3.1 General Frame Structure

The general structure of SafetyNET p frames consists of a 1-byte header section and a variable-size payload [5]. The header contains a code that identifies either the logical channel (CDC or MSC) used for the communication or a specific message of the CMS. The content of the payload field depends on the header code, and its size can vary from 0 to 1499 bytes.

**FIGURE 28.6** Mapping of a SafetyNET p frame onto (a) Ethernet frames and (b) UDP datagrams.

In the RTFL communication model, the CDC (CDCL) is assigned the header values 0x02 and 0x03, to write or read the frame to/from the channel (forward/backward direction), respectively. The header values 0x00 and 0x01 identify the MSC (MSCL) for writing and reading messages.

In RTFN, the CDC (CDCN) is identified by the header value 0x60 while the value 0x70 is used for communication on the MSC (MSCN).

The CMS uses a set of messages to perform network initialization and management operations. Each communication model has its own set of services, and each message is identified by its own unique frame header value, since communication management information is transferred with no reference to any logical channel.

SafetyNET p frames can be transported as the payload of either standard Ethernet frames or UDP/IP datagrams, depending on the communication model used to build the network segment. The general structure of a SafetyNET p frame and its mapping onto Ethernet frames and UDP datagrams is shown in Figure 28.6a and b.

### 28.3.2 Cyclic Data Channel

The CDC is used to transfer cyclic process data. The way the protocol implements the data transfer in the CDC depends on the communication model used in the network segment.

In RTFL, the CDC is a reserved section of the Ethernet frames. In RTFN, instead, the CDC is based on a cyclic sequence of point-to-point communications between couples of devices.

CDCN messages can be transported at either the MAC or UDP level. Each publisher knows the IP or MAC addresses of devices that are subscribed to the reception of its messages, so it is able to create several unidirectional communication links (one for each subscriber) to deliver data consequently. Packets transmitted via the CDCN are unconfirmed, and different cycle times can be used for each link. Only a base RTFN cycle time has to be specified, to set a lower limit on the frequency of CDC message transmissions.

In both communication models, each cyclic data is characterized by a packet identifier (PID), which must be unique in the network segment. If a cyclic datum has to be transferred between different networks, its PID must be unique for all the connected segments.

In RTFL, PIDs allow consumers to identify the sections of the cyclic frame containing data they have to read.

In RTFN, each device knows the set of PIDs that other devices in the network are able to publish. Subscribers use this information to request the setup of unidirectional links with those publishers that

provide cyclic data they are interested to receive. Moreover, PIDs enable the correct association of any received cyclic packet with the data it contains.

The structure of the CDCL and CDCN PDUs is shown in Figure 28.7a and b, respectively.

A CDCL frame is identified by a SafetyNET p PDU header value of 0x02 when the frame is transmitted on the forward channel (devices can write) and by a value of 0x03 when the frame is transmitted in the backward direction (devices can read). A CDCN frame, instead, is identified by a SafetyNET p PDU header value of 0x60.

Both CDCL and CDCN PDUs consist of a set of control fields followed by a CDC payload section. The number and meaning of control fields depend on the adopted communication model, while the CDC payload section is identical for both RTFL and RTFN. CDCL PDUs also include an additional status field, which is used to signal if an error has been detected in the FCS field of the Ethernet frame during its transmission.

CDCL control fields are the following:

- *Cycle counter* (2 bytes) identifies the number of the current cycle.
- *Frame counter* (1 byte) identifies the frame number within the actual cycle.
- *Length* (2 bytes) is the length in octets of the *CDC write pointer* field plus the CDC payload section.
- *CDC write pointer* (2 bytes) identifies the write section for cyclic communication.

CDCN PDUs foresee two control fields only:

1. *Version* (1 byte) identifies the version of the CDCN protocol.
2. *Size* (2 bytes) is the size in octets of the CDC payload section.

The CDC payload section is common to both the communication models and consists of a sequence of process data objects (PDOs) as shown in Figure 28.7. Each PDO, in turn, is made up by three fields:

1. *PID* (3 bytes) uniquely identifies the PDO within the network.
2. *Len* (1 byte) is the length of the whole PDO including the *PID* and the *Len* fields.
3. *Data* (*Len*-4 bytes) are the process data being transmitted.

### 28.3.3 Message Channel

The MSC is used for acyclic communications to transmit data concerning diagnostics and/or parameter settings, when timing is not a critical issue. Devices write data into MSC packets, and information is

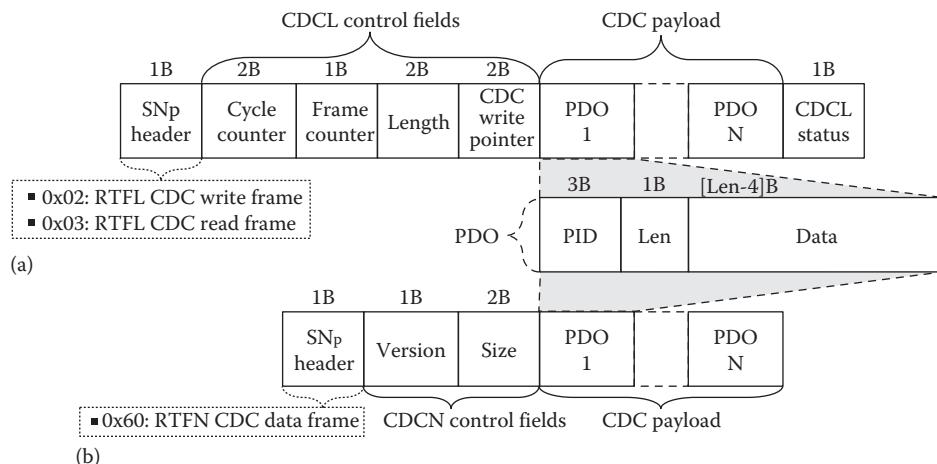

FIGURE 28.7 Structure of CDCL and CDCN PDUs. (a) RTFL CDC frame and (b) RTFN CDC frame.

transferred by means of the MSC message transfer protocol (MSC-MTP). MSC-MTP provides a confirmed service, which implies that the reception of messages is acknowledged of course. MSC-MTP is also in charge of implementing segmented data transmissions in the case the size of the transferred data exceeds a predefined threshold, which is configuration dependent. As for CDC, the implementation of MSC is different for RTFL and RTFN.

When RTFL is used, MSC (MSCL) consists of exactly one frame for each communication cycle. Messages are characterized by a priority that depends on the type of service contained in the message. Three priority levels (from 1 to 3) are foreseen, which are used for bandwidth reservation according to the importance of the message. Priority 1 is the highest level, while 3 is the lowest. The MSCL frame size is configurable, but in the case MSC were not able to accommodate all messages in a single cycle, each OD could reserve additional transfer space for a specific message in one of the following cycles. If more messages require extra transfer space, reservations are made according to the priority of messages.

In RTFN, the implementation of MSC (MSCN) is quite simple. Messages are transferred by means of UDP/IP packets using MSC-MTP without any need of assigning priorities.

MSC-MTP uses six different types of commands to transfer data:

1. *Init frame* is used to initialize a segmented data exchange.
2. *Init fast frame* is used to exchange data without segmentation.
3. *Send frame* is used to transfer a segment of data after the segmented initialization has been performed.
4. *Send last frame* is used to transfer the last segment of data.
5. *Acknowledgment* is used to confirm the reception of data segments.
6. *Abort* is used to interrupt a data exchange.

An MSC-MTP communication session starts with either an *init frame* or *init fast frame* message sent to the destination to propose a handle identifier for the communication session. The communication session is univocally identified by the handle, so that several sessions can be established between the same participants without any risk of ambiguity.

If the size of data to be transmitted is small, the sender invokes the *init\_fast frame* to avoid segmentation. In fact, this request also embeds all data to be transmitted. The destination device responds with an *acknowledgment* message, which contains the proposed handle identifier and the maximum segment size (MSS) the device is able to support. If the communication started with an *init\_fast frame* and the size of the transmitted data is smaller than MSS, the sender is automatically notified that all data have been successfully received and the communication session is closed without the need of any further message.

Otherwise, if segmentation cannot be avoided, the sender uses *send frame* messages to transfer data segments carrying amounts of data smaller than MSS. Any message also contains the *handle identifier* and *byte counter* fields. The destination device sends *acknowledgment messages* to confirm the reception of segments. An acknowledgment is not transmitted on each segment reception, but it is sent only when the amount of data received since the last acknowledgment is larger than a configurable threshold. However, the initialization and last segment messages are always acknowledged, while this never occurs for broadcast and multicast transmissions.

The last segment of data is transmitted by means of the *send last frame* message. Finally, the *abort* message is used by participants to abruptly interrupt the communication session.

The structure of the MSCL and MSCN frames is shown in Figure 28.8a and b, respectively.

An MSCL frame is identified by a SafetyNET p PDU header value of either 0x00 (forward/write direction) or 0x01 (backward/read direction). A 23-byte section follows the header and contains nine control fields, while the MSC data section has a variable size and includes a sequence of MSC-MTP frames. Finally, a 1-byte status field is used to signal if an error in the Ethernet FCS has been detected.

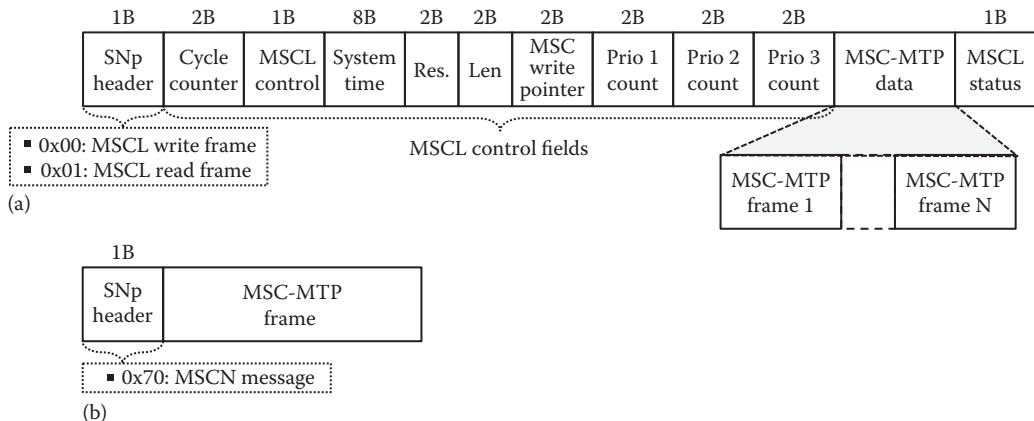

FIGURE 28.8 RTFL and RTFN MSC frame structures. (a) RTFL MSC frame and (b) RTFN MSC frame.

The meaning of the control fields is the following:

- *Cycle counter* (2 bytes) identifies the number of the current cycle.
- *MSCL control* (1 byte) contains control bits to set parameters for the communication. Bit 0 is used to reset previously assigned priorities, bit 1 shows if the line is running in diagnostic mode or not, bit 2 signals whether the PCS clocks are synchronized or a delay measurement is being carried out, and bit 3 is used to know if the local clock is controlled by means of time stamps. The four most significant bits are reserved for future use.
- *System time* (8 bytes) stores the time when the packet was processed by the master clock.
- *Reserved* (2 bytes).
- *Length* (2 bytes) is the length in octets of the *MSC write pointer* header field plus the MSC data section.
- *MSC write pointer* (2 bytes) points to the next write position in the MSC data section.
- *Assigned priority count 1, 2, and 3* (2 bytes each) record how many messages have been assigned to priority levels 1, 2, and 3, respectively.

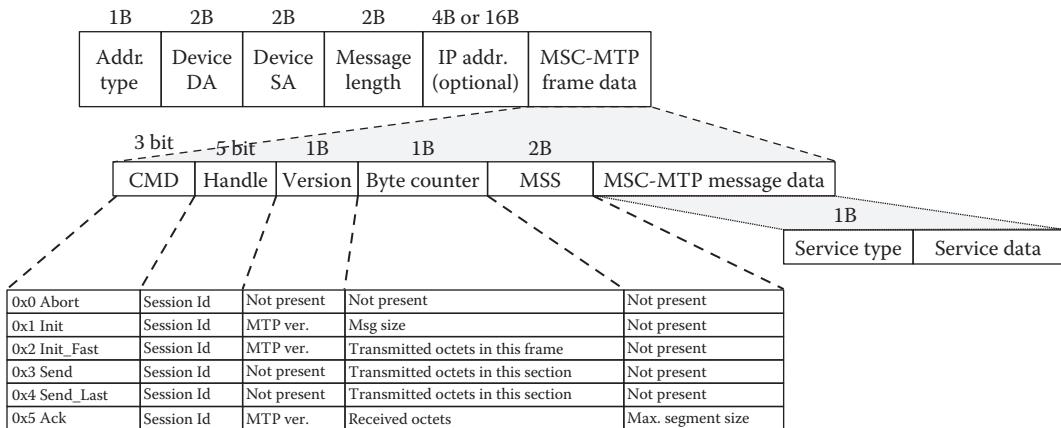

An MSCN frame is identified by a SafetyNET p PDU unique header value of 0x70 followed by one MSC-MTP frame.

MSC-MTP frames are PDUs used by the MSC message transfer protocol for confirmed acyclic message exchanges. The frame structure is shown in Figure 28.9 and is the same for both RTFL and RTFN. The *address type* is an 8-bit field used to store the addressing mode and priority of the message: bits 0 ÷ 2 are reserved and should always be set to 0; bits 3 ÷ 4 are used to encode the priority of the message when the communication model is RTFN; bit 5 is used for the version of the IP protocol (0 for IPv4 and 1 for IPv6), while bits 6 ÷ 7 are used to distinguish between normal addressing mode (00) or extended addressing mode (01 or 10). In the case of extended addressing, the value is used to correctly identify the information contained in the *IP address* optional field.

The *device DA* field (2 bytes) contains the device address of the destination. Special values 0xFFFF and 0xFFFE are used as broadcast and multicast addresses, respectively. In this case, receiving devices do not have to acknowledge the reception of the frame.

The *message length* field (2 bytes) stores the total size of the MSC-MTP frame in octets.

The *IP address* field is optional, and it is used for the source or destination IP address in the case of extended addressing mode, in accordance with the value of bits 6 ÷ 7 in the *address type* field. The size of this field is 4 or 16 bytes, depending on the version of the IP protocol used, as selected by bit 5 of the *address type* field.

**FIGURE 28.9** MSC-MTP frame structure.

The last field, that is, *MSC-MTP frame data*, contains a sequence of subfields and the data section. Subfields are used to identify the type of the MSC-MTP message (*command*), the communication session (*handle identifier*), and the number of data octets that have been transferred since the beginning of the communication section (*byte counter*). The data section (MSC-MTP message data) contains data that are being transferred.

### 28.3.4 Communication Management

The SafetyNET p specification also includes services to initialize and manage the communication. CMSs make use of a specific set of messages that are transferred independently of the protocol logical channels. Each RTF model has its own CMS set of messages, due to the differences in the physical layer and in the way devices transfer data.

In RTFL, CMS are used to set up the communication (physical or logical) double line and to check the device parameter settings. Messages belong to two different classes: network verification and network configuration.

The two most important messages of the network verification class are the *RTFL network verification prepare* and the *RTFL network verification information*. The first message is sent by RD to initialize ODs and to signal that network configuration messages are going to be sent. This message is identified by the value 0x10 in the SafetyNET p frame header and contains a 2-byte sequence number followed by the MAC address of RD.

The *RTFL network verification information* message is used by devices to transmit their status, configuration parameters, and hardware information. This message is identified by a SafetyNET p frame header value of 0x12, followed by a 2-byte sequence number and an *identification data* section. The *identification data* section contains several information fields concerning hardware identification and device status (serial number, vendor ID, product and revision number, status of the physical link, and supported communication models), configuration (symbolic device name, IP configuration parameters, and MAC addresses of both the device and its predecessor), and supported roles (RD, OD, gateway, and switch). The reception of both types of messages mentioned earlier is confirmed by means of a *network verification acknowledgment* message, identified by a SafetyNET p frame header value of 0x13, which contains the sequence number field followed by the same header value as the message that is being confirmed.

The network configuration message class is used by RD to set up the communication line and configure the ODs with functional parameters. Only two messages belong to this class, that is, *RTFL*

*configuration message* and *RTFL configuration acknowledgment*. The former allows RD to configure the ODs, while the latter is used by the ODs to confirm the correct reception of the configuration parameters. The *RTFL configuration* message is identified by the value 0x20 in the SafetyNET p frame header and contains a 2-byte sequence number followed by a *configuration data* section consisting of several fields:

- *Previous MAC address* (6 bytes): is the MAC address of the previous (upstream) device in the line.
- *Next MAC address* (6 Bytes): is the MAC address of the next (downstream) device in the line.
- *Next MAC alternative* (6 bytes) is the MAC address of an alternative successor.
- *Device address* (2 bytes) is the logical address of the device in the line.
- *MSCShortMsgSize* (2 bytes) is the maximum message size for not segmented transfers.
- *Number of frames* (1 byte) is the number of frames for CDC- and MSC-based communications.
- *Cycle time* (4 bytes) sets the period of the communication cycle.
- *RTF timeout* (4 bytes) sets the timeout interval for assuming that not received massages have been lost.
- *Master clock DA* (2 bytes) is the logical address of the device that acts as the master clock.
- *IP configuration section* is a set of fields containing information about the device IP address configuration (IPv4/v6 address, subnet mask, DNS servers, and so on).

The *RTFL configuration acknowledgment* message is identified by a SafetyNET p header value of 0x21 and contains only a 2-byte sequence number.

RTFN CMS adopts two sets of messages: the *RTFN scan network* set, which is used by the protocol to retrieve information about the status of devices, and the *RTFN connection management* set, which is used to initialize and manage links connecting publishers and subscribers.

*RTFN scan network* consists of two messages. The first one, *RTFN scan network read request*, is broadcast to query the status of the network devices. The structure of the message is very simple: It consists of a SafetyNET p frame with a header value of 0x80 and no additional field. The second message, *RTFN scan network read response*, is the reply of any device in the network to the broadcasted request. The message is a SafetyNET p frame identified by a header value of 0x81 and contains an identification data section with the same structure as the *RTFL Network verification acknowledgment* message.

The *RTFN connection management* set consists of five messages: four of them are needed to set up and destroy communication links between publishers and subscribers, while one message is used by subscribers to notify publishers that the link is still active.

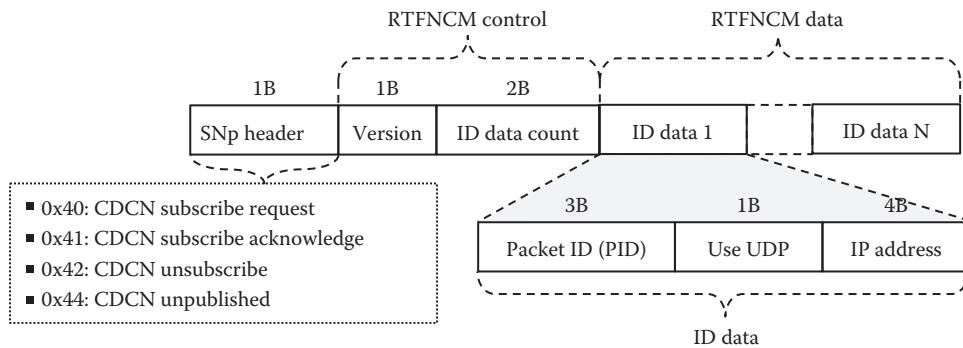

The structure of messages used to set up and destroy communication links is shown in Figure 28.10. The message type depends on the content of the SafetyNET p frame header and the possible meanings are the following:

- *0x40*: the message is a *CDCN subscribe request*. It is used by devices to request the subscription of PDOs published by a specific device.
- *0x41*: the message is a *CDCN subscribe acknowledgment*. It is used by a publisher to confirm that a subscription request has been accepted.
- *0x42*: the message is a *CDCN unsubscribe request*. It is used to unsubscribe the reception of some PDO.
- *0x44*: the message is a *CDCN unpublished*. It is used by a publisher to inform its subscribers that some PDOs will not be published anymore.

The payload of the RTFN connection management frame consists of two control fields and one data section.

The control fields are used to store the version of the CDCN protocol (1 byte) and the number of *ID data fields* that are present in the next frame section (2 bytes).

The *RTFNCM data* section is a sequence of *ID data* elements listing the PDOs to be managed.

**FIGURE 28.10** RTFN connection management frame structure.

Each *ID data* element has a 3-byte *Packet ID* field that contains the PID of the PDO, a 1-byte *Use UDP* field to decide whether pure MAC frames or UDP/IP datagrams are used, and a 4-bytes *IP address* field that contains the address of the subscriber as depicted in Figure 28.10.

To monitor the status of the connection link between a publisher and its subscribers, the *CDCN connection still alive* message is used. The frame header is 0x43, and there are no other data. The message is cyclically sent by subscribers to publishers. The cycle time is configuration dependent and can be different with respect to the period used to transmit process data on CDCN.

### 28.3.5 SafetyNET p Application Layer

All services provided by any SafetyNET p device are made available to the user via the application layer, which is based on the CANopen specifications [8].

In general, different devices have heterogeneous working states, and this implies different communication functions. Roughly speaking, communication functions can be subdivided into two main classes concerning parameterization, also referred to as service data and process data transfer, respectively.

#### 28.3.5.1 CANopen Application Layer in SafetyNET p

CANopen [8] is a nonproprietary open fieldbus standard, specified and standardized by the CAN in Automation organization, which includes the definition of an application layer for industrial applications.

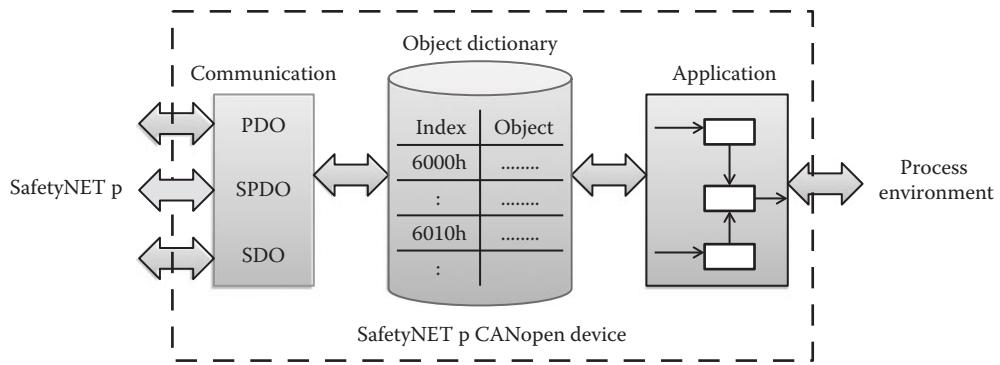

CANopen includes specifications for both communication, to enable networking of distributed automated field devices and application objects based on device profiles.

Device profiles specify functions and parameters/objects for different application areas and automated device groups. This grants compatibility and interchangeability between devices of different manufacturers.

Since device profiles are not bound to a specific communication medium, they are reusable (and have been reused) in SafetyNET p too. This choice has the twofold advantage of providing the system developer with *application interfaces* equivalent to CANopen and enabling manufacturers to reuse device profile-based applications, projects, and developments for SafetyNET.

The SafetyNET p base element inherited from CANopen is the object dictionary (ODIC), which acts as an interface between the application and the communication subsystems as shown in Figure 28.11. Essentially, ODIC is a technique to group objects in a device and specify uniform communication/device parameters, data, and functions that are then stored and retrieved using objects.

Transmission of process data is taken into account in a device ODIC by means of PDOs. ODIC access from other devices is obtained through service data objects (SDOs) that enable reading/writing information from/to remote device ODICs.

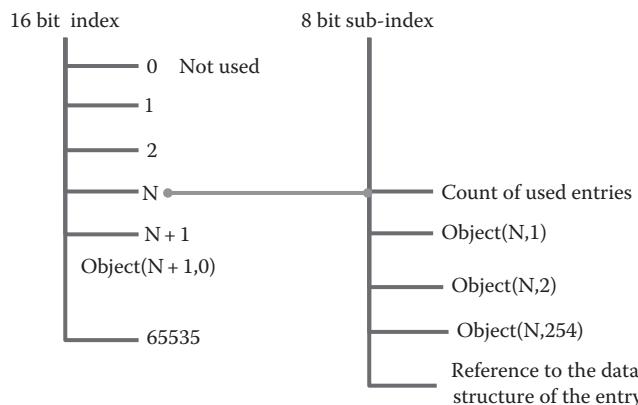

**FIGURE 28.11** Interfacing of the communication and application subsystems by means of the object dictionary.

The dictionary is organized in a logical structure as shown in Table 28.1, while a logical referencing scheme is used for accessing the ODIC as depicted in Figure 28.12.

Each ODIC can contain up to 65,536 objects selected with a 16-bit index. The index, in turn, may include an additional 8-bit subindex that allows the definition of complex object structures such as records and arrays. When this feature is not needed, the subindex value is reset to zero, and the whole

**TABLE 28.1** Object Dictionary Structure

Index (hex)	Object
0001h—001Fh	Basic data types
0020h—003Fh	Complex data types
0040h—005Fh	Manufacturer-defined data types
0060h—007Fh	Device profile-specific basic data types
0080h—009Fh	Device profile-specific complex data types
00A0h—0FFFh	Reserved
1000h—FFFFh	Communication profile section
2000h—5FFFh	Manufacturer-defined profile section
6000h—9FFFh	Standardized device profile section
A000h—BFFFh	Standardized interface profile section
C000h—C8FFh	SafetyNET RTFN interface profile section
C900h—FFFFh	Reserved

**FIGURE 28.12** Object dictionary addressing scheme.

object is managed as a basic type (i.e., integer, Boolean, and so on). Otherwise, the subindex 0 contains the number of elements (subentries) in the object structure. Each subentry, in turn, can be a different basic type.

Process data communication is handled by PDOs in SafetyNET p too. PDOs are logical data containers transferred between SafetyNET p devices over either RTFN or RTFL. PDOs encapsulate application objects referenced in the ODIC.

In RTFL, PDO communication is typically cyclic over the CDC logical channel. Event-driven acyclic transfers for PDOs are allowed as well, thus it is possible to transmit PDOs using either CDC or MSC.

The transmission of PDOs always requires a configuration on both the producer (transmit PDO-TxPDO) and consumer (receive PDO—RxPDO) sides. PDO communication parameters define the communication behavior with respect to the communication subsystem. PDO mapping parameters define the content of each PDO and must include one application object at least.

The length of a PDO is application dependent and is stored in a suitable mapping parameter.

As in CANopen, SafetyNET p grants remote access to the ODIC by means of SDOs. SDOs can be used, for instance, to read or write the PDO configurations.

SDO addressing is obtained by specifying the address of the remote device, the index, and the sub-index of the object to be accessed. In order to provide concurrent SDO service processing in a device, SafetyNET p extends the CANopen SDO services with a job identification.

SDOs are important, in particular, during the configuration phase, where a SafetyNET p device can be configured completely, depending on what entries are made available in the device's ODIC. SDOs can also be used in normal operation, for instance, for status queries.

The SDO communication is based on the client–server model and is implemented using a point-to-point link between two devices. This is why an SDO is always transferred over MSC in SafetyNET p.

The transmission of an SDO message is a confirmed service, and an abort service is also provided to notify any SDO communication error.

Devices can send diagnostic events using the emergency (EMCY) service, which broadcasts standardized messages using either RTFL or RTFN. Diagnostic messages can also be transmitted directly to a specific device.

The heartbeat service allows to monitor the state of communication partners. A heartbeat producer generates a signal that is received by the heartbeat consumers. Each heartbeat consumer can configure its ODIC to select the heartbeat producers to monitor. When the heartbeat is not received, an event is generated at the heartbeat consumer. The heartbeat packet is cyclically sent using the same PDU as for PDO transfers.

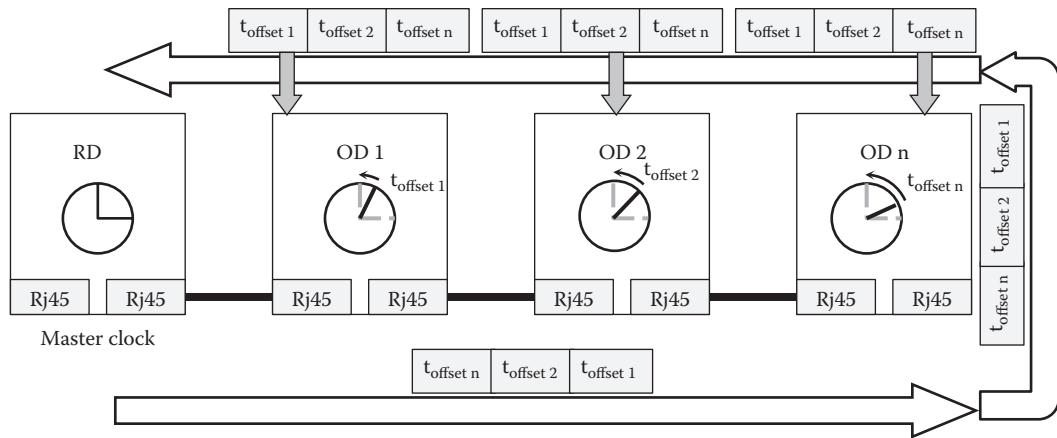

## 28.4 Precise Clock Synchronization

---

Synchronous operations of devices across the network (as needed, e.g., in motion control applications) imply synchronized clocks. In RTFN, this can be achieved by implementing standardized protocols as defined, for instance, in the IEEE 1588 (PTP) specifications [3].

In RTFL, because of the cut-through frame-processing mechanism, a dedicated clock synchronization technique is necessary. SafetyNET p provides suitable configuration and control services to this purpose to be used with RTFL. The PCS protocol is based on a master clock that has to be located in the first device of the line. The master clock then delivers the time base for synchronization to the ODs as shown in Figure 28.13.

When the line is started up, the master clock propagates the current system time to all other devices. As the frame is delayed by a constant amount of time due to processing in each device, the overall transmission time increases during the propagation. The delay is measured in each direction by an internal time-stamping unit included in each device. The bus master, which is aware of the line topology, requests the measured delays to all devices and computes the individual offsets accordingly. The devices,

**FIGURE 28.13** Precise clock synchronization scheme.

in turn, adjust their internal clocks by using the offsets received from the master. The delay measurement procedure is initiated automatically by the bus master when the line is set up. The PCS protocol uses MSC to transfer messages.

## 28.5 Safety Communication Model

A safety system is in charge of detecting faults to prevent failures of critical processes that could cause injuries or damages either to people health, environment, or plant components. Any system that has been designed to deal with safety-related functions is a safety system (e.g., emergency stop procedures, and fire and gas detection systems). When the safety system detects a fault, it must bring the plant to a safe state as soon as possible, for instance, by stopping processes in the affected portion of the system and/or starting emergency procedures (e.g., controlled shutdown of machineries, activation of alarms, or fire protection measures). Networks and protocols in safety systems play a key role because they are in charge of transferring information from safety sensors to safety controllers and from controllers to actuators. The safety protocol must ensure a high integrity level of transmitted data as well as provide a set of measures to monitor the reliability of the communication channel.

For example, an emergency stop system can be built as a distributed application: the emergency button could be placed far from the event controller, and actions on several portions of the plant could be necessary in the case the button were pressed. Such a safety system should ensure that, when the button is pressed, the information is transferred to the controller (e.g., a PLC) and then to the actuators that are in charge of stopping the controlled machineries. The key difference between a standard and a safety system is that, in the latter case, the information about the status of the emergency button is regularly transmitted to the controller and then to the actuators. In the case an anomaly is detected by one of these components (communication error or failure of an element in the safety chain), the system must be brought to the safe state, even if the emergency button has not been pressed.

Even if it might appear counterintuitive, neither redundant physical transmission paths nor dedicated communication lines are strictly necessary in order to set up a safety network. The approach commonly adopted to set up safe communications over conventional networks is based on the concept of black channel that originates from the railway signaling technologies and was introduced in IEC 62280-1 [11,12]. In practice, a safety layer is added on top of the conventional communication stack, that is, over the application layer. The safety layer implements the safety-related transmission functions and also monitors the integrity of the communication channel so as to ensure that the requirements of functional safety are satisfied. This technique has two main advantages: first, the conventional and inexpensive transmission

technologies used in industrial networks can be adopted, and second, both safety and non-safety-related devices can be connected to the same network. The latter aspect also offers the advantage of a full integration of safety and non-safety-related functions that could be exploited to reduce the risk of failures.

Functional safety is dealt with in the IEC 61508 standard [2]. The standard defines the set of communication errors that a safety function must be able to detect and suggests several measures that can be implemented by the protocol in order to detect communication errors. Moreover, the standard defines four SILs, each one characterized by a maximum failure probability of the safety function that must be guaranteed. Level 4 has the most demanding requirements, and it is applied to extremely critical processes such as nuclear plant controls. SIL 3 is the level commonly adopted for industrial control and process applications. This level requires that the probability of failure in high demand rate (i.e., when the system operates continuously) falls between  $10^{-8}$  and  $10^{-7}$  failures per hour. In low demand rate (i.e., when the system operates on demand), the probability of failure has to be comprised between  $10^{-4}$  and  $10^{-3}$  in order to satisfy SIL 3 requirements [17].

### 28.5.1 Black Channel Approach in SafetyNET p

SafetyNET p has been designed to support safety-critical communications on the same network infrastructure used to transfer control and process data, thus making the protocol suitable for safety-oriented applications [10]. The protocol makes available a safe communication channel built on top of CDC that depends on neither the used communication model (RTFL/RTFN) nor the transport layer. The safety channel satisfies the strict integrity requirements of SIL 3. The approach used by the protocol to transmit safety-related data on a conventional communication line is based on the concept of black channel, as depicted in Figure 28.14.

The safety layer is built on top of the application layer. Depending on the nature of the information that has to be transferred, the CDC packet section of the SafetyNET p PDU contains either PDOs for standard cyclic communications or safety process data objects (SPDOs) for cyclic safety-related data exchanges. In the same way, acyclic messages contain either SDOs or safety service data objects (SSDOs), for standard and safe transfers on MSC, respectively. The underlying protocol layers are not aware of the kind (standard or safe) of information that is being transmitted and do not need to implement safety-related functions.

The same principle can be applied to all devices used to build the network infrastructure, such as cables, switches, routers, and so on. These devices are only aware that SafetyNET p frames are transmitted (at either the UDP or Ethernet level), but they do not need to know what kind of data a frame is actually transporting, to carry out their interconnection functions as expected. In this

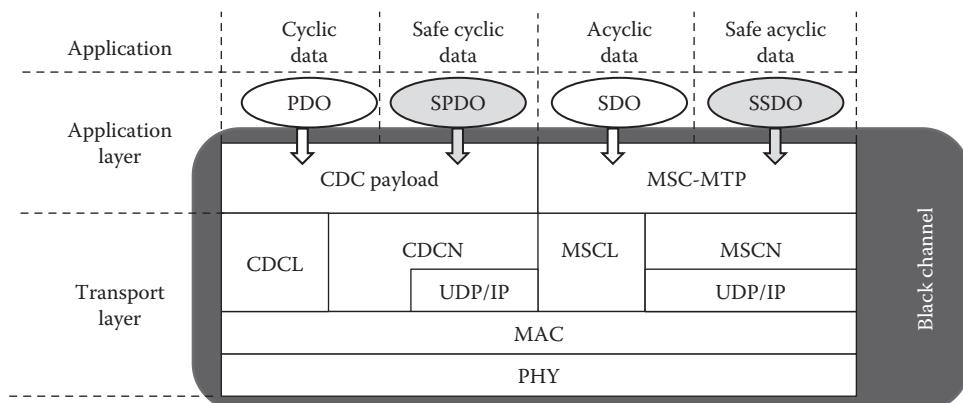

FIGURE 28.14 SafetyNET p black channel implementation.

way, with the exception of the actual safe bus subscribers such as safe sensors, safe PLCs, and safe actuators, all the other network components are considered as non-safety-related devices and are not required to implement any kind of safety function or specific integrity check. The safety layer itself implements a set of detection measures to verify the integrity of the transmission channel and to discover communication errors related to failures in devices used to set up the network infrastructure.

### 28.5.2 SafetyNET p Error Detection Mechanisms

The IEC 61508 standard defines the communication errors that must be detected by the safety layer as well as a set of detection measures that can be implemented by the protocol to cope with such errors. SafetyNET p is able to cope with the following nine types of communication errors:

- *Corruption*—messages may be corrupted due to either errors on the transmission medium or failures in the hardware of devices (even non-safety-related devices) that participate in the communication.
- *Unintended repetition*—due to errors on the communication channel or failures in devices, old messages are transmitted more than once and out of time.
- *Incorrect sequence*—due to errors on the communication channel or failures in devices, the natural sequence of messages transmitted from a particular source is altered.
- *Loss*—due to errors on the communication channel or failures in devices, either a message or an acknowledgment is not received.
- *Unacceptable delay*—messages must be received within a predefined deadline, but they can be delayed during transmission due to several reasons such as congestion of the communication channel, interferences, processing, and management operations carried out by network devices (e.g., switches, bridges, and routers).
- *Insertion*—because of faults, errors on the communication line, or malicious attacks [18], a message that is not related to any expected sender is injected in the network and received by a safe device.
- *Masquerade*—because of communication errors, faults, or malicious attacks [18], a non-safety-related message is treated as safety relevant by the receiver. For example, when safe and standard data are transmitted on the same communication line, an altered standard message could appear as a safe one.
- *Addressing*—due to faults or errors on the communication line, a safety-related message is sent to a wrong destination that considers the message as valid.
- *Revolving memory failures within switches*—failures in the internal memory of switches can cause the forwarding of altered frames in a way that they are still considered as valid by safety-related devices.

Safety NET p introduces a set of techniques that are used to detect the types of communication errors listed earlier. Mechanisms are implemented by means of both additional data fields and additional specific messages used by the protocol when data are transferred on the safe channel. In particular, the SafetyNET p specification includes the following:

- *Sequence number*—an additional sequence number field is adopted for transmissions of SPDOs.
- *Timeout*—the time elapsing between any two messages received consecutively is checked by safety-related devices, and in the case it exceeds a predetermined threshold, an error occurrence is assumed.
- *Connection ID*—an additional identification field is introduced in SPDO transmissions in order to identify the sender of a frame without any ambiguity.

**TABLE 28.2** Communication Errors and Detection Mechanisms

Communication Errors	Safety Measures				
	Sequence Number	Timeout	Connection ID	Data Integrity Assurance	Diff. Data Integrity Assurance
Corruption	—	—	—	X	—
Unintended repetition	X	—	—	—	—
Incorrect sequence	X	—	—	—	—
Loss	X	X	—	—	—
Unacceptable delay	—	X	—	—	—
Insertion	X	—	X	—	—
Masquerade	X	—	X	—	X
Addressing	X	—	X	—	—
Revolving memory failures within switches	X	—	X	X	—

- *Data integrity assurance*—a cyclic redundancy check (CRC) field is introduced to verify the integrity of SPDOs. Moreover, some relevant fields of each SPDO are duplicated to allow cross-checking between the two copies of the received data.
- *Different data integrity assurance*—the same CRC field introduced for data integrity assurance is also used as a detection measure. Different data integrity checks are aimed at detecting standard data that, for some reason, are received modified in such a way that could make devices interpret them as safe data. To reduce the probability of this event, a common approach is a diversification of the CRC calculation method (e.g., algorithm and generator polynomials) among the two classes of data. Since SafetyNET p does not use any CRC when standard data are transmitted, different data integrity is ensured by the CRC introduced for normal data integrity.

Table 28.2 shows the relationships between the types of communication errors for safe data transmissions and the detection measures implemented by the SafetyNET p protocol.

### 28.5.3 Safety Communication Layer

The safe channel is mainly built on top of the standard CDC, since safe data are cyclic in their nature. The MSC is used only to send parameters concerning the configuration of the safety functions by means of SSDOs. Since this kind of communication is not critical, no particular check is needed about the integrity of MSC. The only action taken by SafetyNET p for MSC communications is the protection of SSDOs by means of a CRC field.

The general structure of a cyclical safety PDU is identical to the one used for standard CDC communications. The difference between the standard and safe channels is in the format of the CDC payload section.

In the case of standard communications, in fact, CDC is used only to transfer process data by means of PDOs.

In the case of safe communications, instead, either SPDOs or safety heartbeats (SHBs) are transmitted via CDC. As explained in the previous sections, SPDOs are used to transmit safety application data, while SHBs are used to synchronize the communicating devices and to monitor delays on the communication channel.

#### 28.5.3.1 Safety Process Data Objects

Figure 28.15 shows the typical structures for PDOs, SPDOs, and SHBs. The structure of standard PDOs has already been discussed in Section 28.3.2.

	3B	1B	[Len-4]B									
Standard PDO	PID	Len	Data									
Safety PDO (SPDO)	3B	1B	0B to 117B	2B	1B	4B	0B to 117B	2B	1B	4B		
	PID	Len	Data	SID	CN	CRC	Data copy	SID copy	CN copy	CRC copy		
Safety heartbeat (SHB) request	PID	Len	SCL state	Safety AP state	SID	CN	CRC	SCL state copy	Safety AP state copy	SID copy	CN copy	CRC copy
Safety heartbeat (SHB) response	PID	Len	SID	CN	CRC	SID copy	CN copy	CRC copy				

FIGURE 28.15 Comparison of PDO, SPDO, and SHB structures.

The structure of SPDOs is more complex because it includes a set of additional fields that are used for communication error detection according to Table 28.2.

Figure 28.15 shows that an SPDO contains the following:

- A 3-byte *PID* field to store the PID associated to the transmitted safe process data
- A 1-byte *len* field to store the length (in bytes) of the SPDO, including the PID and LEN fields
- A variable-size *safe data* field that contains the safe process data
- A 2-byte *SID* field to store the safe identifier (SID) of the sender
- A 1-byte *consecutive number* field to store a consecutive (sequence) number
- A 4-byte *CRC* field containing a 32-bit CRC that covers the PID, length, safe data, SID, and consecutive number fields
- A copy of the *safe data*, *SID*, *consecutive number*, and *CRC* fields

The *consecutive number* field implements the *sequence number* safety mechanism, while the couple of PID and SID identifiers is used to build a unique *connection ID*. In particular, SID must be unique across the network, and its value shall not be 0.

The *data integrity assurance* and *different data integrity assurance* are granted by the 32-bit CRC, which is computed using the 0x20044009 polynomial. This polynomial is able to guarantee a residual error probability compatible with the SIL 3 requirements if the overall size of the protected data falls between 0 and 128 octets, including the CRC signature. As a consequence, the maximum size of the *safe data* field is restricted to 117 octets.

The adoption of the redundant *data*, *SID*, *consecutive number*, and *CRC* fields is an additional mechanism used by the safety layer to check the integrity of the communication channel.

When a device receives a CDC message, the safety layer recognizes the type of PDO (standard or safe) in the frame by inspecting the value of the PID field. If the PID identifies an SPDO, the content of the fields following the data section is processed by the safety layer to check the integrity of the received data.

Besides special fields for error detection, the safety layer checks the time elapsed between any two consecutive receptions of SPDOs to monitor the responsiveness of the communication channel. Moreover, since the transmission of safety process data is not a confirmed service, an additional mechanism is required to detect possible failures of devices. In fact, when a device is only a consumer of data, there is no way for the unconfirmed cyclic data transfer service to obtain information about its health status. This check is then carried out by means of the SHB service.

### 28.5.3.2 Safety Heartbeat Service

The SHB service is used by the protocol to monitor the state of both the safety communication layer (SCL) and safe application and to evaluate delays on the communication channel. SHB cannot rely on other heartbeat mechanisms implemented by the protocol, such as, for instance, the exchange of CDCN *still alive* messages used to monitor the status of the conventional CDC.

SHB is a confirmed service, and messages are exchanged in a cyclic way. The cycle time of the service is independent of other communication cycles and mainly checks the delivery time experienced by messages against a maximum predefined threshold.

Each device involved in a communication relationship is forced to monitor its interlocutor by cyclically sending *SHB request* messages. For example, in the publisher–subscriber model, each publisher must send *SHB requests* to monitor the state of its subscribers, and at the same time, subscribers have to send *SHB requests* to their publishers. Each device that receives an *SHB request* must reply with an *SHB response* message.

SHB PDUs have the same structure of SPDO as shown in Figure 28.15. In SHB request PDUs, the PDO data section used to transport safety-related data is replaced with two fields: *SCL state* and *Safety AP state*. *SCL state* contains information about the state of the SCL. Possible SCL state values are the following:

- 0x00: SCL is in BOOTUP state
- 0x04: SCL is in STOPPED state
- 0x05: SCL is in OPERATIONAL state
- 0x7F: SCL is in PREOPERATIONAL state

The *Safety AP state* field contains information about the state of the safety application and is implementation specific.

*SHB response* PDUs do not carry any data and are used to confirm that an *SHB request* has been received.

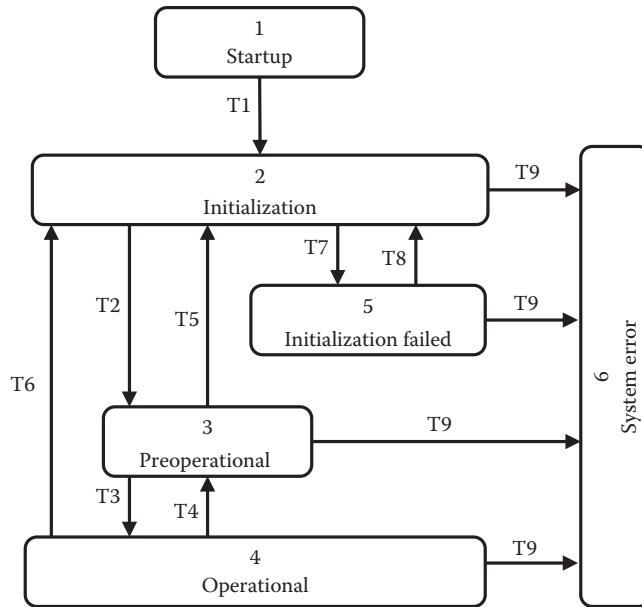

The SHB service is used by all safety devices to determine the actual delay of the safe communication channel and establish whether the received information can be considered valid or not. Since each *SHB request* is acknowledged by the receiver, the sender can monitor the time elapsed between the request and the reception of the relevant acknowledgment. In the case where the measured delay exceeds the predefined threshold, SCL starts a transition to the *fail safe state* to make the application enter a safe state.

### 28.5.3.3 Safety Communication Layer Management

The safety communication layer management (SALMT) is a local service conceived to control the behavior of the safety-related components in the device. The service offers a set of commands to trigger the state of the SCL state machine as shown in Figure 28.16.

At the device start-up, the state machine is in the start-up state, and an automatic transition (T1) is enabled to reach the initialization state. In both the start-up and initialization states, the exchange of SPDOs and SHBs is not allowed. If a fault is detected during initialization, a transition (T7) is automatically triggered to move SCL to the initialization failed state. In this state, SCL can start to send and receive SHB messages, but due to the failure condition, the exchange of SPDOs is not allowed. A new initialization must be invoked using the SALMT command *reset node*, which in turn triggers a transition (T8) to bring SCL back to the initialization state.

Another transition (T2) is triggered by the SALMT *enter preoperational* command to drive SCL from the initialization to the preoperational state, where only the exchange of SHB messages is allowed. From the preoperational state, SCL can move back to the initialization state (transition T5 triggered by either the *reset communication* or *reset node* command).

**FIGURE 28.16** SALMT state machine.

The command *start remote node* is used to move SCL from the preoperational to the operational state (transition T3). In this state, SCL is fully operative, and the exchange of both SHB messages and SPDOs is allowed. A pair of other transitions (T4 and T6) is foreseen to move SCL back to the preoperational and initialization states, respectively. Transition T4 is triggered by the *stop remote node* command, while T6 is controlled by either *reset communication* or *reset node*.

Finally, in each state with the exception of start-up, the detection of a safety-critical error drives SCL to the system error state (transition T9), where no kind of communication is allowed.

## 28.5.4 Safety Application Layer

The safety application layer provides applications with the interface to access the SafetyNET p safe services. The basic element in the data model is the safe ODIC, which is an extension to the standard ODIC.

Entries are identified in the same way using data types, indexes, and subindexes. Access to the safety objects is not allowed to nonsafe services such as SDO. Table 28.3 summarizes the objects that are available in the safe ODIC.

The safe address of a SafetyNET p device is its safety ID (SID). SID is one of the mandatory safety objects.

SPDOs are specified as TxSPDO and RxSPDO on the producer and consumer sides, respectively. Communication parameters specify the SPDO transfer mode, while mapping parameters define the SPDO contents by listing the relevant safe application objects.

For SHB producers, the Failsafe Producer Heartbeat is a record similar to the TxSPDO communication parameters. The Failsafe Consumer Heartbeat list contains, in its turn, parameters needed to program the reception of SHBs as well as SHB responses.

Each object description adopts a standardized format. For instance, the structure of the SID is shown in Table 28.4. The table specifies that SID is a simple 16-bit variable that can be accessed only from the SafetyNET p FS part (FSF). It cannot be mapped onto an SPDO, and its value cannot be 0x0000. SID is also a mandatory object with index value equal to 0x1200.

**TABLE 28.3** Safe Dictionary Objects

Index	Name	Data Type	Description
0x1000	Device type	Unsigned32	Device classification: Lower 16 bits are <i>Device Profile Number</i> , describing the used profile. Upper 16 bits are <i>Additional Information</i> .
0x1200	Safety ID	Unsigned16	Unique identifier for the safety device shall be not zero.
0x1216	Safety consumer heartbeat list	Unsigned256	List of remote devices that need to be monitored by the device.
0x1217	Safety producer heartbeat parameter	PDO COM_PAR	Configured in the same way as SPDO transmission. Shall be configured as cyclic transmission.
0x1218	Safety bus cycle time	Unsigned32	Subindex 0: Number of entries. Subindex 1: RTFN Base Cycle Time. Subindex 2: RTFL Base Cycle Time.
0x121E	SPDO Timeout tolerance $T_{to}$	Unsigned8	Defines how much of an excess of an RxSPDO timeout is acceptable. Unitless number, interpreted as percentage.
0x1C00–0x1cff	RxSPDO communication parameter	PDO COM_PAR	Parameters that define the communication properties of RxSPDOs.
0x1D00–0x1dff	RxSPDO mapping parameter	PDO MAPPING	Parameters to define the data mapping of RxSPDOs.
0x1E00 to 0x1eff	TxSPDO communication parameter	PDO COM_PAR	Parameters that define the communication properties of TxSPDOs.
0x1f00 to 0x1fff	TxSPDO mapping parameter	PDO MAPPING	Parameters to define the data mapping of TxSPDOs.

**TABLE 28.4** Specification of the Safety ID (SID) Object

Attribute	Value
Index	0 × 1200
Name	Safety ID
Description	Unique identifier for device
Object type	VAR
Data type	Unsigned16
Category	Mandatory
Access attribute	FSF
SPDO mapping	No
Value range	0 × 0001 to 0 × FFFF
Value	No

SafetyNET p does not support a master–slave model and delegates the safety configuration management to the system application level. This facilitates the implementation of decentralized and distributed management structures.

The implementation of an ODIC is meaningful only if it is made accessible through the SDO services. Since the safety configuration has to be consistent in the whole system, the access to a single parameter makes little or no sense. In this case, in fact, the ODIC is only a conceptual model description that is used by engineering tools to create the correct SafetyNET p configuration, rather than a physical existing element within a SafetyNET p device.

Note, however, that a safety protocol stack implementation does not necessarily have to provide an ODIC since this is not visible from the outside. A more friendly data model could be used internally instead.

### 29.1 Introduction

---

During the past 30 years, the main focus in the development of field area networks (or fieldbus systems) was on meeting the technical requirements of different application areas, resulting in a wide diversity of systems. Parallel standardization efforts, which still continue, have led to today's widely accepted conclusion that, in order to successfully cope with the requirements found in the application areas of interest, different coexisting solutions are needed [1]. Also conceived in the past two decades were the technologies that make up today's Internet, which, ultimately, led to the enormous surge in Internet usage in the 1990s together with the wide adoption of the Internet protocol (IP) family for the use in local area networks (LANs). This exponential growth of the Internet also sparked new interest in vertical communication flows according to the computer-integrated management (CIM) pyramid.

Vertical integration in the sense of transparent data exchange had been one of the essential goals of the CIM idea already in the 1970s [2]. Nevertheless, automation systems were mostly developed as closed environments without interfaces to the outside, partly also because of missing network solutions. It is thus no wonder that security considerations never played a prominent role in fieldbus systems. Only with the advent of remote access to automation systems and the broad user awareness of security problems in the Internet has security become an issue in automation. Still, it was not before the end of the 1990s that the importance of this topic was highlighted [3–5]. Extending the scope of typical field-level protocols to IP-based networks and interconnecting them even outside the premises by means of well-known IT standards, however, make the need for security obvious. A number of incidents affecting automation systems [6], such as the Stuxnet worm, have clearly demonstrated this. Therefore, solutions have to be found to combat potential security threats well known in the Internet or wireless networks [7–9].

Within the scope of integration in automation, some focus of the discussion is on the connection of field-level networks to *the Internet*. This can be done either via tunneling approaches or through various types of gateways. In this context, the notoriously bad security reputation of the Internet (which in its original form provided no security at all) mandates an awareness of field-level security issues. Still, it is necessary not to limit oneself to studying security issues arising within the context of fieldbus–Internet connections only. A more general approach should be taken instead, one that includes security measures on the field level itself where appropriate. Ultimately, security characteristics should become accepted properties used in the selection of a field-level communication system for a certain application. Security would therefore become as important as other properties such as topology, structure, bus access, and safety features.

## 29.2 Basic Security Measures

---

Security measures for IT systems in any organization aim to achieve three basic security goals, namely, confidentiality, integrity, and availability. These measures protect data from unauthorized entities and unauthorized manipulation and ensure that data are accessible when needed. In addition, another security goal that is often desired is nonrepudiation, which binds an entity to its transacted commitments.

Solutions implemented to achieve these goals are typically based on a security policy that explicitly states the following:

- The security objectives and the scope of the policy defining the organization's approach to risk and describing the assets of an organization.
- A definition of business and security goals to avoid conflicts and possible violations of the policy by the users of a system.
- Who is responsible for implementing and maintaining the policy. Security is a continuous process that needs to be updated regularly.
- A description of the implemented security measures and rules through which people are given access to an organization's assets.

Any such security policy must be backed by the organization's management and be communicated to users of the IT system in question. It is noteworthy that 80% of security needs to be invested in organizational measures that allow security technologies to work properly [10].

A good, informal starting point for developing a security policy is the *Site Security Handbook* [11], which is geared toward systems connected to the Internet. Another good introduction is the *IT Baseline Protection Manual* [12], which aids in the establishment of a security policy and additionally offers common best practices for the implementation of security measures similar to British Standard 7799 (later adopted as ISO/IEC 17799 [13]). Unfortunately, no guidelines for developing a security policy for field-level networks exist. Still, for them, the same basic steps need to be obeyed:

- Risk analysis for identification and categorization of risks; threats are manifold and can range from active (modification of data, replay of data, masquerading as an authorized user, denial of service to authorized users) as well as passive (eavesdropping, information disclosure, or traffic analysis) attacks.
- Threat analysis assigning an occurrence probability and extent of the damage to each risk giving them a certain weight in the context of the security policy.
- Analysis of weaknesses tracking vulnerabilities of the system.
- Planning and implementation of security measures.

Next, we discuss security in the context of the life cycle of IT systems and give an overview of the most common technical means to enforce security goals that are also applicable to field area networks (FANs).

## 29.2.1 Security System Life Cycle

While security activities can be started at any time in the life cycle of a system, it is usually desirable (though often not possible) to integrate them in the whole life cycle [14], where five stages are defined\* (Figure 29.1).

During the initiation phase, when the system is designed, a basic security design is established by means of a sensitivity assessment. This assessment results in an estimation of the data to be handled by the system and its impact on security.

In the development stage, the security requirements as well as the methods with which to implement them are selected and included into the overall system specification. Then follows the implementation phase during which security features of the system are activated and tested.

In the operation and maintenance phase, security-related operations such as key exchanges take place. Also in this stage, system audits and monitoring may lead to system changes if new security risks that need to be addressed are found.

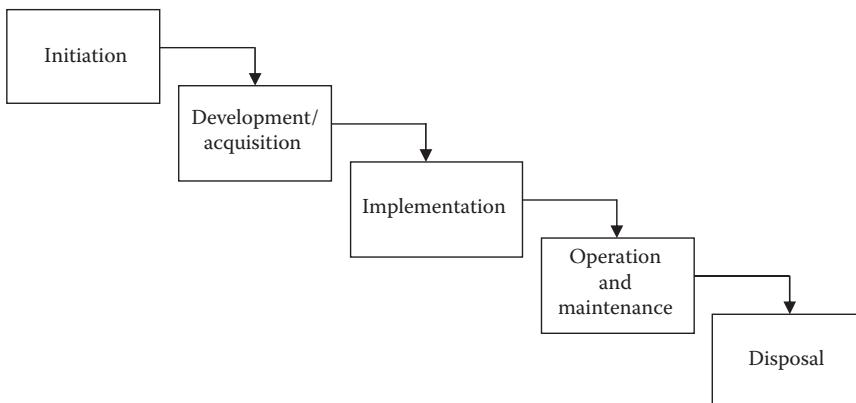

Finally, the disposal of information hard- and software needs to be handled. Here, the long-time storage of cryptographic keys is a major task.

Actual approaches such as the German VDI guideline 2182 [16] structure each phase in a closed loop starting with the identification of assets and security objectives, analysis of threats and risks, selection and implementation of measures, and finally ongoing audit that closes the loop. This structured continuous update of the security policy within a life cycle stage reflects the fact that new threats appear, but also that the applications and the configuration of networks continuously change.

## 29.2.2 Common Security Measures

The notion of security today is most often associated with the Internet. Most security measures presently available—with the exception of cryptography—are in some way tailored to the Internet, although they are also applicable to a wider range of systems. Without going into precise detail, this section introduces the following important security aspects:

- Cryptography
- Authentication and access control
- Firewalls and intrusion detection
- Security evaluations

**FIGURE 29.1** Basic waterfall life cycle model.

\* The activities that follow can also be applied (in a slightly modified way) to other life cycle models like, e.g., the spiral model by Boehm [15].

Cryptography is appropriate for implementing services where confidentiality and integrity are needed. The major building blocks of cryptography are the following:

- Cryptographically secure pseudorandom number generators, used to generate seemingly random entities such as secret keys
- Cryptographic hash functions, either used in conjunction with electronic signatures or to generate message authentication codes (MACs) to protect data integrity
- Symmetric and asymmetric encryption/signature functions used to protect the confidentiality of data or to construct MACs or electronic signatures

Cryptography is discussed in Stinson [17] (with the exception of randomness) and in Menezes et al. [18], which covers all the topics provided earlier and which is a suitable reference for deeper investigation.

Authentication measures are used to establish the identity of an entity, for example, that of a system user. A clear distinction must be made between weak authentication (as found in password-based systems such as Unix or Windows) and strong authentication, which is usually based on challenge-response protocols that rely on either symmetric or asymmetric cryptography like Kerberos [19] and X.509 [20], respectively.

Authenticated entities can be subjected to access control mechanisms that allow the determination of the legality or otherwise of an entity's desired action. Apart from simple models such as access control lists and other discretionary models, mandatory models exist that are mainly found in military systems. Both models can be implemented by the newer role-based access control (RBAC) schemes [21].

Firewalls [22–24] and intrusion detection systems (IDSs) [7,25,26] are complementary technologies usually associated with LAN-fieldbus connections to the Internet, although both are also useful in a pure LAN environment or where a LAN is connected to a field-level network and the LAN is shared by different organizational entities. Firewalls try to prevent illegal access to inbound and outbound connections by, for example, packet filtering while IDSs monitor and analyze network access patterns and try to recognize security breaches and/or attacks, which are then referred to a system administrator (and/or responded to).

The building of a secure system is a complicated task involving a variety of different skills and knowledge, yet might still not succeed even if the necessary care is taken [27]. A prominent example of a failed security system is wired equivalent privacy (WEP), which was designed to protect 802.11 wireless LANs but which failed miserably to do so [28].

Third-party security evaluation is a method with which to build confidence into a system beyond the security statements of the manufacturer. The Common Criteria 2.0 (CC) [29], for example, is an international standard that regulates security evaluations and a positive evaluation of a security target (i.e., the product) against the CC results in an internationally acknowledged certificate. Besides this assurance, which relates to the efforts put into security engineering, the certificate itself contains a description of the security functionality that was assessed during the process.

Additionally, in order to help prepare for certification, there exist so-called protection profiles (PPs) that describe implementation-independent sets of security requirements for specific security areas, for example, firewalls. There are, however, currently no PPs for field-level networks available. Yet, there are initiatives for special application areas such as the German Smart Grid Protection Profile [30].

## **29.3 Security for Automation Networks**

---

For automation networks, in particular, those used for the field level of the automation hierarchy, many different communication technologies are available today [1]. Classical fieldbus systems were the first networks, followed by a number of developments based on Ethernet. In recent years, wireless technologies are becoming increasingly important. All these different networks are different also with respect to their security capabilities.

### 29.3.1 Fieldbus Systems

It is a common prejudice that today's fieldbus systems do not exhibit any security measures. In fact, this is not fully true. There are such concepts in communication systems for building automation [31,32], and there are even traces in some industrial automation fieldbuses [33]. However, these approaches are quite limited in scope and capabilities. The fieldbus systems for industrial and process automation currently standardized by the IEC in the standards IEC 61784-1 [34] and the underlying IEC 61158 series [35] are—despite all efforts—a heterogeneous collection of solutions. As far as *security* features are concerned, however, they fall into two categories. Systems like ControlNet, P-Net, and SwiftNet use hardly any appreciable security strategy at all. Foundation Fieldbus, Profibus, WorldFIP, and Interbus share very similar application layer services and protocols modeled after the fieldbus ancestor MMS. The simple access protection mechanism is inspired by the owner/group/world access rights management in, for example, UNIX-based systems. Every object has a password associated with it (8 bits long) as well as a list of access groups (also an 8-bit word, corresponding to eight different groups). Both password and access group are transferred in plain [33]. If they match for a specific request, the additional access rights parameter further details allowed operations. These rights depend on the type of object (like read, write, execute, delete, etc.) and may be activated for the password (equivalent to the owner in UNIX), the groups, and all communication partners without restriction.

Unfortunately, these security means are not mandatory for implementation, which limits their usability. The password itself has no explicit protection, let alone encryption. This concept resembles weak security measures known from, for example, SNMP, where a community string is defined (even mandatory) to protect data access. Alas, this string is transmitted in clear text and hence rarely used at all (the default value *public* is hardly ever changed). A note in the standard reveals the actual intention of the security mechanisms:

This is not a protection against intentional misuse of the communication facilities of a field device but helps to protect a system for accidental erroneous use of Process Data.

This statement is in fact a generic one and is true for all traditional fieldbus systems in industrial and process automation.

The situation is different in the area of building automation. The two most competing systems on the field level are LonWorks and KNX, both of which have dedicated security features [31]. LonWorks offers an authentication mechanism; KNX offers a password-based access control. However, both approaches are not sufficient from a security viewpoint: The cryptographic algorithm used by LonWorks is based on a four-step challenge-response protocol. The used cryptographic algorithm calculates a 64-bit hash value over the plain message and a random number using a shared secret key. However, the short key length and several protocol flaws render this mechanism insecure [31]. A more advanced one based on MD5 is available for LonWorks/IP. However, since MD5 is not collision resistant, it is also regarded as insecure. KNX provides only a basic access control scheme based on clear text passwords. Up to 255 different access levels can be defined, each of them associated with a different (otherwise unspecified) set of privileges. For each access level, a 4-byte password (key) can be specified. This rudimentary access control mechanism does not, however, provide strong security and is not available for the exchange of process data [36]. The third player in this area, BACnet, is used mainly on the management level, that is, above the others, and is the most recent of the three. The security mechanisms implemented here are the most mature ones and are largely oriented at the current state of the art in information technology, including an authentication service as well as security services that guarantee data confidentiality and integrity. These mechanisms use the symmetric Data Encryption Standard (DES) algorithm and a trusted key server responsible for generating and distributing the secret keys. A more recent security architecture defined in BACnet Addendum g uses AES and HMAC in combination with a message ID and a time stamp. Table 29.1 summarizes the security mechanisms of the various fieldbus systems.

**TABLE 29.1** Security Services for Various Fieldbus Systems

Fieldbus	Security Services
Foundation Fieldbus	Eight access groups, 8-bit unencrypted password
ControlNet	Connection auth., unencrypted password
PROFIBUS	Access control for predefined addresses
P-Net	Simple write protection for variables
WorldFIP	Eight access groups, 8-bit unencrypted password
Interbus	Eight access groups, 8-bit unencrypted password
Swift-Net	None
LonWorks	Challenge-response auth., integrity check, MD5 for IP
KNX	Unencrypted password for management access
BACnet	DES-based encryption, integrity check, authentication
BACnet Addendum g	AES for data confidentiality, HMAC for data integrity, time stamp + message ID for data freshness

The fact that the building automation systems care more about security is not astonishing. First, they were developed significantly later than many industrial automation networks. Second and more important, such systems are far more complex because the number of nodes involved in a single building network can exceed by far that in a production plant comprising usually well-identifiable subsystems. The most important aspect, however, is that potential intruders can have nearly unlimited access to the network.

### 29.3.2 Industrial Ethernet

It has already been stated that security was not a primary concern in the fieldbus development, and that consequently, the mechanisms to protect data and equipment from unauthorized access in contemporary fieldbuses are very limited. By the time the importance of security in automation became obvious [3,4], it was already too late to introduce changes. As far as the field level is concerned, there are in fact not many options to build secure communication channels [37]. With the introduction of Ethernet in automation, a reconsideration of field-level security was possible, and one of the biggest potentials in the development of these new networks would have been to integrate security features on a low level from scratch [38].

The overview of the industrial Ethernet profiles defined in IEC 61784 and their main security features in Table 29.2 shows, however, that unfortunately, this opportunity was not really taken in practice, and the Ethernet-based control networks still today leave security aspects mostly out of their scope. Security mechanisms, if any, focus on special switches to block traffic from network segments or on

**TABLE 29.2** Industrial Ethernet Profiles Defined in IEC 61784

IEC 61784 Profile	Security Services
CPF1—Foundation Fieldbus	Simple access protection, optional ISO/IEC 8802-101.
CPF2—Ethernet/IP	No security measures specified.
CPF3—PROFINet	Protection within switches to avoid overloading of segments with real-time traffic.
CPF4—P-NET on IP	No specific security measures specified.
CPF10—VNET/IP	Security should be in data link layer but is not specified.
CPF11—Tcnet	No specific security measures specified.
CPF12—EtherCAT	No specific security measures specified.
CPF13—Ethernet Powerlink	Protection within switches to avoid overloading of segments with real-time traffic.
CPF14—EPA	Firewall-like security bridges between field domains and process monitoring domains or the Internet.
CPF15—MODBUS RTPS	Access control based on IP addresses.
CPF16—SERCOSIII	No specific security measures specified.

proper device design to avoid overloading of the implemented protocol stack. If security is needed that goes beyond simple traffic management aspects between segments (insight-outside view), upper layers of the protocol stack have to be used.

Nevertheless, many industrial Ethernet solutions permit IP traffic in parallel to time-critical process data communication. Therefore, the same technological communication base as in most LANs and the Internet is available at the field level and in principle permits a seamless application of security mechanisms known from the Internet world. Secure versions of the TCP, UDP, and IP stack might offer valuable security measures. This can be on the network layer, for example, by using IPsec [33], on the transport layer (e.g., using TLS/SSL), or on the application layer (e.g., Kerberos). The disadvantages of these protocols are as follows:

- They decrease the real-time properties significantly. Hence they are mainly applicable to secure transport of configuration data and data transmitted (over public networks) to superior management units.
- The complexity of the secure protocol stacks poses heavy requirements on the computational power of the embedded systems found on the field level and sometimes even on the control level. In particular, asymmetric cryptography puts a high load on the field devices.

At any rate, it must be noted that the possible use of secure versions of the IP suite is not genuinely covered by the industrial Ethernet specifications; it remains a workaround for a very limited range of applications, as will also be shown in Section 29.4.

### 29.3.3 Wireless Networks

Following their success in IT systems and consumer electronics, wireless communications are more and more applied also in automation infrastructures, mostly as hybrid solutions together with wired networks [39–41]. However, industrial wireless networks pose particular security challenges. The typical requirements regarding integrity, authentication, and availability need to be transferred from the traditional wired network domain to wireless networks without impacting the applications' real-time requirements. In comparison to wired installations, which obviously benefit from physical access limitations, for wireless transmission, it is much harder to limit the area of *network* availability because attackers can intrude the system at arbitrary locations. Apart from reliability issues that are still a major obstacle for a straightforward use of wireless technologies, the open medium is evidently prone to eavesdropping and message insertion. Hence the most common wireless network protocols already offer built-in security services on the data link layer, such as data confidentiality, data integrity, and replay protection, though providing different levels of complexity and robustness.

The IEEE 802.15.1 standard supports mutual and one-way authentication and encryption. Four different entities are used for providing this: the device address (48 bits), an authentication key (128 bits), an encryption key (8–128 bits), and a pseudorandom number (128 bits). During the initialization of a connection, the secret keys are derived. The encryption key has varying size and is always based on the authentication key and a pseudorandom number.

IEEE 802.15.4 supports security mechanisms at the data link layer, and the application can choose between eight different security levels depending on its requirements. The security services for no security, only authentication, only encryption, and encryption and authentication are realized using AES for encryption and message authentication applying Cipher Block Chaining (CBC), Counter (CTR), or CCM mode. The message integrity code for data authenticity can have increasing levels. The security classes are using authenticated encryption algorithm CCM\*, which is an extension of the generic counter with cipher block chaining MAC (CCM), approach. ZigBee is defined on top of IEEE 802.15.4 and thus utilizes its security mechanisms. However, as important implementation issues are left open in IEEE 802.15.4, ZigBee enhances them with more advanced security services, such as the support of different key types and key management services.

Security services in 802.11 WLANs were initially provided by the WEP algorithm. However, many potential and critical flaws were discovered, and the algorithm was ultimately broken in 2001.

The 802.11i amendment now specifies the robust security network for authentication and encryption. The authentication of a client to an access point consists of a sequence of the mandatory open systems authentication and association, followed by an extensible authentication protocol involving a third entity, the authentication, authorization, and accounting server, in order to derive the 512-bit master session key (MSK) and the pairwise master key (PMK, consisting of the first 256 bits of the MSK). Finally, the PMK is used to derive transient keys for the encryption during the four-way handshake used to set up the secure data exchange.

### **29.3.4 IP-Based Networks**

IP-based networks dominate the management level and also backbone networks interconnecting separated automation systems. Recently, motivated by the low costs for IP cabling and network components, even small microcontrollers are equipped with IP stacks, and IP is gaining a strong momentum at the field level. This IP connectivity down to the field node is also in favor of a real end-to-end communication transparency supporting originally management-level services such as web services or context management.

From the security point of view, this openness and standard conformity makes such networks more prone to security attacks. Many of these vulnerabilities stem from the fact that IP originally had no security measures built in, and that even IPv6, the newest version of the protocol, has its native security mechanisms disabled by default. Threats can be classified into accidental attacks caused by interference of traffic stemming from other applications that now can share the field-level network since gaining (remote) access to the network is easier. Byres and Lowe [10] list such incidents on automation networks. The vision of isolated automation islands is definitely outdated on a protocol level but also often even on a physical level equal to office standards.

The most common IP security measures suitable and used for industrial communication systems are listed in the following:

Internet Protocol Security (IPsec) [42] is the native security extension to the IP v6 implemented on the network layer, which also has been ported to IPv4 commonly used in today's (automation) IP networks. IPsec offers services for data integrity, replay protection, authentication, and confidentiality natively within the IP layer. It is implemented in the two independent services: the Authentication Header (AH) providing authentication and integrity protection of complete IP packets, and the Encapsulating Security Payload (ESP) offering only encryption and integrity verification of the payload [43,44]. In both services, a cryptography integrity check value (ICV), commonly implemented by an HMAC-SHA, is used for message integrity protection and authentication. For encryption, various algorithms such as 3-DES or AES can be selected. For key exchange, the Internet Key Exchange (IKE) protocol is used, which uses asymmetric algorithms like RSA, ECC, or symmetric algorithms with preshared secret keys, alternatively. All security parameters are maintained in a security association (SA) setup between communication partners. Most important for automation networks is the fact that IPsec can operate in two modes: transport mode, which adds security headers (and trailers in ESP) to protect a single packet, and tunnel mode, which, on the other hand, allows securely interconnecting two networks. In this mode, the original IP packets are transmitted as payload of a new security IP packet between two networks. The big overall advantage of IPsec is that its security services are independent from applications and transparent for all traffic. This fact can tremendously ease the security management in multiapplication environments. Additionally, in contrast to layer 2 security services, IPsec is also transparent beyond network borders and avoids possible vulnerabilities caused by a break of end-to-end security at network borders.

Transport Layer Security (TLS) [45] as well as its ancestor Secure Sockets Layer (SSL) is a protocol developed for securing communication between two entities on layer 4 of the OSI stack. TLS can be divided into five sub-protocols: TLS record protocol is responsible for the end-to-end encryption via symmetric ciphers like 3-DES or AES and for message integrity protection and authentication using

MACs like HMAC-SHA. Based on this protocol are the TLS Handshake protocol that is responsible for the initial negotiation of security parameters and the symmetric keys for the TLS record protocol, the TLS change cipher spec protocol changing the ciphers according to the negotiated security parameters, the TLS alert protocol implementing error notification, and finally the TLS application data protocol responsible for fragmentation and management of payload data. The initial negotiation of security parameters is based on asymmetric algorithms and public-key certificates. It serves the proper authentication of sender and receiver and the derivation of the symmetric keys for the TLS record protocol using the Diffie–Hellman key exchange. During the following transmission, payload data are then transmitted fully transparent and not interpreted at all. Both a drawback and an advantage is that TLS only protects traffic between two entities. Hence, there is no possibility to securely interconnect two networks like in IPsec tunnel mode, yet TLS is also very flexible to be retrofitted into existing protocols such as web services, mail, or network management. For example, [46] shows an implementation of a complete secure web server using HTTP and TLS.

Virtual private networks (VPNs) are a technique to interconnect multiple private networks via a public network in a secure way. One can distinguish end-to-site VPNs where nodes are integrated in a private network, end-to-end VPNs creating a completely virtual network, and site-to-site VPNs connecting two compatible private networks. In all cases, the VPN creates a private, closed, and individually configurable virtual network between the connected entities. In contrast to native network security such as IPsec, VPN does not use the security of the public network. IP packets are encapsulated in TCP or UDP packets carrying the VPN packets that are protected by TLS. Most common are end-to-site VPNs for remote access to an automation network fully integrating a computer of, for example, a service engineer into the private automation network via a VPN gateway. Site-to-site VPNs are usually implemented using IPsec and not by a dedicated VPN software. A widely used VPN implementation for IP-based networks is OpenVPN [47]. In OpenVPN, each node opens a secure unicast connection to the VPN gateway, tunneling the whole network traffic to and from the node (end-to-site). The tunneling connection is authenticated by preshared symmetric keys, a username and password, or TLS certificates. The data transmission is then protected using TLS.

It is noteworthy that most of these measures have been designed for different applications and therefore have to be carefully deployed especially if hard real-time and low-bandwidth constraints need to be observed. The next section is addresses such issues.

## 29.4 Adding Security to Legacy Field-Level Networks

---

What is currently at hand on the field level in terms of security mechanisms is largely not very promising. Hence, if security is an issue in a given application, appropriate add-ons must be designed. When considering extensions, the common consent is to obey Kerckhoff's principle stating that only well-known and well-tested security mechanisms should be employed, which in turn means using mature approaches known from the IT world. While this is in general the only viable solution, one must observe that the IT and automation environments are considerably different:

- Security protocols for the Internet such as SSL/TLS [45] and IPsec [42,48] operate on top of or at network layers (according to ISO/OSI). These layers are not defined in many fieldbus systems where, for reasons of speed and simplicity, one normally finds only layers 1, 2, and 7.
- Fieldbuses have no built-in provisions for security and are usually designed as lightweight communication systems. Security services added to an existing application area might introduce a large overhead.
- Cryptographic operations such as encryption needed to secure field-level communication might be prohibitive because of the limited processing power of current fieldbus nodes, even more so if real-time needs have to be addressed. Cryptography might thus be limited to maybe configuration or management operations.

- A fieldbus might be installed in *hostile* surroundings where the transmission media and the fieldbus nodes are located at the premises of the adversary. This is the case in building automation; another extreme example is the case of remote metering [49,50].
- The variety of fieldbus systems is too high to allow for unified solutions. Well-known security mechanisms fitting for one fieldbus might be inappropriate for another.
- Proprietary security extensions added to a given fieldbus protocol will inevitably lead to incompatibility with the standard and legacy installations.
- The application of cryptographic operations might be prohibitive in some application areas, for example, where real-time responses are demanded. Execution times on fieldbus controllers with limited processing power in general exceed overall response times or individual channel access limits.
- Security and easy network management are often contradictory. In some cases, it is possible to access configuration and application data of a node without authentication and to reprogram a node by directly writing to its memory [3].

Taking all these into account, the only option left is to use the fieldbus simply as a transport channel and to tunnel secure packets over standard fieldbus protocols and services. Such an application-level approach could easily achieve end-to-end security, which is desired in most applications, anyway. Unfortunately, adding such a security mechanism is likely to cause problems with interoperability unless all nodes in the network adhere to this enhanced standard, that is, a mixture of secure and insecure devices would normally not be feasible. Another problem is the limited message size in some fieldbuses that leaves only little room for efficient security extensions. Especially, integrity services require additional data blocks for, for example, hash codes, thereby reducing the actually available payload per packet and consequently the performance of a secure channel.

#### 29.4.1 Network Protocol Aspects

While security was for a long time no issue in automation networks, things went faster in the world of tightly interconnected computer networks. Security was already discussed in the Internet predecessor Arpanet [51], but without any direct consequences. The security deficiencies in the overall Internet design were recognized only in the 1980s. Finally, in 1989, but still long before the invention of the WWW and the subsequent success of the Internet, the ISO issued a new part 3 of the OSI model covering security issues in open communication systems [52]. This amendment identifies several security services and maps them to the seven layers of the model for possible implementation (Table 29.3). Furthermore, it describes

**TABLE 29.3** OSI Security Services in the Different Layers

Security Service	Possible Layer(s)
Peer entity authentication	3, 4, 7
Data origin authentication	3, 4, 7
Access control service	3, 4, 7
Connection confidentiality	1, 2, 3, 4, 6, 7
Connectionless confidentiality	2, 3, 4, 6, 7
Selective field confidentiality	6, 7
Traffic flow confidentiality	1, 3, 7
Connection integrity with recovery	4, 7
Connection integrity without recovery	3, 4, 7
Selective field connection integrity	7
Connectionless integrity	3, 4, 7
Selective field connectionless integrity	7
Nonrepudiation origin	7
Nonrepudiation delivery	7

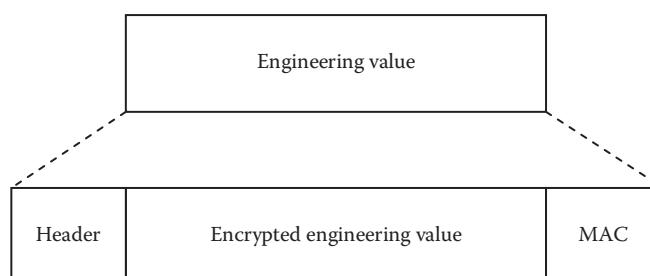

security mechanisms that may be used to achieve the desired services. While the proposed security architecture is not as widely used and known as the original OSI model, the layered approach is useful, especially for networks that do not implement all seven layers, which is the usual case for fieldbus systems. Security services above the application layer, which are often desirable to achieve end-to-end security, are out of scope and therefore not covered in the standard. The following discussion adheres to this model.

Addressing the dominant security goals mentioned in Section 29.2, we now focus on possible solutions for confidentiality and integrity. Provisions to ensure availability in a field-level environment (apart from the provisions already designed into the fieldbus) will be hard to achieve. In the following discussion, the placement of security functions according to ISO/OSI will be helpful. Attention needs to be paid to the often reduced set of implemented OSI layers. Concerning the placement of confidentiality services in the network stack, the majority of these are placed at layers 1, 2, and 7, although placement above layer 7 is also possible. Integrity services can be placed at layers 3, 4, and 7 of the OSI stack or, again, above layer 7. However, the restriction to layers 1, 2, and 7, often necessary in a fieldbus environment, limits the application of integrity services to layer 7 or above.

Taking into account that on the field level one often finds dedicated microcontrollers designed to handle a specific fieldbus interface and protocol, a security solution that is targeted above layer 7 appears to be a sensible choice in all cases where one tries to secure an established fieldbus system. Moreover, in systems where one finds an abstraction layer above layer 7, an inclusion of security services in this layer would be of special interest. Such a solution would have the special benefit that the user layer of a fieldbus system is typically targeted at the standardization of interoperable services or application profiles. The process of standardizing such services is carried out by a user group (usually comprised of the organizations that are involved in the development of the fieldbus), leading to a broad acceptance in industry. Apart from the expected acceptance, this solution is also of security interest as it provides end-to-end security in its narrowest sense: it secures all communication between two nodes at the application level. In the absence of a widely accepted user layer into which security services could be integrated, or in instances where a specific user group sees no necessity to add such services (as may often presumably be the case), a generic solution above layer 7 can still be devised. The drawback though would be a loss of interoperability with other solutions, resulting in increased development efforts and consequently increased costs.

In both approaches, security services could be provided by a wrapping mechanism. This mechanism takes an engineering value (i.e., a measured input value that has either been sampled with a sensor or first sampled and then preprocessed at the node) and applies this value to either an integrity mechanism or to both an integrity and a confidentiality mechanism. Figure 29.2 shows an example of the second case where the field header contains information about the security transformations applied. The MAC field contains integrity check information.

The integration of both integrity and confidentiality mechanisms into most of today's fieldbus systems could be prohibitive as they require processing power that might be out of range for the typical low-cost 8-bit microprocessors found in typical environments. Another drawback of solutions such as that depicted in Figure 29.2 is that the limited payload of fieldbus messages might not allow for the message

**FIGURE 29.2** Wrapping an engineering value.

expansion needed to add confidentiality and/or encryption. This is a problem especially for integrity mechanisms as they always add additional data to the transmitted message. For *confidentiality-only* mode, one could simply encrypt the engineering value and omit the header of the message. In this scenario, the two communicating nodes would need to know in advance whether or not the data to be sent/received was in encrypted form.

If missing processing power in the nodes is a concern, one could also think of applying the necessary security services to the lower layers in the OSI stack. Although a first look at Table 29.3 shows that only confidentiality services can be added at the lower level, it is still possible to add the required services at layer 2 if the necessity arises. This has actually been the case with Ethernet, where IEEE [53] augments the services found in the OSI security model to also include integrity, authentication, and access control. While this could be a feasible solution, one has to keep in mind that the resulting protocol will also need to support nonlayer 2 management functionalities handling, for example, key exchange.

A solution for providing confidentiality and/or integrity would, however, still leave a major security threat unanswered: network management. In today's fieldbuses, this functionality is typically achieved in an unauthenticated manner, an approach that is tantamount to an invitation to an informed attacker who has gained access to the network. Management functionality might even include the possibility to totally reprogram a node by, for example, directly overwriting parts of the node's memory. This would enable an attacker to gain complete knowledge about the programming of the node by reading out configuration and application data from the memory. It is not difficult to imagine situations where such behavior is not acceptable.

The minimum functionality needed to achieve security in this area would be the provision of an access control mechanism, a task that could be supported by integrity mechanisms that allow the authentication of configuration communication messages. The implementation of access control for network management should pose few problems. While the data transmitted might be larger than usual messages and maybe even multipart messages might be needed, such operations are usually not time critical. Restrictions as to the acceptable maximum length of a message and the maximum time a transmission may take are also usually very relaxed.

The situation is even more challenging when the physical access to the field devices as well as to the underlying communication media is controlled by a user (or a group of users) who is not the owner of the system [37]. From a security viewpoint, such users have to be considered to be adversaries. Common examples are a utility company's remote metering device deployed at a customer's site in a smart grid scenario or a fieldbus deployed in a car. Another comparable situation that has been well studied, but where neither security mechanism nor attack results are openly published, is the transmission of secure pay-per-view programs via cable or satellite where only entitled subscribers should be able to unscramble the program.

Such uncontrolled installations seem to be more at risk because the adversary has more possibilities to circumvent possible security measures. As far as ways and means to secure them concerned, one natural possibility are physical measures to secure the different nodes as well as the sensors and actuators connected to them. Depending on the security policy, this can lead to simple solutions where seals are attached to the devices (as is often done today to prevent the manipulation of power meters). In this case, it is the legal implication associated with the removing of the seal that acts as a deterrent. Technologically stronger solutions attempt to construct tamper-proof devices that either notify the system owner if they are tampered with or deactivate themselves. In the latter case, apart from trying to prevent physical access to the nodes, one usually finds special security modules such as smart cards that are useful to protect sensitive data as well as to recognize attempted tampering.

If it is not possible or feasible to physically protect the nodes, their programs, and their memory, then security considerations regarding lower layers of the network stack are in vain: the protection possibly achievable at those layers does nothing to prevent possible attacks at higher levels. Together with physical node protection, lower-layer security is of course of interest again and might help to remedy problems that could arise with the use of integrity services.

Continuing considerations regarding physical security and the automatic deactivation of nodes in case of tampering, the possibility to include intrusion detection mechanisms in a node seems to be an interesting topic of research for the future. Such a mechanism could become feasible in installations that remain unchanged after deployment, meaning that no nodes are added or removed and that the communication patterns between the nodes remain unchanged or only change in a way that can be anticipated. If such an analysis were possible, a node that detects an intrusion could either contact the system owner or deactivate itself. The actual action taken would depend on the system configuration, for example, a failure to contact the system owner after detecting an intrusion would also result in deactivation. It would, however, also be necessary to determine the correct point in time for deactivation as, for example, it would be both inconvenient and dangerous if communication system in a car were to stop working while the car was being driven.

#### 29.4.2 Implementation of a Secure Node

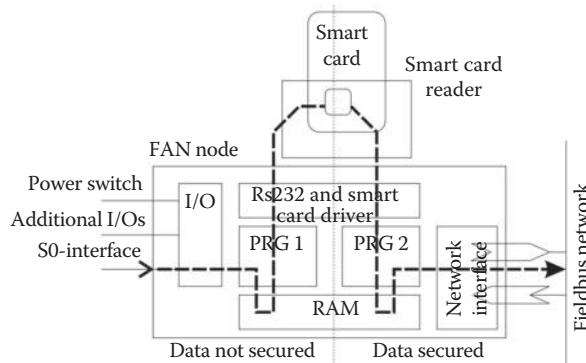

In the absence of native built-in security mechanisms in the communication system, the hardware is also usually not prepared for security extensions. One possibility to cope with both problems is the introduction of dedicated security tokens like smart cards that are widely used in, for example, cellular phones. The benefit of such devices is that they can be used as crypto coprocessor to execute all security algorithms needed for en- or decryption and authentication of data packets. Furthermore, they are a secure container for the keys required for the crypto algorithms. There has always to be one smart card on either side of a communication channel to achieve security. In fact, from the viewpoint of security, the communication takes place directly between the smart cards, and all other network entities see nothing but encrypted and thus incomprehensible data packets.

It must however not be overlooked that the integration of security devices is not at all straightforward. Rigorous security entails the restriction of communication relations, which is usually a problem for all broadcast- or multicast-oriented functions. The performance of fieldbus node processors and the secure serial communication links to smart cards is limited, so that the encryption or authentication may be too time-consuming for real-time process data. Finally, the physical integration in the node hardware is a challenge as well. Fieldbus systems usually have a highly sophisticated network management, which is optimized for efficiency and extensibility and often needs access to at least parts of the controller's internal memory [3], which constitutes a potential security leak. So, if the smart card together with some glue logic is placed between the fieldbus controller and the sensor device, the fieldbus management can no longer access the memory. If both components are integrated behind the fieldbus controller (seen from the fieldbus), a preprocessing of the sensor data in the controller is no longer possible and makes the whole device relatively inflexible.

The following discussion uses LonWorks as an example of how to extend fieldbus nodes by smart cards to implement security services for a secure end-to-end communication. Nevertheless, the main results are applicable to many other fieldbus systems. A schematic of this setup is shown in Figure 29.3.

Since the whole protocol stack of LonWorks is implemented in hard- and firmware within a dedicated microprocessor, security measures have to be implemented above layer 7. In this case, the system still fully complies with the LonWorks standard although interoperability is confined to secured nodes by defining special user-defined structures. If an attacker has appropriate tools and physical access, nodes are not well protected. Properties of a node from simple configuration properties to the whole application and data storage can be read and often changed with common administration tools. Some kind of security token must, therefore, be introduced that securely stores the secret keys and can execute cryptographic operations in a secure manner.

The first step to achieve this goal is the implementation of a smart card interface for the node. Although all interfaces to a smart card are well defined [54], it is generally not possible to integrate any of the ISO 7816 protocols in software, due to limitations in memory and computing power of the node.

**FIGURE 29.3** Schematic of secure fieldbus node.

Hence, an appropriate smart card reader has to be selected, which is a complicated task since only few readers offer a lightweight protocol for low-end microprocessors.

In a second step—during operation of the fieldbus—the raw sensor data (in this example from an S0 power meter input) are preprocessed by the node and transmitted to the smart card that secures the data to be transmitted over the network. The integrity of the data is secured by the HMAC [55] algorithm using SHA-1 as the hash function and encrypted using the 3-DES algorithm. It should be emphasized at this point that the design of a proprietary security algorithm is usually a bad idea and highly error-prone. Instead, one should use algorithms that have been scrutinized by the security community for a substantial amount of time and are considered to be secure. In a third step, the secured data are finally passed to the network protocol stack and transmitted to the recipient's node, where the procedure is executed in reverse.

The selection of the applied security measures is determined not only by the strength of cryptographic algorithms but also by the restrictions of the network. One of the most important restrictions is the limited packet size of fieldbus protocols, because often packet segmentation and reassembly mechanisms (SAR) are not available. In the presented setup, the packet size is limited to 31 ASCII-encoded characters. According to prior research [31], this is no limitation for the processed 2-byte sensor value and should be fine with most other data to be transmitted. However, this limitation could cause problems with asymmetric encryption schemes like RSA [56], which requires a minimum packet size of 128 bytes to achieve adequate security.

Another important issue is the additional delay introduced by transmitting data to and processing the data within the smart card. Whereas this usually is not a big issue for building automation control systems, where delays introduced by the smart card communication can be neglected in normal operation, the impact on networks with real-time requirements such as in industrial automation systems must be analyzed much more carefully. Finally, even in this setup, the node's memory is still unprotected, therefore allowing the possibility of data being read before they are encrypted (Figure 29.3, left side). Solutions to this problem would most likely need additional hardware or the redesign of existing nodes to supply protected areas.

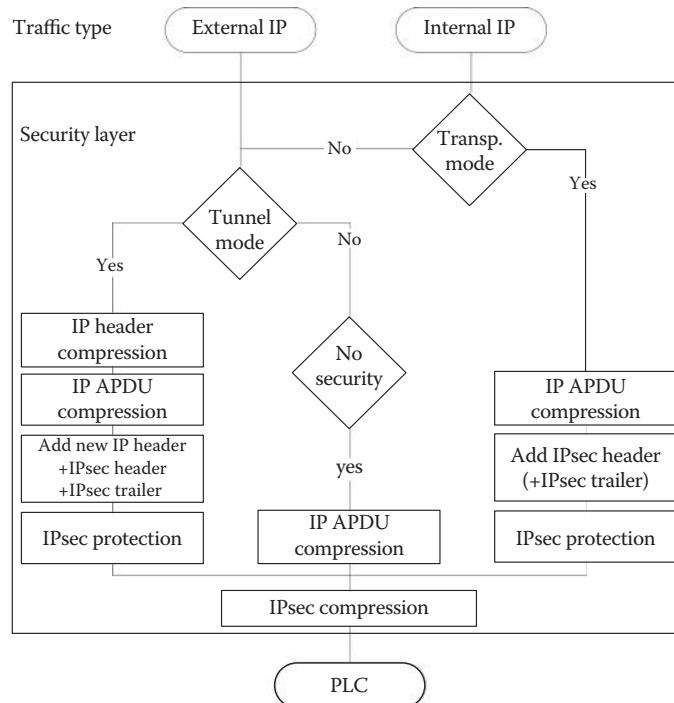

### 29.4.3 IP Down to the Field Devices?

It is predicted that IP will take on an important role in many control application fields. One of the most prominent fields is the energy sector and the future smart grid communication solutions [57]. Advantages such as improved interoperability and seamless interconnection across network borders in hybrid wired and wireless networks and backbone networks are major benefits seen in having a common protocol independent of the used network technology. But deploying IP and IP security to field-level networks in a straightforward way often violates application requirements such as available bandwidth or latency important on the field level.

In the following, the transport of secure IP over a highly resource-limited field-level network, namely, a last-mile powerline communication (PLC) network, is presented as prototype to efficiently tunnel IP packets. The example is based on IPv6 [58], which offers advantages for the smart grid application due to its much larger address space than IPv4 and its improved packet format designed for efficient packet header processing. Yet, results are also applicable to today's most common IPv4 and other applications, since a versatile IP channel transparent to the field-level network is set up. Using the IPv6 protocol and its security extension, IPsec (see also Section 29.3.4) carries a significant overhead, which must be managed to retain its benefits.

The general approach to reduce the payload penalty of IP is to compress in particular the large address fields of IP (each 16 bytes large) and omit/reconstruct unused flags. Robust header compression (ROHC) [59,60], which is a common protocol that can strip the 40-byte IPv6 header down to 2–4 bytes, was used in this case study. Although ROHCv2 also supports the compression of IPsec IPv6 extension headers, security has two inherent drawbacks for compression: First, encrypted data are random data by nature that cannot be compressed, and second, the combined application of AH and ESP protocols required by the security requirements of many industrial applications produces a large overhead of cryptographic ICVs that are also noncompressible data.

To address the first issue of payload compression, the order of compression is important. In particular, for IPsec tunnel mode, the application protocol data unit data have to be compressed before IPsec protection. For integrity check, the order is not mandatory, yet in the above order, less effort is required for the cryptographic calculation of the ICV, especially interesting for the verification of authenticity at the receiver. Additionally, the IPsec protection building block in Figure 29.4 includes specific compression for the different header and trailer fields of IPsec. In particular, Next Header and Payload Len, Reserved data, Sequence Number fields, and ICV padding can be reduced for transmission under special application-dependent conditions [61].

**FIGURE 29.4** Security module for efficient transmission of IPsec (internal IP stems from the device hosting the security module, and external IP refers to traffic of an additional network connected to the device).

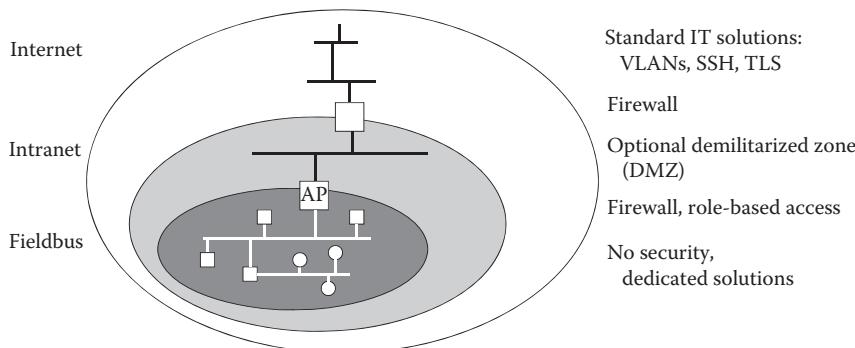

The second issue stems from the design of IPsec offering two independent security services, namely, AH protecting the integrity of the complete packet including header fields, and ESP only guaranteeing the confidentiality and integrity of the payload, both having their own ICV. Since for automation applications, in general, both services are required,\* two 20-byte ICVs and two headers with 30 and 12 bytes have to be transmitted offering no additional security. This is a strong drawback not only concerning packet size but also concerning computational power required to (cryptographically) process these packets. Hirschler and Treytl [62] introduce a new approach called ESP+ to overcome these issues. ESP+ is a modification of the ESP scheme merging the full integrity protection of AH with the ESP ICV calculation offering a constant overhead for all service calculation equal to the smallest IPsec header. Savings up to 50% of the original bandwidth required by standard IPsec can be achieved. Additionally, ESP+ is more energy aware, since one CPU-intensive intense cryptographic operation can be omitted. One of the big advantages of ESP+ is the full standard compatibility. Standard compression such as ROHC can be directly applied, and if required, ESP+ can be used to reversibly compress a combined AH-ESP service if the FAN is just used as a transport network. For smart grids, this is very important, since the backbone networks are not expected to use ESP+, and full IP(sec) transparency down to the nodes is targeted.

## 29.5 System-Level Approach—Defense in Depth

Given that automation systems today typically consist of a hierarchy of networks, one can also adopt a hierarchical security model following the defense-in-depth approach first suggested in [37]. The idea is to focus on the network levels that are normally separated from each other by dedicated network nodes. These nodes, which link the typical field-level network with the upper network levels, are usually equipped with more powerful hardware and can be used as anchor points for the security strategy. Defense in depth relies on different security layers to protect valuable assets: Using the famous onion analog on, we see that removing the outmost (security) layer reveals another layer and many more remain to be peeled away before the assets become vulnerable.

### 29.5.1 Three-Zone Security Model

The three-zone security model shown in Figure 29.5 is optimized for industrial communication applications and follows the typical network levels inside a company [63,64]: The inner zone comprises the field-level communication systems located at the shop floor, where security mechanisms might be

**FIGURE 29.5** Three-zone security model implementing the defense-in-depth approach.

\* First complete packet authentication is required to identify counterfeit components and devices injecting malicious packets in the network. This is only guaranteed by AH. Second confidentiality is needed not only for privacy protection of consumers but also to prevent disclosure of information between the multiple utilities using the same infrastructure.

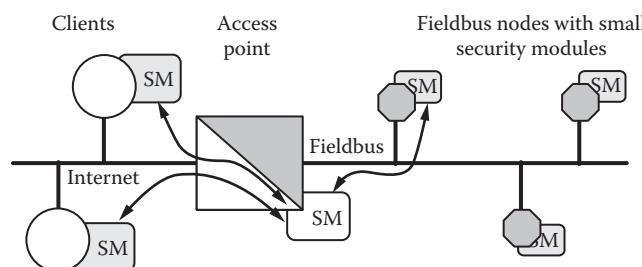

limited as discussed in the preceding sections. The intranet zone is often built upon IP-based LANs inside the plant and may also include demilitarized zones (DMZs) and checking domains or inner security structures to strengthen the security. Finally, the Internet zone connects multiple plants, customers, or suppliers horizontally along the value chain. On the IP-based levels of the automation system, the standard security mechanisms known from the IT world such as IPsec or TLS can be used. In the wake of e-commerce, such setups have been considered rather early for the horizontal integration of enterprises, leaving aside the special requirements of automation [65].

The nodes separating different zones always have been natural points to implement security. They are the only part of the automation system where security can easily be applied, since most field-level systems lack security. In the following, this node is called access point due to the fact that it often includes protocol translation and other means to negotiate between the two networks.

The access point itself has so far been the focal point of interest for most researchers. One very common approach in the defense-in-depth model is to combine the access point with a firewall, which is the most widely employed security measure in the design of network interconnections today even in the field of automation [66,67]. For higher security, it is also possible to implement the access point as a DMZ, where the gateway is shielded by two firewalls on each side.

The main purpose of a firewall is to separate a private, restricted intranet from a network that is accessible to a larger community [24,68]. This separation is normally implemented on the IP level by granting access only to computers from a predefined set of IP addresses or domains. Only requests from such addresses are accepted by the firewall, and all others are denied. This requires that the firewall should also work as an IP router connecting the private IP segment and the *open* segment reachable from the Internet. As the entire network traffic is controlled by the firewall, the intranet behind can be completely hidden from the outside world. The other way, from the intranet to the Internet, is less restricted: The firewall directly forwards the request from the internal node. Ideally, the node in the intranet does not even notice the presence of the firewall. Due to this asymmetric operation, the firewall is best tightly integrated into the access point and use, for example, port forwarding to control the traffic [67]. Additionally, a typical scenario is to make the firewall a VPN gateway, where the firewalls route the control network traffic into the VPN. Such implementations are mostly based on IPsec and are especially intriguing as key distribution is built in. A VPN also provides an easy answer for IP-based extensions of clear-text control network protocols.

Apart from providing basic firewall functionality, the access point is also the ideal point to control and manage access to the fieldbus zone. For the implementation of any security policy, end-to-end security is desirable, that is, the client in the Internet establishes a secure channel to the data source in the fieldbus irrespective of the network structure in between. In standard e-business, this can be achieved because only few entities are involved in a secure communication. In automation applications, the number of nodes needing secure communication is potentially very high. In fact, every sensor or actuator is affected, which makes the handling of communication relations and thus security keys extremely complex, even if technical aids like security tokens are employed [37]. A practicable compromise is to intercept the secure channel at the access point and introduce a two-step communication architecture (Figure 29.6).

**FIGURE 29.6** Two-step security architecture using security modules or security tokens (e.g., smart cards) for improved key manageability.

The access point maintains a list of the authorized connections in the Internet zone and directly controls the access to data objects or communication channels, depending on the access point's operation as tunnel entrance or gateway [68]. The fieldbus nodes, on the other side, only need to connect to their access point and can get along with smaller security tokens, if any [3]. This solution makes updates of the user structure easier [69]. A suitable model for handling the access rights in such a scenario is RBAC [21], where all communication partners (users, devices, and tools) are associated with particular roles depending on the context of the data exchange. In the IT world, this concept is widely employed, and it can also be used in an automation context [70,71].

### 29.5.2 Smart Grid Case Study

Smart grids are among the most novel large-scale industrial networks and transfer sensitive data that must be properly protected. Blackouts, privacy issues, poaching of customers, or even terroristic attacks can be results of missing security [72]. Since smart grids are relatively young, a lot of architectures for the communication systems exist, and multiple communication technologies are deployed. The following overview is based on a case study done in the project DLC+VIT4IP [61]. The structure shown in Figure 29.7 reflects the defense-in-depth approach facilitating a combination of firewalls filtering traffic and various SA endpoints deliberately breaking the communication flow to establish independent security domains.

Most obviously, the web access of customers via the Internet is separated in a single zone. Two firewalls define a DMZ, where only the web server(s) can provide data to the Internet and retrieve data from the intranet. In the intranet (zone), several application servers like billing, SCADA, and demand-side management are located. Pure office PCs are not depicted and usually combined in a distinct zone.

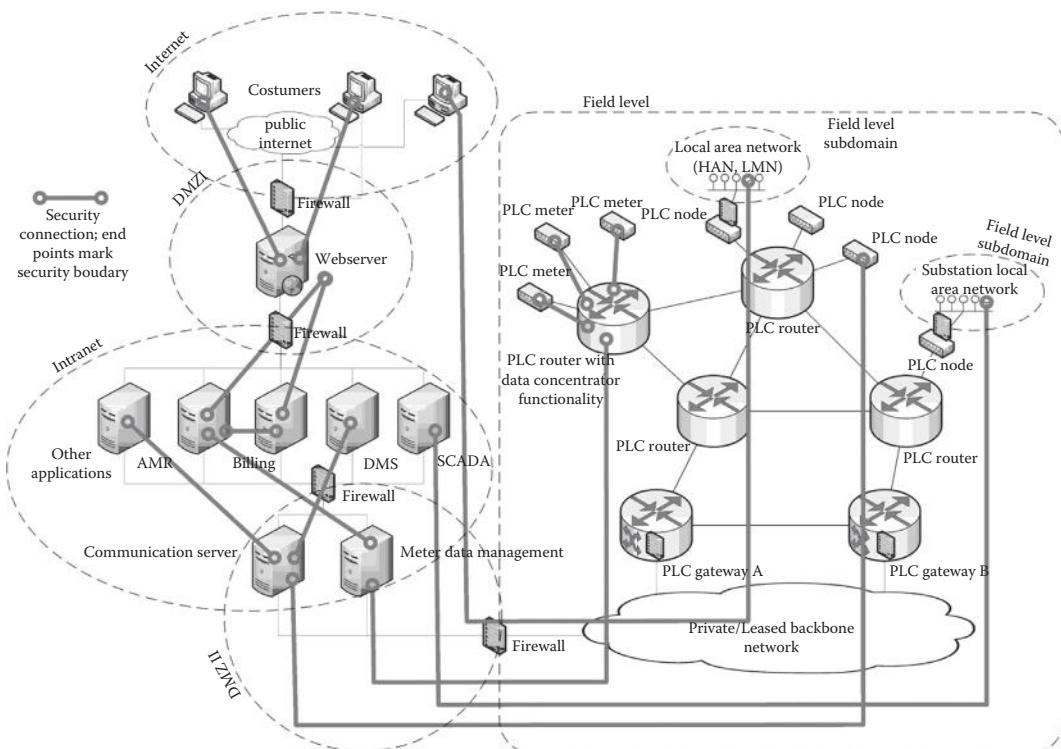

FIGURE 29.7 Communication scenario case study in smart grids.

A second intranet DMZ shields field-level communication. Various communication servers such as meter data management separate the actual field system from the application servers introducing an additional security perimeter. The next security zone is the access network, which is using public lines as well as the utility-owned PLC. The powerline gateway again implements firewall functionality to shield against the public network. Finally, either nodes directly connect to the access network or additionally multiple security zones can exist. In addition to the powerline network, each end node can connect to a LAN. In smart grids, one can distinguish between home automation network (HAN) or local metrology network (LMN) to interconnect home appliances or metering equipment, respectively, on the customer side or LANs for substation automation. The PLC node therefore includes some firewall functionality to separate the powerline access network from the HAN or LMN.

Solid bold lines introduce the security connections inside the network. Often a break of security is desired to either translate data or to deliberately interrupt the connection such as done at the web server providing data to the customers. Also systems such as the AMR are handled by a special server. In this case, the reason is abstraction to hide technical details from the metering system rather than security issues. Domotic applications on the other end can form a complete end-to-end connection from the security point of view. At the access network, communication should be as transparent as possible, although also on this level, devices such as data concentrators doing data preprocessing and aggregation are an interruption of the security chain.

Two design aspects gaining high importance in the implementation are connections transparently concatenating different network technologies and key management. The common trend for transparent communication is the usage of IP. Consequently, also standardized security protocols need to be used to offer end-to-end security and avoid breaking the security at network borders. IPsec and the presented ESP+ can offer such a transparency allowing seamlessly connecting IT equipment (private/leased backbone network) and the powerline access network. This results in a noninterrupted security chain between the desired endpoints independent of network type and also network operator. Key management is the other strong issue. In contrast to the Internet or telecom systems, automation systems require unattended operation and often do not foresee the interaction with an end user who can confirm or deny security requests. Public key cryptography offers the advantage of easier distribution and is therefore favored by several authors. Yet, also symmetric keys have big advantages in terms of execution speed and block size. Discussion is ongoing [73–75].

## 29.6 Conclusions

---

Security has become an issue in automation. Though not foreseen at the beginning of the development of automation systems, the ever-increasing degree of integration and interconnection of automation islands has unveiled security deficiencies that need remedy. The general path to security in automation is quite clear: Only proven strategies can be employed, which is tantamount to using security mechanisms developed in and for the much bigger domain of IT applications, where security has been a focal topic for a longer time and where the community devising and testing new security concepts and algorithm is much larger.

Yet, even though the security technologies from the IT world are mature, their application to automation systems is not straightforward. Too different are the requirements in IT and automation applications. Even if the defense-in-depth approach largely solves the technical problems, what remains are the organizational difficulties of defining and enforcing a security strategy. This applies in particular to security management. For instance, methods based on TLS are actually not ideal for data servers in automation applications. TLS requires a separate certificate for each node in the network that provides data. Methods based on plain TLS are therefore mostly found when sites or campuses are interconnected, which possess a well-defined set of access points visible to the Internet.

Especially in building automation or in smart grids, there are numerous access points in the backbone. This makes key distribution during commissioning or later on during operation a logistical

challenge and still leaves room for the development of innovative approaches. Even if security tokens are used as easy-to-handle key containers for system installation, key updates during normal operation should rather be done over the network, or if network bandwidth is scarce, distributed key derivation schemes should be devised. Without accounting for such special organizational needs in automation systems, security is difficult to achieve in practice.

### 30.1 Introduction

---

Wireless communication systems have diffused into an ever-increasing number of application areas and have achieved wide popularity. Wireless telephony and wireless mobile Internet access are now an important part of our daily lives, and wireless local area network (WLAN) technologies—for example, WiFi-based—have become more and more the primary way to access business and personal data. Two important benefits of wireless technology are key to this success: the need for cabling is greatly reduced,

and computers as well as users can be truly mobile. This saves costs and enables new applications. In factory plants, wireless technology can be used in several interesting ways [37,113,116]:

- WLAN technology can provide the communications services for distributed control applications [42] involving mobile subsystems like autonomous transport vehicles, robots, or turntables.
- Implementation of distributed control systems in explosive areas or in the presence of aggressive chemicals.
- Frequent plant reconfiguration gets easier as fewer cables have to be remounted.
- Mobile plant diagnosis systems and wireless stations for programming and on-site configuration.

However, when adopting WLAN technologies for the factory floor, some problems occur. The first problem is the tension between the hard reliability and timing requirements (hard real-time) pertaining to industrial applications on the one hand and the problem of wireless channels having time-variable and sometimes quite high error rates on the other. A second major source of problems is the desire to *integrate* wireless and wired stations into one single network (henceforth called a *hybrid system* or *hybrid network*). This integration calls for the design of interoperable protocols for the wired and wireless domains. Furthermore, using wireless technology imposes problems not anticipated in the original design of the (wired) fieldbus protocols: security problems, interference, mobility management, and so on.

In this chapter, we survey some issues pertaining to the design and evaluation of protocols and architectures for (integrated) wireless industrial LANs and provide a selective overview of the state of the art. There is an emphasis on aspects influencing the time and reliability behavior of wireless transmission. However, we not only discuss the problems but also present different solution approaches on the physical, medium access control (MAC), or data-link layer. These layers are key to the success of wireless fieldbus systems because they have important responsibilities in fulfilling timing and reliability requirements, and furthermore, they are exposed most directly to the wireless link characteristics. In the second part of this chapter, we focus on specific technologies and the creation of hybrid systems. On the one hand, there are a number of existing fieldbus standards like controller area network (CAN), factory instrumentation protocol (FIP)/WorldFIP, or PROFIBUS. For these systems, we discuss problems and approaches to create hybrid systems. On the other hand, one could start from existing wireless technologies and ask about their capabilities with respect to timeliness and reliability. The most widely deployed WLAN technology is currently the IEEE 802.11 WLAN standard [47], and its suitability for industrial applications is discussed.

This chapter is structured as follows: In Section 30.2, important general considerations and problems of wireless industrial communications and wireless fieldbus systems are presented. In Section 30.3, we discuss some basic aspects of wireless LAN technology and wireless wave propagation. The transmission impairments resulting from certain wave propagation effects and some physical layer approaches to deal with them are presented in Section 30.4. Wireless wave propagation has also some interesting consequences on the operation of the MAC and data-link layer; these are discussed in Section 30.5. The following two sections, Sections 30.6 and 30.7, take a more technology-oriented perspective. Specifically, in Section 30.6, we survey the state of the art regarding wireless industrial communication systems and wireless fieldbus systems. In Section 30.7, we present the important aspects of the IEEE 802.11 WLAN standard with respect to the transmission of real-time data. Finally, in Section 30.8, we provide a brief summary.

The chapter restricts itself to the consideration of protocol-related aspects of wireless transmission; other aspects like signal processing, analog and digital circuitry, and energy aspects are not considered. There are, for example, many introductory and advanced books on wireless networking [1,18,34,50,72,78,87,92,97,98,104]. Several separate topics in wireless communications are treated in [32]. Furthermore, this chapter is not intended to serve as introduction to fieldbus technologies; some background information can be found in [21,69]. Finally, there is also no discussion of wireless industrial sensor networks like, for example, Wireless HART [37,39,40].

## 30.2 Wireless Industrial Communications and Wireless Fieldbus: Challenges and Problems

In this section, we survey some of the problem areas arising in wireless fieldbus systems.

### 30.2.1 System Aspects

First of all, wireless fieldbus systems will operate in similar environments as wired ones. Typically, in factory automation applications, a small to moderate number of stations are distributed over geographically small areas with no more than 100 m between any pair of stations [45]. Wired fieldbus systems traditionally offer bitrates ranging from hundreds of kilobits to (tens of) megabits per second (real-time Ethernet systems can achieve higher rates [20]), and wireless fieldbus systems should have comparable bitrates. The wireless transceivers have to meet electromagnetic compatibility requirements, meaning that they not only have to restrict their radiated power and frequencies, but also should be properly shielded from strong magnetic fields and electromagnetic noise emanated by strong motors, high-voltage electrical discharges, and so on. This may pose a serious problem when off-the-shelf wireless transceivers are used (e.g., commercial IEEE 802.11 hardware), since these are typically designed for office environments and have no industrial-strength shielding.

Another problem is that many small fieldbus devices get their energy supply from the same wire as used for data transmission. If the cabling is to be removed from these devices, there is not only the problem of wireless data transmission but also the issue of wireless power transmission [43,95], which requires substantial effort.

For battery-driven devices, the need to conserve energy arises. As is known from the realm of wireless sensor networks, this has important consequences for the design of protocols [26,35,54] but is not discussed any further in this chapter.

### 30.2.2 Real-Time Transmission over Error-Prone Channels

In industrial applications, often *hard real-time* requirements play a key role. In accordance with [84], we assume the following important characteristics of hard real-time communications: (1) safety-critical messages must be transmitted reliably within an application-dependent deadline, (2) there should be support for message priorities to distinguish between important and unimportant messages, (3) messages with stringent timing constraints typically have a small size, and (4) both periodic and aperiodic/asynchronous traffic are present. The qualifier *hard* stems from the fact that losses or deadline misses of safety-critical packets can damage equipment or can even cost life. Both periodic and aperiodic messages in fieldbus systems can be subject to hard real-time constraints.

Wireless media tend to exhibit time-variable and sometimes high error rates, which creates a problem for fulfilling the hard real-time requirements. As an example, the measurements presented in [115] have shown that in a certain industrial environment, for several seconds, no packet gets through the channel. Therefore, seeking deterministic guarantees regarding timing and reliability is not appropriate. Instead, *stochastic guarantees* become important. The percentage of safety-critical messages which can be transmitted reliably within a prespecified time-bound should be at least 99.x%. Of course, the error behavior limits the application areas of wireless industrial LANs—when a safety-critical application requires deterministic guarantees in the range of 10–100 ms, wireless transmission is essentially ruled out. However, if occasional message loss or deadline misses are tolerable, wireless technologies can offer their potential. The goal is to reduce the frequency of losses and deadline misses.

How transmission reliability can be implemented depends on the communication model. In many fieldbus systems (e.g., PROFIBUS), packets are transmitted from a sender to an *explicitly addressed* receiver station without involving other stations. Reliability can be ensured by several mechanisms, for example, retransmissions, packet duplications, diversity mechanisms, error-correcting codes,

or a combination thereof. On the other hand, systems like FIP/WorldFIP [106] and CAN [48] implement the model of a *real-time database* where *data* are identified instead of stations. A piece of data has one *producer* and potentially many *consumers*. The producer broadcasts the data, and all interested consumers copy the data packet into an internal buffer. This broadcast approach inhibits the use of acknowledgments and packet retransmissions, but error-correcting codes and diversity mechanisms can still be used to increase transmission reliability. Often, the data are transmitted periodically, and (repeated) packet losses can be detected by comparing the known period and the time of the last arrival of a data packet. This *freshness* information can be used by the application to react properly.

### 30.2.3 Integration of Wired and Wireless Stations/Hybrid Systems

There are a huge number of existing and productive fieldbus installations, and it is very attractive to integrate wireless stations into these. Such a network with both wireless stations (stations with a wireless transceiver) and wired stations are called *hybrid systems* [14]. The most important requirements for hybrid systems are as follows:

- *Transparency*: There should be no need to modify the protocol stack of wired stations.
- *Using specifically tailored protocols*: Most fieldbus systems are specified on the layers one (physical), two (MAC and link layer), and seven (application layer) of the OSI reference model. The introduction of a wireless physical layer affects the behavior and performance of both the MAC and link layer. The existing protocols for wired fieldbus systems are not designed for a wireless environment (see [117] for an example) and should be replaced by protocols specifically tailored for the wireless link. However, this comes at the cost of *protocol conversion* between wired and wireless protocols.
- *Portability of higher-layer software*: If the link layer interface is the same for both the wireless and wired protocol stacks, implementations of higher-layer protocols and application software can be used in the same way on both types of stations.

The different approaches to integrate wireless stations into wired fieldbus LANs can be classified according to the layer of the OSI reference model where the integration actually happens [19,112]. Almost all fieldbus systems are restricted to the physical, data-link, and application layers [21]. The classification is as follows:

- *Wireless cable-replacement approach*: All stations are wired stations and thus attached to a cable. A piece of cable can be replaced by a wireless link, and special bridge-like devices translate the framing rules used on the wireless and wired media, respectively. In this approach, no station is aware of the wireless link. A typical application scenario is the wireless interconnection of two fieldbus segments.
- *Wireless MAC-unaware bridging approach*: The network comprises of both wired and wireless stations, but integration happens solely at the physical layer. Again, a bridge-like device translates the framing rules between wired and wireless media. The wireless stations use merely an alternative physical layer (PHY), but the MAC and link layer protocols remain the same as for wired stations.
- *Wireless MAC-aware bridging approach*: The LAN comprises of both wired and wireless stations, and integration happens at the MAC and data-link layer. There are two different MAC and link layer protocol stacks for wired and wireless stations, but both offer the same link layer interface. The wireless MAC and link layer protocols should be (1) specifically tailored to the wireless medium and (2) easily integrable with the wired MAC and link layer protocols. An intelligent bridge-like device is responsible for both translating the different framing rules as well as inter-operation of the different MAC protocols.
- *Wireless gateway approach*: In this approach, integration happens at the application layer or even in the application itself. Entirely different protocol stacks can be used on different types of transmission media.
- Some mixture of these approaches.

All of these approaches require special *coupling devices* at the media boundaries. For the wireless cable-replacement and the MAC-unaware bridging approaches, these devices can be relatively simple, whereas the other approaches may require complex and stateful operations. Hence, failures of such devices and proper redundancy need to be addressed.

### 30.2.4 Mobility Support

The potential station mobility is one of the main attractions of wireless systems. We can assume that wireless fieldbus systems will be mostly infrastructure based (meaning that there are base stations or access points [APs] that facilitate network operation). A *handover* must be performed when a mobile station moves from the range of one AP into the range of another AP [2,28]. Typically, handover processes involve exchange of signaling packets between the mobile station and the APs. Ideally, a station can fulfill timing and reliability requirements even during a handover. The applicability and performance of handover schemes depend on the maximum speed of a mobile station, on the wireless technology, and on other circumstances, for example, how well the trajectory of a mobile station can be predicted. In industrial applications, it is often forklifts, robots, or moving plant subsystems that are mobile, and it is safe to assume that these devices move with velocities of no more than 20 km/h [45].

A simple consequence of mobility is that stations may enter and leave a network at unpredictable times. To support this, a protocol stack at minimum must offer functionalities to make a new station known to the network/the other stations, and sometimes also address assignment is needed. On the other hand, fieldbus systems and their applications often are designed with the assumption that the network is set up once and not changed afterward. Consequently, some fieldbus systems do not easily support some dynamics in their set of stations. Consider, for example, the FIP/WorldFIP fieldbus [106]. This system belongs to the class of real-time database systems, and the producers of data items (called process variables) are polled by a dedicated central station, the *bus arbiter*. The bus arbiter keeps a table of variable identifiers and traverses it cyclically. To include a new station into the system, the arbiter's table has to be modified by a human operator. It is worth noting that the most widely used fieldbus systems do not offer any support for dynamic address assignment.

### 30.2.5 Security Aspects and Coexistence

Security played no important role in the initial design of the fieldbus standards. This was reasonable, because physical access to a wire is needed to eavesdrop or inject packets. However, the introduction of wireless media allows an attacker to eavesdrop packets at some distance, for example, on the factory's parking lot. Even worse, an attacker could generate interference on the operating frequency of a wireless fieldbus system and distort all transmissions (including the time-critical and important ones). An attacker might also try to inject malicious packets into the network, for example, false valve commands. Therefore, security measures (integrity, authentication, and authorization) have to be added to wireless fieldbus systems [94].

Noise and interference is not only generated deliberately by an attacker, but can also come from collocated wireless systems working in the same frequency band. As an example, both IEEE 802.11 and Bluetooth use the 2.4 GHz ISM band and create mutual interference. This coexistence problem is explored in [16].

## 30.3 Wireless LAN Technology and Wave Propagation

---

In this section, we discuss some basic characteristics of WLAN technology and present some of the fundamental wave propagation effects. In Sections 30.4 and 30.5, we discuss physical layer and MAC/link layer approaches to overcome or at least relax some of the problems created by the propagation effects.

### 30.3.1 Wireless LANs

Wireless LANs are designed for packet-switched communications over short distances (up to a few hundred meters) and with moderate to high bitrates. Nowadays, the dominant wireless LAN technology is IEEE 802.11 [47], also often referred to as WiFi. As an example, the IEEE 802.11a and 11g WLAN standard offers bitrates between 1 and 54 Mbps, whereas the draft 802.11ac standard offers bitrates up to 866.7 Mbit/s, using a system bandwidth of 160 MHz and MIMO transmission. WiFi uses radio frequencies in the 2.4 and 5 GHz frequency bands. More specifically, WiFi uses so-called ISM bands (industrial, scientific, and medical), which are particularly attractive, since they allow for license-free operation, and the only restriction in using this band is a transmit power limit. On the other hand, since anyone can use these bands, several systems have to coexist. Radio waves below 6 GHz propagate through walls and can be reflected on several types of surfaces, depending on both frequency and material. Thus, with radio frequencies, non-line-of-sight communications is possible.

WiFi networks can be operated in two different modes. In the infrastructure mode, centralized facilities like APs or base stations are responsible for tasks like radio resource management, forwarding data to distant stations, mobility management, and so on. In the ad hoc mode, there is no prescribed infrastructure, and the stations have to organize network operation by themselves [102].

Infrastructure-based WLANs offer some advantages for industrial applications. Many industrial communication systems already have an asymmetric structure that can be naturally accommodated by infrastructure-based systems. The often used master-slave communication scheme serves as an example. Furthermore, the opportunity to offload certain protocol processing tasks to the infrastructure allows to keep mobile stations more simple and to make efficient centralized decisions.

As compared to other wireless technologies like cellular systems and cordless telephony, WLAN technologies seem to offer the best compromise between data rate, geographical coverage, and license-free/independent operation.

### 30.3.2 Wave Propagation Effects

In the wireless channel, waves propagate through free space, which is an unguided medium, that is, propagation is not spatially confined. The wireless channel characteristics are significantly different from those of guided media like cables and fibers, and they create unique challenges for communication protocols.

A transmitted waveform is subjected to phenomena like path loss, attenuation, reflection, diffraction, scattering, adjacent- and co-channel interference, thermal or man-made noise, and finally imperfections in the transmitter and receiver circuitry [12,87].

The path loss characterizes the loss in expected received signal power when increasing the distance between a transmitter  $T$  and a receiver  $R$ . In general, the average received power level  $P_{\text{Rx}}$  can be represented as the product of the transmit power  $P_{\text{Tx}}$  and the path loss PL:

$$P_{\text{Rx}} = P_{\text{Tx}} \cdot \text{PL}$$

The path loss PL itself is distance dependent. A typical path-loss model for omnidirectional antennas is given by [87, Chapter 4.9]:

$$\text{PL}(d) = C \cdot \left( \frac{d}{d_0} \right)^n$$

where

$d \geq d_0$  is the distance between  $T$  and  $R$

PL ( $d$ ) is the path loss at distance  $d$

$d_0$  is a reference distance that depends on the antenna technology (it is  $\approx 1$  m for WiFi systems)

$C$  is a technology- and frequency-dependent scaling factor

$n$  is the so-called path-loss exponent

Typical values for  $n$  are in the range between 2 (free-space propagation) and 5 (shadowed urban cellular radio), see also [87, Chapter 4.9].

Reflection occurs when a waveform impinges on a smooth surface with structures significantly larger than the wavelength. Not all signal energy is reflected; some energy is absorbed by the material. The mechanism of diffraction allows a wave to propagate into a shadowed region, provided that some sharp edge exists. Scattering is produced when a wavefront hits a rough surface having structures smaller than the wavelength; it leads to signal diffusion in many directions.

The most important types of interference are co-channel interference and adjacent-channel interference. In co-channel interference, a signal transmitted from  $T$  to  $R$  on channel  $c_1$  is distorted by a parallel transmission on the same channel. In case of adjacent channel interference, the interferer  $I$  transmits on an adjacent channel  $c_2$ , but due to imperfect filters,  $R$  captures frequency components from  $c_2$ . Alternatively, an interferer  $I$  transmitting on channel  $c_2$  leaks some signal energy into channel  $c_1$  due to nonperfect transmit circuitry (amplifier).

Noise can be thermal noise or man-made noise. Thermal noise is created in the channel or in transceiver circuitry and can be found in almost any communications channel. Man-made noise in industrial environments can have several sources, for example, remote controls, motors, or microwave ovens. The predominant model for noise is white noise or Gaussian noise, which operates additively on signals. Gaussian noise is characterized by its noise power, which depends on physical factors like the system temperature, the system bandwidth, and others. It is also common to model interference as noise of higher power.

## 30.4 Physical Layer: Transmission Problems and Solution Approaches

---

The previously discussed wave propagation effects can lead to channel errors. In general, their impact depends on a multitude of factors, including frequency, modulation scheme, and the current propagation environment. The propagation environment is characterized by the distance between stations, interferers, the number of different paths and their respective loss, and more. These factors can change when stations or parts of the environment move. Consequently, the transmission quality is time variable.

### 30.4.1 Effects on Transmission

The notion of slow fading refers to significant variations in the mean path loss, as they occur due to significant changes in distance between transmitter  $T$  and receiver  $R$ , or by moving beyond large obstacles. Slow-fading phenomena usually occur on timescales significantly longer than a packet; they often coincide with human activity like mobility. For short durations in the range of a few seconds, the channel can often be assumed to have constant path loss.

An immediate result of reflection, diffraction, and scattering is that multiple copies of a signal may travel on different paths from  $T$  to  $R$ . Since these paths usually have different lengths, the copies arrive at different times (delay spread) and with different phase shifts at the receiver, where they are superposed. This has two consequences:

1. Overlapping signals can interfere constructively or destructively. Destructive interference may lead to up to 40 dB loss of received power. Such a situation is often called a deep fade.
2. Delay spread leads to intersymbol interference, since signals belonging to neighbored information symbols overlap at the receiver.

If the stations move relative to each other or to the environment, the number of paths and their phase shifts vary in time. This results in a fast fluctuating signal strength at the receiver (called fast fading or multipath fading). It is important to note that these fluctuations are much faster than those caused by

slow fading. Fast fading happens on time scales of milliseconds to tens of milliseconds (which for WiFi can overlap with several packet transmissions), whereas slow fading happens at timescales of seconds or minutes. On the timescale of milliseconds, the mean signal strength is constant. If the delay spread is small relative to the duration of a channel symbol, the channel is called non-frequency-selective or flat; otherwise, it is called frequency selective.

These phenomena translate into bit errors or packet losses. Packet losses occur when the receiver fails to acquire carrier or bit synchronization [115]—a lost packet in this sense is (at the receiver) indistinguishable from a packet never sent. In case of bit errors, synchronization is successfully acquired, but a number of channel symbols are decoded or demodulated incorrectly. The bit error rate can, for example, be reduced by using forward error correction (FEC) techniques [17,67]. The statistical properties of bit errors and packet losses on wireless links were investigated in a number of studies [8,24,76,115,120]. While the results are not immediately comparable, certain trends show up in almost every study:

- Both bit errors and packet losses are *bursty*; they occur in clusters with error-free periods between the clusters. The distributions of the cluster lengths and the lengths of error-free periods often have a large coefficient of variation or even seem to be heavy tailed.
- Bit error rates depend on the modulation scheme; typically, schemes with higher bitrates/symbol rates exhibit higher error rates.
- Wireless channels can be much worse than wired channels; often bit error rates of  $10^{-2}$  to  $10^{-5}$  can be observed. Furthermore, the bit error rate can vary over several orders of magnitudes within minutes.

Some knowledge about error generation patterns and error statistics can be helpful in designing more robust protocols.

### 30.4.2 Wireless Transmission Techniques

A number of different transmission techniques have been developed to combat the impairments of the wireless channel and to increase the reliability of data transmission.

Many types of WLANs (including the older versions of IEEE 802.11) rely on spread-spectrum techniques [33], where a narrowband information signal is spread to a wideband signal at the transmitter and despread back to a narrowband signal at the receiver. By using a wideband signal, the effects of narrowband noise or narrowband interference are reduced. The two most important spread-spectrum techniques are direct-sequence spread spectrum (DSSS) and frequency-hopping spread spectrum (FHSS).

In DSSS systems, an information bit is multiplied (XORed) with a finite bipolar chip sequence such that transmission takes place at the chip rate instead of the information bitrate. The chip rate is much higher than the information rate and consequently requires more bandwidth; accordingly, the duration of a chip is much smaller than the duration of a user symbol. The chip rate is chosen such that the average delay spread is larger than the chip duration; thus, the channel becomes frequency-selective. Receivers can explore this in different ways. To explain the first one, let us assume that the receiver receives a signal  $S$  from an LOS path and a delayed signal  $S'$  from another path, such that the delay difference (called lag) between  $S$  and  $S'$  is more than the duration of a single chip. The chip sequences are designed such that the autocorrelation between the sequence and a shifted version of itself is low for all lags of one chip duration or more. If a coherent matched-filter receiver is synchronized with the direct signal  $S$ , the delayed signal  $S'$  appears as white noise and produces only a minor distortion. In the RAKE receiver approach, delayed signal copies are not treated as noise but as a useful source of information [97, Section 30.4]. Put briefly, a RAKE receiver tries to acquire the direct signal and the strongest time-delayed copies and to combine them coherently. However, RAKE receivers are much more complex than simple matched-filter DSSS receivers.

In FHSS, the available spectrum is divided into a number of subchannels. The transmitter hops through the subchannels according to a predetermined schedule (often based on a pseudorandom

sequence), which is also known to the receiver. The advantage of this scheme is that a subchannel currently subject to transmission errors is used only for a short time before the transmitter hops to the next channel. The hopping frequency is an important parameter of FHSS systems, since high frequencies require fast and accurate synchronization. As an example, the FHSS version of IEEE 802.11 hops with 2.5 Hz, and many packets can be transmitted before the next hop. In Bluetooth, the hopping frequency is 1.6 kHz, and at most one packet can be transmitted before the next hop. Packets are always transmitted without being interrupted by hopping.

In the last decade, there was a strong uptake of OFDM-based transmission technologies [6,66,108], which have been adopted in the LTE [55] technology for 4G mobile broadband, in WiMax (or IEEE 802.16), and also in the newer physical layers adopted for IEEE 802.11 (formerly known as the IEEE 802.11a and g extensions). OFDM stands for orthogonal frequency division multiplexing. In OFDM, the available spectrum is subdivided into a number  $N$  of small and closely packed subchannels or subcarriers (the 5 GHz OFDM physical layer of IEEE 802.11 uses 52 subcarriers). The bandwidth of each subcarrier is small enough to obtain a frequency-nonselective channel. Data are transmitted over all subcarriers in parallel; the data rate on each subcarrier (using standard modulation schemes like BPSK, QPSK, and so forth) is small enough so that (due to the additional presence of a guard interval) the delay spread is much smaller than the average symbol duration and inter-symbol interference can be avoided. The OFDM scheme used in IEEE 802.15.4 additionally applies error-correction coding such that coding is applied *across* subcarriers instead of applying it to each subcarrier separately.

Another large class of transmission techniques are so-called diversity techniques. In general, diversity methods aim to provide the receiver with several independently faded copies of the same signal, which it can then suitably combine [87]. Intuitively, when several *independently faded* signal copies are available at the receiver, the chance that all of them are in a deep fade *simultaneously* (thus leaving the receiver with no chance of proper decoding) shrinks quickly with the number of signal copies. Three basic forms of diversity are time diversity, frequency diversity, and spatial diversity. With time diversity, different copies of the same signal/packet are achieved by repeating the signal at different times on the same channel, such that the spacing between different copies is larger than the so-called channel coherence time, which can be regarded as the time over which the channel stays roughly constant. Even when the coherence time is known, time diversity has unfavorable properties in real-time settings, as generally waiting times need to be inserted before the next copy can be sent. With frequency diversity, the same signal is repeated over different frequencies, where the frequencies are either used sequentially in time (when only one transceiver is available) or in parallel. Finally, in spatial diversity methods, diversity is obtained from placing multiple antennas with a certain spatial separation [23]. For example, in receive diversity, the transmitter uses a single antenna and the receiver uses multiple antennas. This not only effectively increases the received energy per symbol, the receiver can also combine the signals received over different antennas suitably. With transmit diversity, the transmitter has several antennas, but the receiver has only one. The transmitter could use his or her antennas sequentially (sending only on one antenna at a time), or it could transmit on all antennas in parallel. Finally, the case where multiple transmit and multiple receive antennas are present simultaneously is known as Multiple Input Multiple Output (MIMO) transmission [80,81]. MIMO approaches have been adopted recently into the IEEE 802.11 standard; formerly, they were proposed as an extension known as 802.11n. With MIMO systems, it is possible to use the multiple antennas either for increasing transmission rates (in fact, MIMO is the key for driving WiFi rates close to the Gigabit/s range, and theoretical results assert that if both transmitter and receiver have  $n$  antennas, then the capacity of the MIMO channel scales linearly with  $n$ ), essentially by sending a different symbol over each transmit antenna, or for improving reliability, by sending the same symbol over all transmit antennas. Through usage of so-called space-time codes, it even becomes possible to trade off rate and reliability against each other [64,100].

True MIMO transmission does not only offer increased reliability or increased rates but also presents some problems specifically for energy-constrained (e.g., mobile) devices. One problem is the relatively

large form factor of stations that is required to achieve a certain minimum spacing of antennas—antenna separation should be about half a wavelength to obtain uncorrelated signals. The second problem is that MIMO techniques require complex signal processing at the receiver. As an alternative, cooperative communication schemes have been developed recently [58,62,68,77,93,109]. In these schemes, all involved stations require only a single antenna, and virtual antenna arrays are formed by cooperation among them.

## 30.5 Problems and Solution Approaches on the MAC and Link Layer

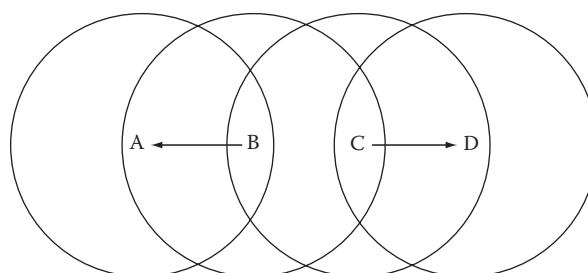

The MAC and the link layer are exposed most to the error behavior of wireless channels and should do most of the work needed to improve the channel quality. Specifically for hard real-time communications, the MAC layer is a key component: If the delays on the MAC layer are not properly bounded, the upper layers cannot compensate this. In general, the operation of the MAC protocol is heavily influenced by the properties of the physical layer. Some of the unique problems of wireless media are discussed in this section. For a general discussion of MAC and link layer protocols, we refer the reader to [22,36,59,99,107].

### 30.5.1 Problems for Wireless MAC Protocols

Several problems arise due to path loss in conjunction with a threshold property—wireless receivers require the signal to have a minimum strength to be detectable. For a given transmit power, this requirement translates into an upper bound for the distance between two stations wishing to communicate\*; if the distance between two stations is larger, they cannot hear each other's transmissions. For MAC protocols based on carrier sensing (carrier sense multiple access [CSMA]), this property creates the hidden terminal problem [101] and the exposed terminal problem.

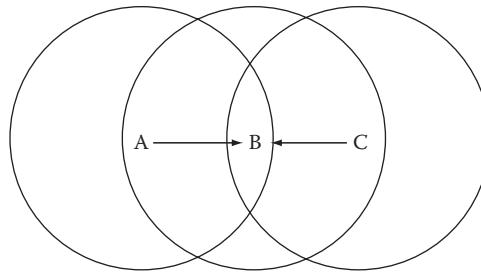

The hidden terminal problem is sketched in Figure 30.1. Consider three stations A, B, and C with transmission radii as indicated by the circles. Stations A and C are in the range of B, but A is not in the range of C and vice versa. If C starts to transmit to B, A cannot detect this by its carrier-sensing mechanism and considers the medium to be free. Consequently, A also starts packet transmission, and a collision occurs at B.

The exposed terminal problem is also a result of false prediction of the channel state at the receiver. An example scenario is shown in Figure 30.2. The four stations A, B, C, and D are placed such that the pairs A/B, B/C, and C/D can hear each other, but all other combinations cannot. Consider the situation where B transmits to A, and one short moment later, C wants to transmit to D. Station C performs

**FIGURE 30.1** Hidden terminal scenario.

\* To complicate things, wireless links are not necessarily bidirectional: It may well happen that station A can hear station B but not vice versa. This can, for example, happen if the two stations use different transmit powers or if the antennas are directional and both stations' antennas are not well aligned to each other.

**FIGURE 30.2** Exposed terminal scenario.

carrier sensing and senses the medium busy due to B's transmission. Consequently, C postpones its transmission. However, C could safely transmit its packet to D without disturbing B's transmission to A. This leads to a loss of efficiency.

Two approaches to solve these problems are busy tone solutions [101] and the RTS/CTS protocol. In the busy tone solution, two channels are assumed: a data channel and a separate control channel for the busy tone signals. The receiver of a packet transmits a busy tone signal on the control channel during packet reception. If a prospective transmitter wants to perform carrier sensing, it listens on the control channel instead of the data channel. If the control channel is free, the transmitter can start to transmit its packet on the data channel. Under ideal circumstances, this protocol solves the exposed terminal problem. The hidden terminal scenario is also solved, except perhaps for those rare cases where A and C start their transmissions truly simultaneously. However, if the busy tone is transmitted only when the receiver detects a valid packet header, the two colliding stations A and C can abort their transmissions quickly when they perceive the lack of a busy tone. The busy tone solution requires two channels and two transceivers. Furthermore, if the range of the busy tone signal is smaller than the range of the data signal, then collisions and hidden-terminal scenarios can still occur. On the other hand, if the range of the busy tone signal is larger than the range of the data signal, then it might happen that perfectly legal transmissions might be suppressed.

The RTS/CTS protocol attacks the hidden terminal problem using only a single channel. Here we describe the variant used in the IEEE 802.11 WLAN, there are other ones. Consider the case that station A has a data packet for B. After A has obtained channel access, it sends a short request-to-send (RTS) packet to B. This packet includes the time duration needed to finish the whole packet exchange sequence including the final acknowledgment. If B receives the RTS packet properly, it answers with a clear-to-send (CTS) packet, again including the time needed to finish the packet exchange sequence. Station A starts to transmit its data packet immediately after receiving the CTS packet. Any other station C, hearing the RTS and/or the CTS packet, defers its transmissions for the indicated time, this way not disturbing the ongoing packet transmission. It is a conservative choice to defer on any of the RTS or CTS packets, and in fact the exposed terminal problem still exists. One solution could be to let C defer only on reception of a CTS frame and to allow C a packet transmission if it hears an RTS without corresponding CTS frame.\* The RTS/CTS protocol described here does not prevent collisions of RTS packets, and it is still susceptible to subtle variants of the hidden terminal problem [86]. Its biggest problem, however, is the large overhead especially for small data packets as they are prevalent in industrial data traffic.

A significant problem of wireless transceivers is that usually they are not able to transmit and receive simultaneously on the same frequency band. Hence, a fast collision detection procedure similar to the CSMA/CD protocol of Ethernet is impossible to implement. Instead, collision detection has to resort to other mechanisms like the busy tone approach described earlier (rarely used) or the use of MAC layer acknowledgments (used frequently). Unfortunately, there are fieldbus systems relying on such a feature,

---

\* Clearly, if C receives a distorted CTS packet, it should defer.

for example, the CAN fieldbus [48] with its priority arbitration protocol. In this class of protocols, each message is tagged with a priority value, and this value is used to deterministically resolve collisions. In the CAN protocol, all stations are tightly time synchronized, and the priority field is always at the start of a packet. All contending stations start packet transmission at the same time. Each contender transmits its priority field bit by bit and reads back the signal from the medium. If the medium state is the same as the transmitted bit, the station continues; otherwise, the station gives up and waits for the next contention cycle. This protocol requires not only the ability to simultaneously listen and receive on the same channel, but also that the channel must also produce meaningful values from overlapping signals. Alternative implementations are sketched in Section 30.6.1.

Even receiver-based collision detection may not work reliably due to the near–far effect. Consider two stations A and B transmitting packets in parallel to a station C. For simplicity, let us assume that both stations use the same transmit power. Station A is very close to C, whereas station B is far away but still in reach of C. Consequently, A's signal at C is much stronger than B's. In this case, it may happen that C successfully decodes a packet sent by A despite B's parallel transmission. This situation is advantageous for the system throughput but disadvantageous for MAC protocols relying on collision detection or collision resolution.

### 30.5.2 Methods for Combating Channel Errors and Channel Variation

A challenging problem for real-time transmission is the error-prone and time-varying channel. There are many possible control knobs for improving the channel quality, for example, transmit power, bitrate/modulation, coding scheme/redundancy scheme, packet length, choice of retransmission scheme (automatic repeat request [ARQ]), postponing schemes and timing of (re-)transmissions, diversity schemes [79], and adaptation as a meta method [27]. In general, adaptation at the transmitter requires feedback from the receiver. This feedback can be created by using immediate acknowledgment packets after each data packet.

The variation of transmit power and of the bitrate/modulation scheme are both equivalent to varying the energy per bit, which in turn influences the bit error rate [44,85,87]. Roughly, a higher transmit power increases the signal-to-noise ratio and by this reduces the bit error rate and in turn the rate of required retransmissions. However, an increased transmit power might create more interference to other devices sharing the same frequency band (e.g., WiFi and Bluetooth operating in the 2.4 GHz band), which in turn might trigger them to increase their transmit power as well. When adjusting the modulation scheme, the general trade-off is that slower modulation schemes (with fewer levels per time step) have lower bit error rates than faster schemes.

A common way to protect data bits against bit errors is to use redundancy. Example approaches are error detecting and correcting codes (also called FEC) [65] and the transmission of multiple copies of a packet [3]. The latter approach can also be classified as a time-diversity scheme [79]. It is beneficial for the overall throughput to control the amount of redundancy according to the current channel state such that none or only a little redundancy is added when the channel currently shows only few errors [15,24].

Another standard way to deal with transmission errors is retransmissions and suitable ARQ schemes [38]. For channels with deep fades lasting several packet transmission times, it is not useful to retransmit the same packet immediately on the same channel. Specifically, when the mean length of deep fades or error bursts is of the same order or larger than the packet length, both the original packet and its immediate retransmission are likely to be hit by the same error burst. Hence, under these circumstances, an immediate retransmission wastes time and energy.

The transmitter can *postpone* the retransmission for a while and possibly transmit packets to other stations/over other channels in the meantime. If the postponing delay is well chosen, the channel has left the error burst when it is revisited, and the retransmission is successful. Indeed, it has been demonstrated in [5,9,10] that such an approach can reduce the number of wasted packets and increase the throughput significantly. But how to choose the postponing delay? One option is to adopt some fixed value that could be based on measurements or on an a priori knowledge about the channel. Another option is to send occasionally small probing packets [119], which the receiver has to acknowledge.

If the transmitter captures such an acknowledgment, it assumes the channel to be back in good state and continues data transmission. For real-time systems, the postponing decision should consider not only the channel state but also the deadline of a packet. The authors of [25] describe a scheme that takes both the estimated channel state (for postponing decisions) and the packet deadline into account to select one coding scheme from a suite of available schemes.

Retransmissions do not necessarily need to use the same channel as the original packet. It is well known that wireless channels are spatially diverse: A signal transmitted by station A can be in a deep fade at geographical position  $p_1$  and at the same time good enough to be properly received at another position  $p_2$  having the same distance to the transmitter but being separated from  $p_1$  by at least about half a wavelength.\* This property is exploited by MIMO and cooperative communication schemes, and it can be explored at the level of ARQ protocols. Assume that station A transmits a packet to station B. The channel from A to B is currently in a deep fade, but another station C successfully captures A's packet. If the channel from C to B is currently in a good state, the packet can be successfully transmitted over this channel. Therefore, station C helps A with its retransmission. This idea has been applied in [112] to the retransmission of data packets as well as to poll-packets in a polling-based MAC protocol.

In general, ARQ schemes can be integrated with FEC schemes into hybrid error control schemes [67]. Ideally, for industrial applications, deadlines should be taken into account when designing these schemes. In [4,105], retransmissions and FEC are combined with the concept of deadlines by increasing the coding strength with each retransmitted packet as the packet deadline approaches. This is called deadline-dependent coding. Another interesting hybrid error control technique is packet combining [41,52,110]. Put briefly, in these schemes, the receiver tries to take advantage of the partially useful information contained in already received erroneous copies of a packet. For example, if the receiver has received at least three erroneous copies of a packet, it can try to figure out the original packet by applying bit-by-bit majority voting. There are other packet-combining techniques, for example, equal-gain combining or based on intermediate checksums [114].

Sometimes, the packet error probability (and therefore the need for retransmissions) can be reduced by proper tuning of packet sizes. Intuitively, it is clear that larger packets are more likely hit by errors than smaller ones. On the other hand, with smaller packets, the fixed-size packet header becomes more dominant and leads to increased overhead. If the transmitter has estimates of current channel conditions, it can choose the *appropriate* packet size giving the desired trade-off between reliability and efficiency [71,96].

## 30.6 Wireless Fieldbus Systems: State of the Art

---

Fieldbus systems are designed to deliver hard real-time services under harsh environmental conditions. A wireless fieldbus [19] should be designed to provide as stringent stochastic timing and reliability guarantees as possible over wireless links. We discuss existing approaches for different popular fieldbus systems.

### 30.6.1 CAN

As already described in Section 30.5.1, the CAN system [48] uses a priority arbitration protocol on the MAC layer, which cannot be implemented directly on a wireless link. Some approaches have been developed to circumvent this; here we discuss a centralized and two distributed solutions [61].

The distributed WMAC protocol uses the scheme CSMA with collision avoidance (CSMA/CA) with priority-dependent backoffs. A station wishing to transmit a packet uses a carrier sense mechanism to wait for the end of an ongoing packet transmission. After this, the station picks a backoff time depending on the priority value of the current packet. The station listens to the channel during the backoff time. If no other station starts transmission, the station assumes that it has the highest priority and starts transmitting

---

\* More precisely, the two antennas should at minimum have a mutual distance of 40% of the wavelength [87, Chapter 5]. If the system operates in the 2.4 GHz ISM band, this amounts to 5–6 cm.

its own packet. Otherwise, the station defers and starts over after the other packet has been finished. In another distributed scheme, the CAN message priority value is mapped onto the channel using an on-off keying scheme [60]. A station transmits a short burst if the current priority bit is a logical one; otherwise, it switches into receive mode. If the station receives any signal, it gives up; otherwise, it continues with the next bit. The priority bits are considered from the most significant bit to the least significant bit. If the station is still contending after the last bit, it transmits the actual data packet. This approach requires tight synchronization and fast switching between transmit and receive modes of the radio transceiver, which is a problem for certain WLAN technologies. A similar scheme has also been proposed in [82].

The centralized RFMAC protocol leverages the fact that CAN belongs to the class of systems using the real-time database communication model. Data items are identified by unique identifiers. Similar to FIP/WorldFIP, all communications are controlled by a central station broadcasting the variable identifiers and causing the producers of the corresponding data items to transmit the data.

### 30.6.2 FIP/WorldFIP

The FIP/WorldFIP fieldbus uses a polling table to implement a real-time database [106]. To couple wired and wireless stations, in [74], a wireless-to-wired gateway is introduced, serving as central station for the wireless part. The wireless MAC protocol uses time division multiple access (TDMA), and each TDMA slot is used to transmit one data item (also called process variable).

In the OLCHFA project, a prototype system integrating wired and wireless FIP stations has been developed. This system worked in the 2.4 GHz ISM band using a DSSS physical layer [49]. The available publications put emphasis on the management of configuration data and on distributed algorithms for clock synchronization. The MAC and data-link protocols of FIP were not modified. Since FIP broadcasts the values of process variables periodically, the protocol contains no retransmission scheme for the time-critical data. Instead, the OLCHFA approach is to enhance the FIP process variable model with the so-called time-critical variables, which provide freshness information to the applications. Applications can use this to handle cases of repeated losses.

### 30.6.3 PROFIBUS

The R-FIELDBUS project ([www.rfieldbus.de](http://www.rfieldbus.de)) evaluated how IEEE 802.11 with DSSS can be used in a PROFIBUS fieldbus system and how such a system can be used for transmission of IP-based multimedia data [45,90]. Two different architectures have been proposed: the single logical ring and the multiple logical ring solution, discussed later. Both solutions run the (almost) unmodified PROFIBUS protocol. The PROFIBUS protocol uses token-passing on top of a broadcast medium. The token is passed between active stations along a logical ring, and much of the protocol's complexity deals with ring maintenance. The token itself is a small control frame.

In the single logical ring solution, all wired and wireless stations are integrated into a single logical token-passing ring. The coupling devices between the wired and wireless domains simply forward all packets. This approach is easy to realize but subjects both data packets and control packets like the token-frame to the errors on wireless links. It is shown in [117] for the PROFIBUS and in [51] for the similar IEEE 802.4. Token Bus protocol that repeated losses of token-frames can create severe problems with the achievable real-time performance. Since there is only a single logical ring, the whole network is affected.

In contrast, in the multiple logical ring solution [30], wireless and wired stations are separated into several logical rings. These rings are coupled by intelligent devices called brouters (a merger from bridge and router). In this solution, transmission problems distort only one ring; the other logical rings remain operational. A second benefit of having multiple rings is traffic segmentation. If the segments are chosen carefully, most of the traffic will be intrasegment, and thus, the overall traffic capacity can be increased. A drawback of the multiple logical ring solution, however, is that intersegment traffic is not natively supported by the PROFIBUS protocol, and extensions are required.

In [111,112], a system following the wireless MAC-aware bridging approach is proposed. On the wireless side, specifically tailored polling-based protocols are used, whereas wired stations run the unmodified PROFIBUS protocol stack. The goal is to avoid token-passing on wireless segments. It is shown that for bursty channel errors, the polling-based protocols achieve substantially better performance in terms of stochastic hard real-time behavior than the PROFIBUS token-passing protocol; for certain kinds of channels, the 99% quantile of the delay needed to successfully transmit a high-priority packet is up to an order of magnitude smaller than for the PROFIBUS protocol. To integrate both protocols, the coupling device between wired and wireless media provides a virtual ring extension [111]. In this scheme, the coupling device acts on the wired side on behalf of the wireless stations. For example, it creates token-frames and executes the ring maintenance mechanisms.

Finally, in [63], a scheme for integration of wireless nodes into a PROFIBUS-DP network (single master, many slaves, no token-passing) is described. An application layer gateway is integrated with a *virtual master* station. The virtual master acts as a proxy for the wireless stations; it polls them using standard IP and IEEE 802.11 distributed coordination function (DCF) protocols.

### 30.6.4 Other Fieldbus Technologies

For the IEC Fieldbus [46] (which uses a centralized, polling-based access protocol for periodic data and a token-passing protocol for asynchronous data) in [11], an architecture that allows coupling of several fieldbus segments using a wireless backbone based on IEEE 802.11 with point coordination function (PCF) is proposed.

In [75], it is investigated how the MAP/MMS application layer protocol can be enhanced with mobility. In the proposed system, the IEEE 802.11 WLAN with DCF is used; time-critical transmissions and channel errors are not considered. In [73], the same question was investigated with digital European cordless telephone as underlying technology.

## 30.7 Wireless Ethernet/IEEE 802.11

---

Instead of developing WLAN technology for the factory floor from scratch, existing technologies can serve as a starting point. A good candidate is the IEEE 802.11 WLAN standard [47], since it is the most widely used WLAN technology. It has also been considered extensively in the context of wireless industrial communications (see, for example, [8,13,53,57,70]).

The IEEE 802.11 standard belongs to the IEEE 802.x family of LAN standards. The standard describes architecture, services, physical layers, and protocols for an Ethernet-like wireless LAN, using a CSMA/CA-based MAC protocol with enhancements for time-bounded services. The protocols run on top of several physical layers, using different transmission schemes ranging from FHSS and DSSS to OFDM. The former 802.11a and g variants of the standard offered physical layer bitrates from 6 to 54 MBit/s, using OFDM and various coding schemes with different code rates. The former 802.11n variant couples MIMO and OFDM to achieve bitrates up to 150 MBit/s.

The standard describes an ad hoc mode and an infrastructure-based mode. In the infrastructure mode, all communications is relayed through fixed APs. An AP constitutes a so-called service set, and mobile stations have to associate with the closest AP. The APs can be connected by a distribution system that allows to forward data packets between mobile stations in different cells. In the ad hoc mode, there are neither APs nor a distribution system, and stations communicate in a peer-to-peer fashion.

### 30.7.1 DCF

The basic MAC protocol of 802.11 is called the DCF. It is a CSMA/CA protocol using the RTS/CTS scheme described in Section 30.5.1 and different interframe gaps to give control frames (e.g., acknowledgments and CTS frames) priority over data frames. However, data frames cannot be differentiated according

to priorities. The IEEE 802.11 MAC provides a connectionless and semireliable best-effort service to its users by performing a bounded number of retransmissions. Furthermore, it is not possible to specify attributes like transmit power, modulation scheme, or the number of retransmissions on a per-packet basis. This control would be desirable for treating different packet types differently. As an example, one could transmit high-priority packets with high transmit power and low bitrate to increase their reliability.

In more detail, the DCF operates as follows. When a station gets a new packet for transmission, it senses the medium (carrier sensing). When the medium is idle for a certain amount of time (called interframe space), the station starts to transmit. Otherwise, the station enters backoff mode. In this mode, it first waits until the medium is idle for at least distributed interframe space (DIFS) time. Then the backoff slots start. If the station was not in backoff mode before, it draws a random number out of the current contention window and stores it in a counter variable. Then the station observes all subsequent timeslots and decrements the counter when the slot was empty. If the counter reaches zero, the station starts to transmit. When a slot is busy, the process of decrementing the counter is suspended and is resumed once the medium becomes idle again for at least DIFS time.

The contention window size changes over time. It is initialized with a preconfigured value of  $CW_{\min}$ . When a packet transmission fails, the contention window is doubled, until a maximum of  $CW_{\max}$  is reached. The contention window is set back to  $CW_{\min}$  after a successful transmission.

### 30.7.2 QoS Support

The former IEEE 802.11e extension (which has been incorporated into recent versions of the standard) adds quality-of-service (QoS) support to the standard, which provides time-bounded and deterministic services in infrastructure networks. The QoS support is known as the hybrid coordination function and operates on top of the DCF. There are both a distributed scheme and a centralized QoS support scheme; the latter requires a centralized control entity called the hybrid coordinator (HC) that is collocated with an AP. Other stations can send reservation requests to the HC, asking it to schedule so-called transmit opportunities (TXOP). If granted, the requesting station can use the medium exclusively for a limited amount of time to transmit one or more frames including MAC layer acknowledgements to any station in the network. A TXOP can be granted once or periodically. A key function in the HC is the admission control component, which decides whether a new TXOP request can be accommodated without breaking guarantees given to other requesters. The precise admission control algorithm is not prescribed by the standard but left to the implementers.

On this basis, the standard defines two access schemes for QoS support: the enhanced DCF (EDCF) and the hybrid coordination function controlled channel access (HCCA). We describe both of them briefly.

#### 30.7.2.1 EDCF

The EDCF is a distributed scheme that operates similar to the DCF. However, the higher layer labels each packet as belonging to one out of four available QoS classes (also called access classes). To each class corresponds a separate value of the interframe space. For the  $i$ th class, the interframe space is called  $AIFS[i]$ . The  $AIFS[i]$  values can be configured but need to be different. Furthermore, the EDCF defines separate values of the minimum and maximum contention window ( $CW_{\min}$  and  $CW_{\max}$ ) for each QoS class.

When a station wishes to transmit a packet of priority  $i$ , it executes the same protocol as in the DCF, but now using the  $AIFS[i]$  as the interframe space and the  $CW_{\min}[i]$  and  $CW_{\max}[i]$  values for the contention window. By proper choice of these parameters, it is possible to ensure with high probability that a packet of a better access class wins over a contender having a packet of lower access classes. Hence, a stochastic prioritization is achieved. Another difference between the DCF and the EDCF is that in the DCF, the contention winner is allowed to transmit only one packet, whereas in EDCF, the winner receives a TXOP, which, as explained earlier, may cover several packets of the winning or higher access classes.

A number of performance analyses of the DCF and EDCF are available in the literature [29,56,83,91,57,118].

### 30.7.2.1.1 HCCA

In the HCCA, the central HC coordinates access to the medium, based on reservation requests from stations. The HC receives requests, performs admission control, and, if granted, is responsible for actual scheduling of TXOPs. However, the HC does not control the channel all the time; scheduled TXOPs alternate with phases where stations contend for the medium using the EDCF. The reservation requests can either be sent as separate packets (using the EDCF) or be piggybacked onto data packets. To gain control over the channel, the HC uses the basic DCF mechanism with an interframe space that is shorter than DIFS and all AIFS[i] values. To start a TXOP, the HC sends a poll packet to the owner of the TXOP, which then can transmit one or multiple packets. This approach prevents the system from achieving perfectly periodic services, as the medium might still be busy when the HC tries to gain access to the medium.

The HCCA is rather complex as there are rich interactions with other features of the IEEE 802.11 protocol like, for example, the rate adaptation feature of some of the physical layers. It is similarly complex as the PCF of the original IEEE 802.11 standard, which is still present in the 2007 version and which can be operated jointly with the HCCA. The author is not aware of any existing implementation of the HCCA.

A key research issue is the design of appropriate admission control scheduling policies, which has, for example, been done in [7,88,89]. Its usage in industrial scenarios has been considered in [53,103].

## 30.8 Summary

---

This chapter presented some problems and solution approaches to bring WLAN technology to the factory plant and to benefit from reduced cabling and mobility. The basic problem is the tension between the hard timing and reliability requirements of industrial applications on the one hand and the serious error rates and time-varying error behavior of wireless channels on the other hand. Many techniques have been developed to improve the reliability and timeliness behavior of lower-layer wireless protocols, but up to now, wireless fieldbus systems have not been deployed on a large scale as the problem of reliable transmission despite channel errors is not solved satisfactorily. It is not clear which combination of mechanisms and technologies has the potential to bound the number of deadline misses under realistic channel conditions.

It seems to be an open question whether just some more engineering is needed to make wireless transmission suitable for fulfilling hard real-time and reliability requirements, or whether there is really a limit of what can be achieved. Fortunately, wireless communications and WLAN technology is a very active field of research and development. New technologies are created, and existing technologies are enhanced. As an example, the IEEE 802.11g and IEEE 802.11e working groups aim to deliver higher bitrates and better quality of service to users. It will be exciting to see how industrial applications can benefit from this.

### 31.1 Introduction

---

The use of wireless technology for industrial applications is really attractive, as confirmed by the constantly increasing adoption of the *wireless fieldbus* term. Avoiding the use of cables allows to minimize not only costs but also cabling errors, which are the most common reason of communication systems failure in plants (not just in the commissioning stage). As a matter of fact, the adoption of wireless technology in the industrial world is not new, but usually was limited to niche applications due to lack of standard and well-accepted solutions. In particular, peculiar requirements of industrial communications related to determinism, low cost, availability, reliability, and security oblige the development of specific wireless standards, due to the inadequacy of consumer-oriented solutions.

In the following section, for the sake of clarity, the classic International Standards Organization/Open Systems Interconnection (ISO/OSI) model (limited to the physical, data link, network, and application layers) has been used to identify and show the main requirements for each level from the industrial point of view.

## 31.2 Requirements of Wireless Fieldbuses

### 31.2.1 Physical Layer

Key issues are the low power consumption and robustness to interference (intentional or unintentional). The wireless nodes must be truly autonomous (i.e., completely untethered), and in most of cases, this need is satisfied using batteries, whose life must be on the order of several years, that is, comparable with wired counterparts. In addition, the communication usually takes place in a license-free industrial, scientific, medical (ISM) band, thus facilitating worldwide market penetration and lowering the cost, but creating coexistence issues with all the other systems operating in the same region of the spectrum.

Less critical aspects are the communication range (which strictly depends on the application, e.g., ranging from less than 100 m for factory automations to several hundreds of meters for process automation) and the data rate, as the typical industrial devices transmit small amounts of data per cycle (e.g., consider the typical transfer rate of commonly adopted wired fieldbuses). What is really important is the end-to-end delay, that is, the throughput at the application level, which mostly depends on upper layers.

### 31.2.2 Data Link Layer

The industrial communication is normally based on the exchange of periodic events and some sporadic acyclic data such as alarms. Thus, the main requirements are to meet real time and guarantee the determinism.

The technique of media access becomes crucial in this regard. The most suitable technique appears to be the time division multiple access (TDMA, as in wired counterparts), flanked by some form of frequency diversity to improve interference resistance. In turn, this approach implies that the whole network must be somehow synchronized.

### 31.2.3 Network Layer

A possible solution to ensure high network reliability is the adoption of redundant routes from the source to the destinations. The network level is therefore required to implement some kind of mesh networking through which each device acts not only as a data source or sink but also as a repeater, forwarding the packet until it reaches the desired destination. In such a way, large distance can be covered with low power. The network layer must also ensure high scalability, that is, the capability of the network set to increase the number of active nodes without degradation in performance.

A critical point, which mainly depends on both the data link and the network layer, is the trade-off between the number and density of nodes to be served (affecting the mesh depth) and the end-to-end delay or throughput at the user level. It must be emphasized that this requirement can be very different for factory or process automation, for example, ranging from ms to several seconds or minutes, respectively.

### 31.2.4 Application Layer

At this level, compatibility and interoperability among devices of different manufacturers must be ensured. This problem is usually solved standardizing not only the application protocol but also different profiles dedicated to the well-defined applications (e.g., clearly specifying how data must be formatted and so on).

In addition, security is a key issue in any communication system and must be ensured across the whole protocol stack. Nowadays, the most common approach adopts encoding and encryption mechanisms to protect the data, trying to mask the data, making them unreadable and complex. Such techniques usually operate across the whole different stack layers, offering increasing security level.

In the following sections, the solutions adopted by WirelessHART (the first open standard available tailored for process control applications) to solve these requirements are briefly resumed.

### 31.3 HART and WirelessHART

---

The HART Communications Protocol (an acronym for Highway Addressable Remote Transducer Protocol) is one of the first fieldbuses to appear on the market. It was originally designed to add diagnostic information to process devices still preserving compatibility with legacy 4–20 mA analog instrumentation. In particular, the HART protocol shares the same pair of wires used by the legacy analog system, reducing the cost. Probably, the HART protocol is nowadays one of the most deployed protocols for industrial communications with the largest number of installed nodes.

The protocol was originally proposed by Rosemount Inc. in the mid-1980s for their smart field instruments. It was based on the Bell 202 communications standard, which AT&T developed for serial communication over a modem operating in the audio frequency range. Starting from 1986, it was made an open protocol, paving the way for several improvements, as proved by the numerous revisions to the specification published in the past.

Overall performance has been designed in order to satisfy the needs of process automation. If used in multichannel input/output (I/O) system, it allows for about one transaction per second (if Frequency-Shift Keying (FSK) modulation is adopted), with latencies on the same order of magnitude (depending on the number of nodes). In addition, it is able to work on distances up to 1500 m.

Starting from 2007, with the advent of the HART7 specification, the WirelessHART has been defined as an extension of the traditional wired solution. The target goal was to preserve performance on the same order of magnitude (or even improve them) allowing the implementation of a truly autonomous sensor. In fact, as suggested by its name, it employs a different physical layer that uses radio frequencies (RFs) as the communication medium with a nominal coverage area of hundreds of meters (in line-of-sight [LOS] conditions) and devices that are normally battery powered, but may also exploit power cables or some form of energy harvesting (e.g., solar) or a combination of all these sources.

#### WirelessHART

- Implements an RF self-healing mesh network
- Allows for network-wide time synchronization
- Enhances the publish/subscribe messaging (i.e., burst mode)
- Adds network and transport layers
- Adds a *fast pipe* for time critical traffic and, last but not least, adds ciphering

A comparison among the traditional HART protocol communication layers, the WirelessHART solution, and the well-known consumer world ZigBee protocol is given in Table 31.1, following the ISO/OSI model.

A resume of main WirelessHART characteristics is provided in the following:

- Low power consumption and low-cost devices (comparable with wired counterparts)
- Raw data rate of 250 kbps per channel in the 2.4 GHz ISM band with 15 different channels worldwide available
- Based on the diffused and well-accepted Institute of Electrical and Electronics Engineers (IEEE) 802.15.4-2006 physical layer
- Based on a proprietary data link layer, based on TDMA and carrier sense multiple access with collision avoidance (CSMA/CA)
- Support of *channel hopping* and *channel blacklisting* mechanisms to improve interference rejection
- Network layer implementing self-healing mesh network, thus introducing redundancy and improving reliability
- Application layer fully compatible with HART

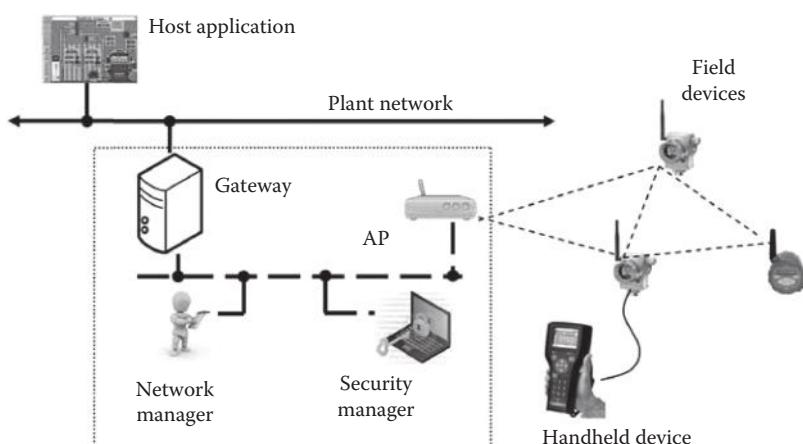

**TABLE 31.1** ISO/OSI 7 Layer Model: Comparison among HART, WirelessHART, and ZigBee

Layer \ Standard	HART	WirelessHART	ZigBee
Application	Command oriented, predefined data types and application procedures		Application and security
Presentation	—	—	—
Session	—	—	—
Transport	Auto-segmented transfer of large amount of data, reliable stream transport, and negotiated segment sizes		—
Network	—	Power Optimized redundant path mesh network	Ad-hoc routing, mesh networks
Data link	Token passing master/slave	Time synchronized channel hopping	IEEE 802.15.4-2006
Physical	Simultaneous analog and digital signaling (4–20 mA wire)	IEEE 802.15.4-2006 at 2.4 GHz	IEEE 802.15.4-2006

### 31.3.1 WirelessHART: The Network Architecture

Each WirelessHART network includes four main elements:

1. The wireless instruments (i.e., the field devices), directly connected to the process equipment in the plant. This kind of devices is further divided into two groups:
  - a. The actual WirelessHART process transmitters.
  - b. The wireless adapters, that is, devices that provide a wireless interface for legacy analog 4–20 mA transmitters; in addition, if the wired device is compliant with HART, diagnostic information can be extracted.
2. The gateway, which acts as a bridge between the WirelessHART network (reached by means of access points) and the already existing wired infrastructure (e.g., most of commercial solutions exploit an Ethernet or RS485 infrastructure based on Modbus Transmission Control Protocol (TCP) or remote terminal unit (RTU), respectively).
3. The only one network manager, responsible for network configuration, communication among devices, management of routing messages, and monitoring of network conditions. In particular,

**FIGURE 31.1** Simplified diagram of a typical WirelessHART network.

according to the so-called neighbor reports, the network manager dynamically updates the knowledge about the network status adjusting devices and network parameters in order to maximize availability and reliability.

4. The security manager, which deals with the management of security and encryption, setting up and managing the network and session keys, and managing their periodical change.

Moreover, there can be also devices that lack the connection with the process and wireless communication facilities; for instance, they are handheld devices used for commissioning and/or maintenance purposes.

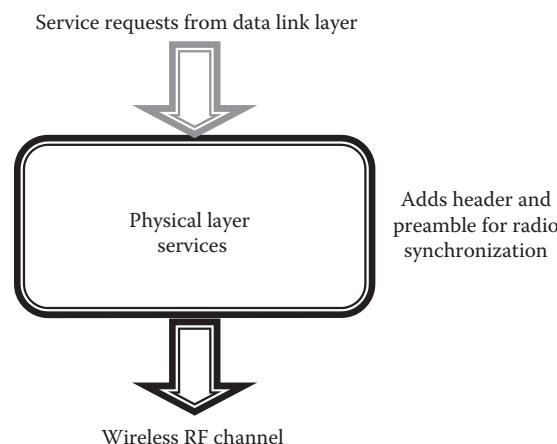

A simplified diagram of a typical WirelessHART network is sketched in Figure 31.1.

## 31.4 WirelessHART Protocol Stack

### 31.4.1 WirelessHART Physical Layer

The lowest layer on the OSI model is the physical layer, responsible for sending the *bits* across the network media (as depicted in Figure 31.2). Differently said, it enables the transmission and reception of the protocol data across the physical radio channel. In particular, the WirelessHART physical layer is based on a tailored adoption of the IEEE STD 802.15.4-2006, with the intent of exploiting mass volume production of consumer market devices. This standard is intended to conform to regulations in Europe, Canada, Japan, China, and the United States. The primary goal of the IEEE 802.15.4 is to create a low-cost, low-data-rate, and low-power-consumption wireless communication system, meeting specific needs typically offered by sensors and control devices. In contrast to the IEEE 802.15.1 (Bluetooth) and IEEE 802.11 (WLAN), the IEEE 802.15.4 has been specifically developed for wireless sensor network (WSN) implementations, especially in those applications where many devices sporadically transmit small packets of data towards a sink (acting as the network coordinator and usually mains supplied). Formally, the IEEE 802.15.4 defines the specifications for the physical and the data link layer of the so-called low-rate wireless personal area networks (LR-WPANs) and is not concerned of the higher levels. For instance, the ZigBee solution is an example of a standard protocol defining upper layers.

However, it must be underlined that the use of this protocol (IEEE 802.15.4) without any modification would pose several issues when used in industrial applications. For instance, the use of a fixed channel limits the robustness to interferences, making it coexistent with other colocated wireless solutions operating in the same band unsafe and unreliable. For this reason, only a simplified set of services is inherited and some amendments have been added.

**FIGURE 31.2** Schematic representation of the physical layer.

The WirelessHART radio must operate exclusively in the 2.4 GHz band, that is, well above unintentional radiators commonly found in plants. The offset quadrature phase shifting keying (O-QPSK) with direct sequence spread spectrum (DSSS) modulation is used; the raw data rate over the air is 250 kbps. This choice is dictated by a trade-off among the easiness of implementation, the noise rejection, and the communication performance. Sixteen channels (each one 5 MHz apart and with a 3 MHz null-to-null bandwidth) are available; however, channel 26 (centered around 2480 MHz) is not supported since it is not license-free in many countries. Some additional restrictions on clock stability, channel switching time, and power-up sequence have been included to satisfy the WirelessHART medium access strategy and lower the power consumption. The RF transmitting power must be regulated in the range from  $-10 \text{ dBm}$  up to  $10 \text{ dBm}$ . Some mechanisms to perform the clear channel assessment (CCA) (in particular, the CCA mode 2, carrier sense of IEEE 802.15.4) must be also provided. Additionally, the WirelessHART physical layer defines two different operating states: awake, during normal operation, and sleep, when it is inactive.

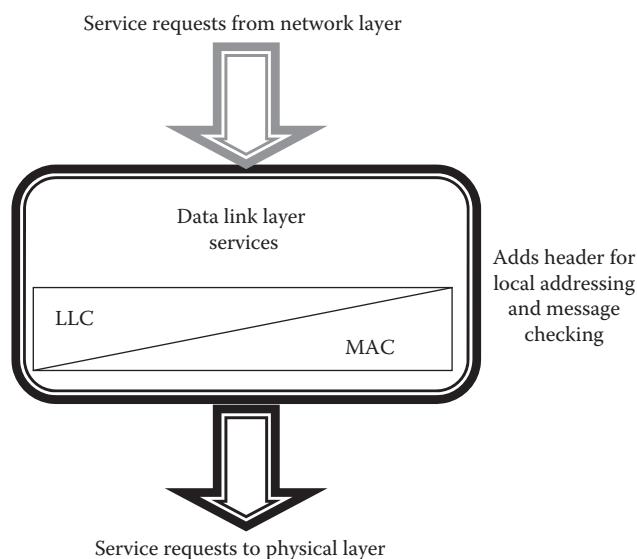

As a matter of fact, a WirelessHART node can be implemented using most of IEEE 802.15.4 *commercial off the shelf* available radio transceivers with great benefits to the overall cost.

### 31.4.2 WirelessHART Data Link Layer

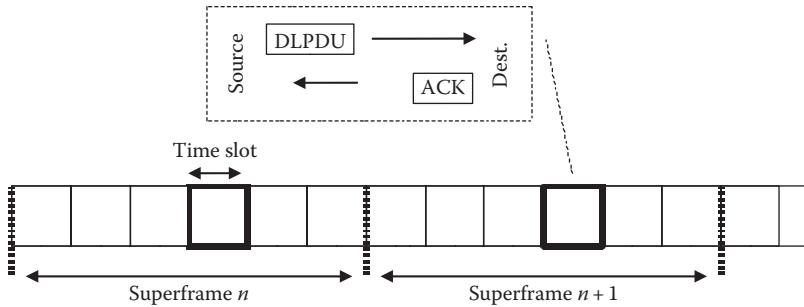

According to the ISO/OSI model, the data link layer provides a reliable means to transfer data between two nodes in the network, detecting and possibly correcting errors that occur in the physical layer due to noise (e.g., retransmitting corrupted data). This level also has the important role of creating and managing data messages. Usually, it is divided into two sublayers (as in Figure 31.3):

1. Medium access control (MAC)
2. Logical link control (LLC)

The LLC sublayer defines the services offered at the next upper level (i.e., the network layer), while the MAC sublayer arbitrates how the common medium must be shared among nodes and tries to avoid or at least to minimize the effect of collisions.

**FIGURE 31.3** Schematic representation of the data link layer.

**FIGURE 31.4** Basics of WirelessHART TDMA mechanism.

Addresses at the data link layer have only local scope and can be duplicated in other local links. The data link layer is also the lowest information-centric layer.

It must be stressed that the MAC sublayer, directly exploiting services of the physical layer (i.e., controlling the radio itself), has a major impact on the overall energy consumption and, hence, the lifetime of a node.

As previously stated, WirelessHART uses TDMA and channel hopping to control accesses to the network. It is well known that TDMA is a common technique that allows deterministic communications and it is the preferable solution in most of wired fieldbuses. When the TDMA approach is used, communications between devices are organized into time slots, which are grouped together into (continuously repeated) structures called superframes. The actual time slot has a fixed length of 10 ms, enough to contain a message (whose payload is the Data Link Protocol Data Unit [DLPDU]) from the source to the destination and a successive acknowledge (ACK) message. In the ACK, the *response code* specifies if the communication was successful or, conversely, if the request has arrived but was not managed (an *error code* reports the possible causes). A schematization of this mechanism is proposed in Figure 31.4.

Resuming, the main tasks of the WirelessHART data link protocol are as follows:

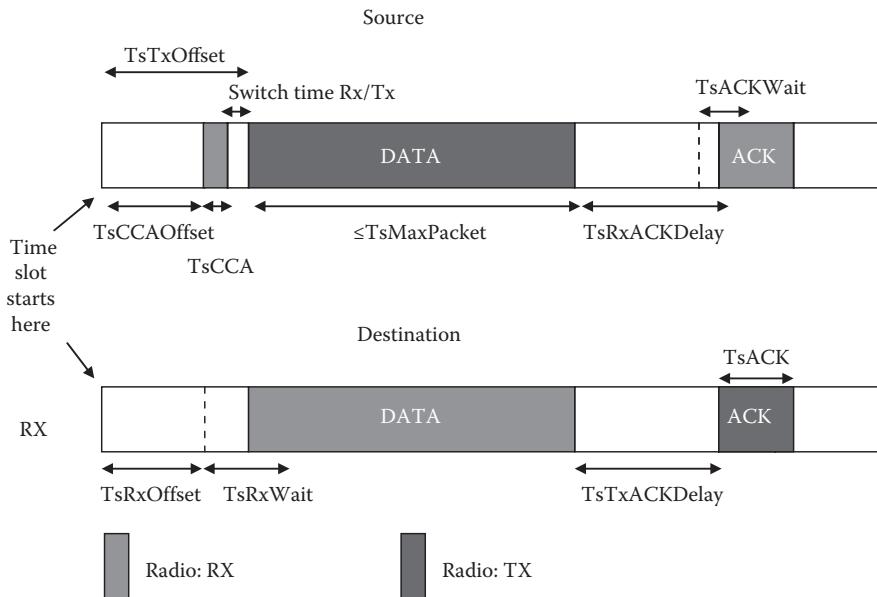

- Synchronization of the slots
- Identification of the devices that need to access to the medium
- Propagation of received messages at the network layer
- Listening to packet propagated by neighbors

Usually, time slots are univocally dedicated to a couple of devices in what is called a *link* (i.e., an opportunity to communicate) in a time slot of the superframe. However, some of them, called shared slots, may be used by multiple devices using a hybrid approach based on both the TDMA and the CSMA/CA techniques to access the medium. In addition, communication links are specified not only by the time slots they occupy but also by a *channel offset* (used by the channel hopping technique) and by their *direction*. All devices must support multiple links, which are assigned in a centralized way by the network manager. The number of possible links is, typically, equal to the number of channels utilized by a network times the number of slots in the superframe. For example, using 15 channels and 9,000 slots per superframe results in 135,000 possible links.

All devices must support multiple superframes, in order to satisfy different cycle time requirements (e.g., one superframe for data from the field and another one for maintenance).

For effective and efficient TDMA communication, clock synchronization between devices in the network is crucial. Consequently, the tolerances on the local clocks are well defined (oscillator must have  $\pm 10$  ppm stability), and some synchronization mechanisms have to be implemented.

For sake of clarity, the format of a time slot is shown in Figure 31.5.

**FIGURE 31.5** Packet timing and time slot format. Light gray is for reception state and dark gray is for transmitting state of devices.

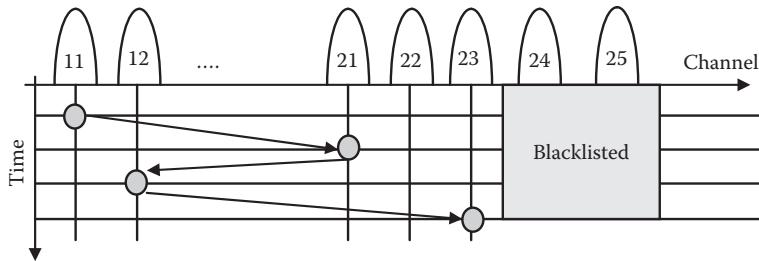

In particular, the exchange of a unicast message between a source device (*A*) and a destination device (*B*) is considered. Despite the synchronization mechanism, nodes may have a slightly different sense of time (e.g., due to clock and temperature drift and aging), and for this reason, they may have *different* instants representing the starting time of a slot. According to the standard specifications, the source node has to wait  $TsTxOffset = 2.12 \text{ ms} \pm 0.1 \text{ ms}$  (see Figure 31.5) before starting the actual transmission, whereas the destination node has to wait the interval  $TsRxOffset = 1.12 \text{ ms} \pm 0.1 \text{ ms}$  (as in Figure 31.5) to set up the radio and has to turn on the receiver in the following interval:  $TsRxWait = 2.2 \text{ ms} \pm 0.1 \text{ ms}$  (as in Figure 31.5). In other words, a guard time of  $\pm 1 \text{ ms}$  is offered.

In addition, before the source node starts transmitting, it should also perform a *listen before talk* procedure (i.e., CCA), which starts after the  $TsCCAOFFSET (=1.8 \pm 0.1 \text{ ms})$  and lasts  $TsCCA (=0.128 \text{ ms})$  in order to improve coexistence with other wireless networks.

The data transaction is completed by the acknowledgment packet (ACK) sent by the destination. The ACK payload specifies the detected synchronization error and notifies possible detected errors. The ACK has a length of 26 bytes (i.e., it lasts  $TsAck = 0.832 \pm 0.1 \text{ ms}$ ) and the destination node must send the ACK after  $TsTxAckDelay = 1.0 \pm 0.1 \text{ ms}$  from the end of the incoming message (such a short time ensures that the cumulated synchronization error is necessarily small).

To enable these services, the WirelessHART device implements and maintains neighbors, superframes, and link tables (the neighbors table is filled each time new neighbor nodes in the radio coverage of the node join the network). All these tables are constantly read by the network manager to maintain an updated snapshot of the network status.

As previously stated, channel hopping (see Figure 31.6) is combined with TDMA in order to enhance reliability. It provides frequency diversity, which can avoid interferers and reduce multipath fading effects. Differently said, each new link will occur on a different channel, thus limiting the effect of interferences that are usually well localized in time and frequency, that is, they have a bursty nature. Each device gets from the network manager an array containing the list of the active (i.e., usable) channels. The current channel to be used is computed by the device as the remainder of the ratio between the sum of the absolute slot number (ASN) (i.e., the time slot sequence number from

**FIGURE 31.6** Frequency diversity mechanism of WirelessHART.

the network creation) plus the channel offset of the current link and the number of available (active) channels, as shown by the following equation:

$$\text{Current Channel} = (\text{Channel Offset} + \text{ASN}) \% \text{ ActiveChannels}$$

This algorithm computes a sort of *logical channel* that moves within the band actually available, and it is identified by the physical channel offset only.

In this way, the same time slot may be used on multiple channels by different nodes, simply changing the channel offsets.

The channel blacklisting mechanism has been also implemented, which allows the network administrator to restrict the active channels usable in the channel hopping procedure, even if its usefulness is not very clear even in a very crowded environment.

### 31.4.2.1 Link Scheduling Procedure

The main function performed at the data link level by the network manager is the link scheduling, that is, the centralized process by means of which it is decided whether a packet can be sent or received in the current time slot according to its assigned link.

All network details are stored in tables by each node; these tables are initially written by the network manager itself and subsequently appropriately updated according to the evolution of the network.

In particular, each device must be aware of the time slot in which it can communicate (i.e., has the right to occupy the channel) and the channel offset in order to actuate the channel hopping technique; in other words, each device must be aware of the superframe(s) arrangement and the links they are made of. It must be highlighted that this information is handled in a centralized way in order to reduce as much as possible the complexity (and the cost) of field devices. For this reason, only the network manager can dynamically and periodically update superframe arrangement. For instance, depending on the policies adopted by the network manager, the link scheduling decisions can be oriented to the latency reduction, to increase the reliability or to improve load balancing maximizing energy efficiency.

Nevertheless, the planning algorithm should be simple, scalable, and adaptable, for example, to different application requirements. As an example, consider the need to handle messages with different priority requirements.

### 31.4.2.2 Time Synchronization

The adoption of the TDMA as the basis for the MAC mechanism requires that all the nodes in the network share a common sense of time. Despite the requirement of 10 ppm or better oscillator, local clock skew and drift must be somehow confined in order to allow the node to respect time slot guard limit. Since communications occur on a per packet basis, also timing information must be exchanged using data packets. Devices must be capable to accurately time-stamp the time of arrival of an incoming packet, so that it can be compared with the theoretical (ideal) one, that is, the time slot beginning decided by the network manager. Each destination node of a transaction in a link must estimate this

sort of time error (in its local time scale) and forward it to the source node in the ACK payload. In this way, some kind of servo clock can be implemented (but the standard does not specify how). The *quality* (i.e., accuracy) of local clocks is flooded to each node by the network manager itself during the affiliation process, so that nodes can choose the best available. The error estimation procedure can be repeated across multiple network hops, so that network-wide time synchronization is reached. In order to avoid a very long silent period (e.g., due to very low update rate), a keep alive message exchange must occur at least every 30 s.

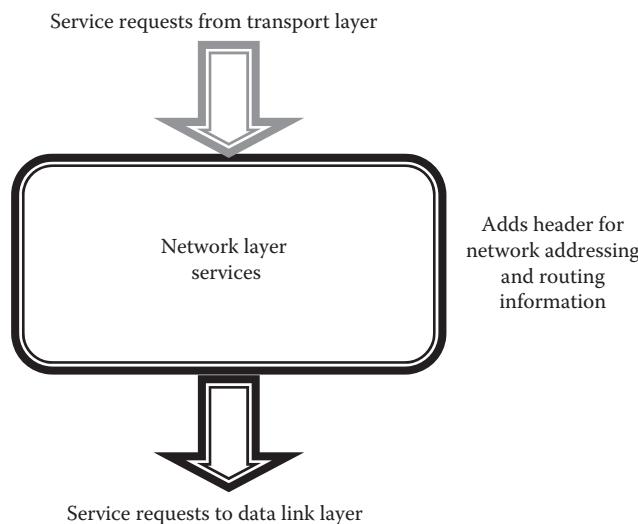

### 31.4.3 WirelessHART Network Layer

The network layer is primarily responsible for the routing policies, that is, it routes packets destined for other devices by adding the necessary information (network addresses; see Figure 31.7). In addition, it also provides some security mechanism to end-to-end communications and furnishes some services to the (upper) transport layer. The network layer manages the so-called sessions, that is, the logical confinement of end-to-end data exchanges.

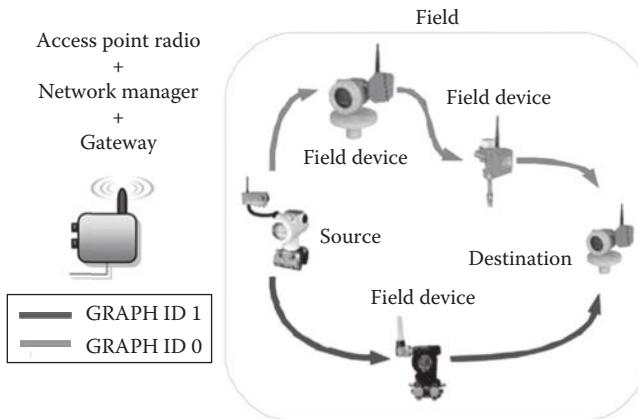

Communication between a pair of network addresses is organized in sessions for security purposes, since each session is ciphered. Four sessions are set up as soon as any device joins the network:

1. Unicast session between the device and network manager—it is used by the network manager to manage the device.
2. Broadcast session between the device and network manager—it is used to globally manage devices. For example, this can be used to roll a new network key out to all network devices. All devices in the network have the same key for this session.
3. Unicast between the device and the gateway—it carries normal communications (e.g., process data) between the gateway and the device.
4. Broadcast session between the device and the gateway—it is used by the gateway to send the identical application data to all devices.

In addition, each device has a join session and it cannot be deleted. The join key is unique; it is the only key that can be written by directly connecting to maintenance port physically implemented on the device itself. It can also be written by the network manager.

**FIGURE 31.7** Schematic representation of the network layer.

**FIGURE 31.8** Graph routing mechanism.

Similarly to the link scheduling described in the data link layer, the routing layer determines in a centralized way where the packet should be sent. This decision is taken by each node according to two possible approaches: the graph routing and the source routing. The graph route is a set of oriented links (*arrows*), each one representing a single hop between one source and one destination device (data link neighbors). Clearly, redundant paths may be arranged to interconnect a couple of nodes, thus greatly improving the overall robustness. On the other hand, in source routing, each message contains the entire list of hops from the source towards the destination; this is not a very efficient routing procedure and it is reserved only for commissioning.

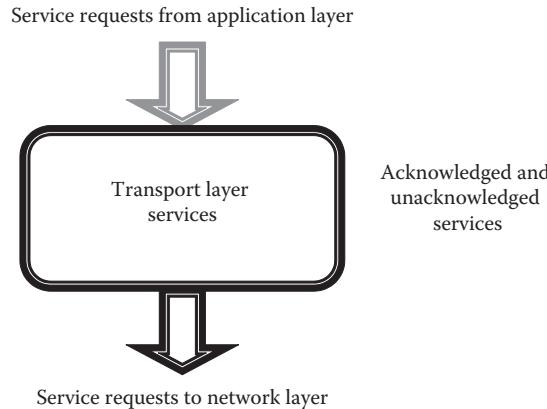

As said, all the computational tasks are performed by the network manager, which is the only device in the network capable to handle a complete list of all the devices and has full knowledge of the network topology. The network manager may, for example, collect all the *neighbor tables*, together with the current status of node batteries, and build the optimal paths (i.e., route graphs). The routing graphs are not unique and can therefore overlap; they are however unidirectional and are identified by a unique graph ID (e.g., refer to the simple example in Figure 31.8). The graph ID is thus the only information that must be propagated by the network layer header in order to determine which path has to be followed. As a rule of thumb, each device should possess at least two neighboring nodes in each graph route to ensure two different forwarding options and, therefore, ensure better reliability.

Routing policies adopted by the network manager may greatly affect overall performance in a number of factors such as energy efficiency, reliability, and latency. The network manager manufacturer has to choose among these (and many possible others) function costs to be minimized (or maximized) by the route scheduling algorithm. Reducing the average hop length decreases energy consumption, but also the redundancy is limited, compromising the reliability of the network; choosing instead longer range will favor direct communication with the gateway (i.e., star topology), reducing latency but increasing the power consumption.

According to the graph routing mechanism previously described, it is clear that WirelessHART generally permits a variety of network topologies, including star, mesh, and a combination of both. This allows taking advantage of the strengths of each: If the focus is on the network's range, reliability, or flexibility, a mesh network will usually be the best choice. If maximum battery life is desirable, a star topology or point-to-point communication is recommended.

### 31.4.4 WirelessHART Transport Layer

The transport layer ensures the success of end-to-end communication. In other words, it is the transport layer that ensures that packets are successfully delivered to the final destination in a multihop communication (see Figure 31.9).

**FIGURE 31.9** Schematic representation of the transport layer.

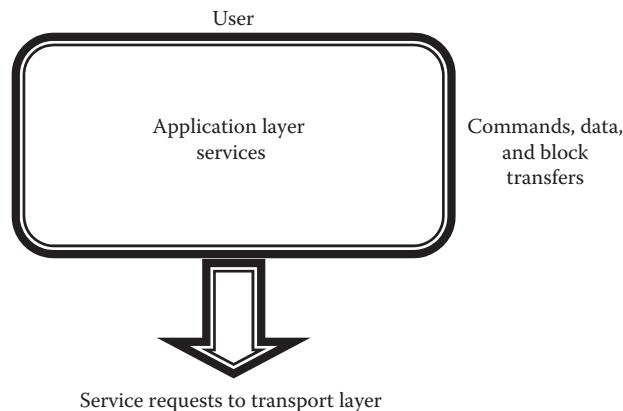

In detail, the transport layer of WirelessHART supports both an acknowledged transfer mechanism (useful for event notification) and an unacknowledged mechanism for the transfer of process data (requiring real-time and lower latencies). The service with acknowledgment provides the use of automatic repeat request (ARQ) mechanism to ensure end-to-end delivery of messages. The default number of retransmission is set to five.

### 31.4.5 WirelessHART Application Layer

The application layer is the closest to the end user, as shown in Figure 31.10.

It provides the upper host application a way to access to process information traveling on the network. Its functions usually include the identification of originating and sinking data device, the verification of resource availability, and the synchronization of application data.

The WirelessHART application layer follows the well-known HART application layer, being totally compatible and interoperable with it. For these reasons, description of the application layer is out of the scope of this chapter.

**FIGURE 31.10** Schematic representation of the application layer.

As for the wired HART counterpart, all the available commands are divided into classes, which are the following:

- Universal commands, which are commands supported by all HART devices
- Common practice commands, which are supported by a large number of HART devices
- Wireless commands, which are supported by the WirelessHART products
- Device family commands, which are used to set up and configure devices without using device-specific driver
- Device-specific commands, which are defined by the manufacturer for the needs of their own devices

### 31.5 Message Format

In the following subsections, a brief description of the actual message format is furnished, with some details about the headers added at the different protocol stack levels. Figure 31.11 describes the encapsulation mechanism of different layers according to the WirelessHART specifications, described in the following subsections.

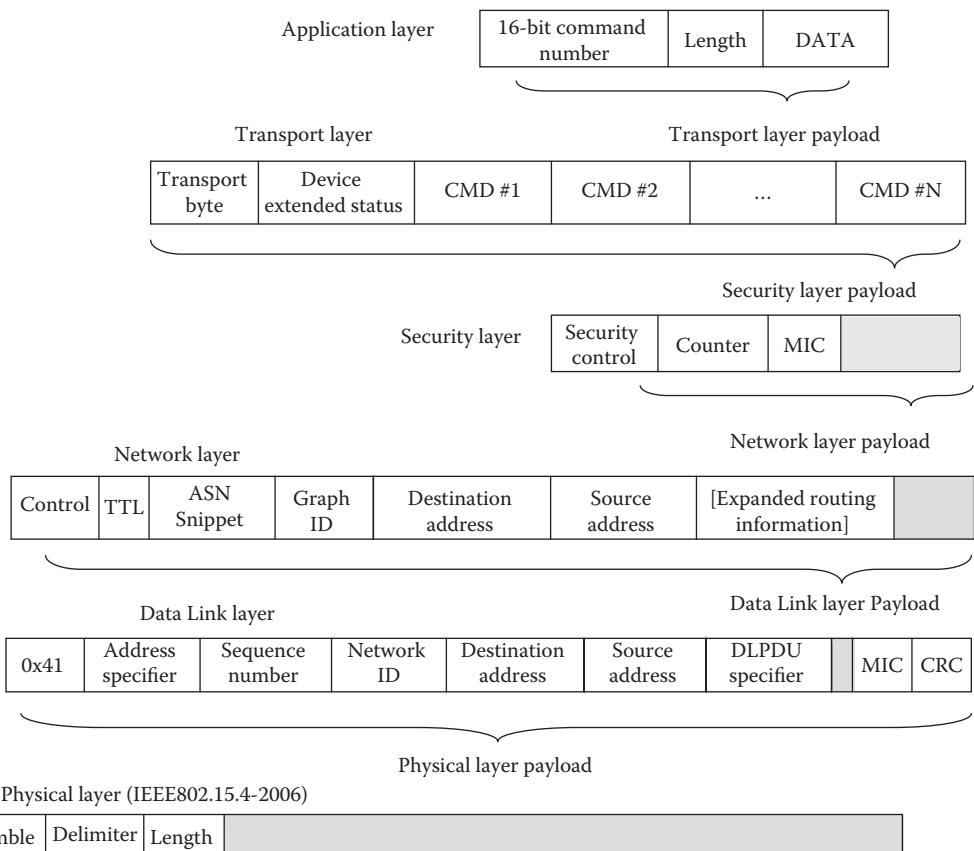

FIGURE 31.11 WirelessHART message format.

### 31.5.1 Physical and Data Link Layer Datagram

This subsection specifies the format of the data link datagram; each DLPDU consists of the following fields:

- A single byte set to 0x41 (so that WirelessHART messages are recognized as IEEE 802.15.4 data messages)
- A 1-byte address specifier, indicating if long (Extended Unique Identifier [EUI], 64 bits) or short (16 bits) addresses are used
- The 1-byte sequence number
- The 2-byte network ID, which univocally identifies the network
- Destination and source addresses, either of which can be 2 or 8 bytes long
- A 1-byte DLPDU specifier, which allows to distinguish the message priority (*command, process data, normal, and alarm*) and the message type (*ACK, advertise, keep alive, disconnect, and data*)
- The data link layer payload
- A 4-byte keyed message integrity code (MIC)
- A 2-byte cyclic redundancy check (CRC16) (imposed by the IEEE 802.15.4-2006)

In particular, while the data link layer packet is en clair, the MIC is enciphered for link layer authentication of the received datagram; it is generated and confirmed using CCM\* mode (combined counter with cipher block chaining-message authentication code (CBC-MAC) [corrected]) in conjunction with the AES-128 block cipher to provide authentication of the originator.

### 31.5.2 Network Layer Datagram

The network layer datagram consists of the following fields:

- A 1-byte control field, specifying if short (16 bits) or long (EUI, 64 bits) addresses are used for source and destination and if optional routing information are attached.
- The 1-byte time to live (TTL) hop counter.
- The least-significant 2 bytes of the ASN (latency count).
- A 2-byte graph ID.
- The (final) destination and (original) source addresses.
- Optional routing fields; when the third bit of the control byte is set, the 2-byte short address of the proxy parent for the final destination is indicated in the proxy address optional field. If the proxy address matches, the device is responsible for forwarding the message to the device indicated by the destination address. When proxy routing, the destination address must be an EUI-64 address. If source routes are used, each source route field contains four addresses that designate the route the packet must follow from the original source device to the packet's final destination. Each address is a 2-byte short address. Each byte of the addresses not used must be set to 0xFF.

A security layer is encapsulated within this datagram together with the enciphered payload.

### 31.5.3 Transport and Application Layer Datagram

Each transport layer packet consists of the following fields:

- A transport byte, specifying the session characteristics
- A device status byte, which shows the status of the device
- An additional byte of an extended device status
- One or more HART commands (representing the actual application layer data)

The transport byte indicates if the transfer has to be acknowledged or not; it specifies if the message is a response or not and if the current session is broadcast or unicast; finally, it implements a 5-bit sequence number counter used to sort the data traffic.

Referring to the application level messages, the organization of a single HART command is arranged very similarly to the wired counterpart; the command fields are the following:

- A 2-byte command number, which is used to identify the command
- A 1-byte length, which indicates the number of bytes present in the subsequent data field
- A variable number of bytes containing the request or response code of the command, depending on whether a request or a response was issued, and the actual command-specific data

## 31.6 Join Procedure

New devices that want to participate to the network exploit information flooded in the *advertise* packets; in particular, these packets allow the device to synchronize the local clock with join superframe, where dedicated join links can be used to start a join request.

The *advertise* includes basic network information, including the ASN (i.e., the current time slot sequence number, originated by the network manager during the network creation), the position of the join links in the superframe, the security levels supported by the network, and the information necessary for the identification of the channel to be used to transmit. Since *advertise* packets follow a regular transmission pattern, they can be used by unsynchronized nodes to *follow* their parent clocks.

All the join links are time-shared slots, and the new device that wishes to join the network must communicate only in these time slots until it is authenticated by the network manager.

The join request sent (see Figure 31.12) by the new device is encrypted with the join key (user decided) by means of the AES128 CCM\* algorithm; the join request payload is made of the following HART commands in the format of *response*:

- Command 0, containing information on the type and revision of the device and on its unique identification number
- Command 20, containing the long tag of the device
- Command 787, containing information on the health of neighbors

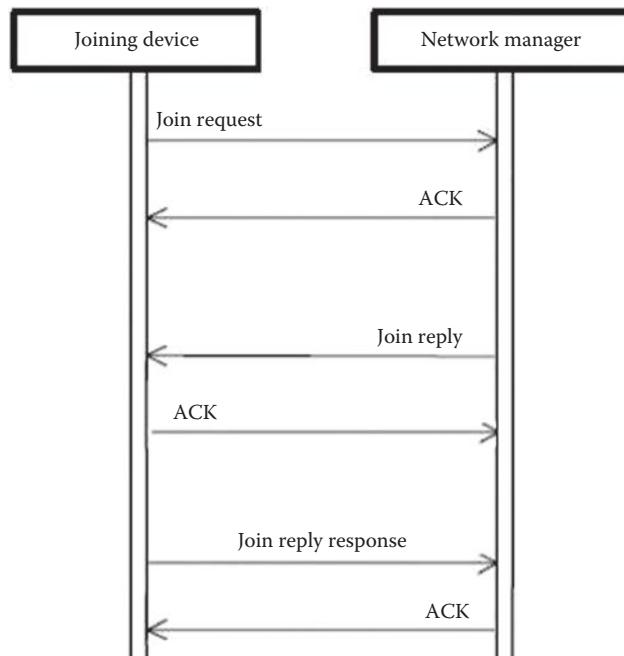

FIGURE 31.12 Sequence diagram of the join phase.

The network manager will first of all send an ACK (see Figure 31.12) to complete the transaction; after a certain amount of time, it will reply with a join reply, also encrypted with the same join key, which contains the following HART commands in the *request* format:

- Command 963, containing the session key to be used
- Command 962, containing the network key to be used
- Command 961, containing the device nickname (short address)

Starting from this point on, the short address will be used as the address of the device in the network, and the payload of all the following messages exchanged with the gateway will be encrypted using the session key, still performing MIC authentication using the network key.

For safety reasons, the session key is periodically changed by the network manager using the command 963. Some details about keys are given in Section 31.7.

## 31.7 Security Aspects

---

Security is a very critical aspect in industrial communications solutions. For this reason, WirelessHART has been designed in order to have a security level comparable with wired solutions. Security services are offered not only at the data link layer but also at the network layer. All messages have to be enciphered so that malicious listeners cannot exploit on the air information. Since the ACK packet has to be necessarily sent within the same data time slot, a low computational power mechanism has to be implemented at this level. In particular, the MIC included in the data message is used as a sort of signature just to confirm the identity originating device, without the need of decrypting the message content. The payload of the network layer can be thus decrypted later with relaxed time constraints.

Following the IEEE 802.15.4 approach, the AES-128 algorithm is used with the CCM\* mode. Particularly, four different kinds of keys are used in a network: public keys (used at the data link layer by joining devices), network keys (common to all joined devices and used to verify the MIC), join keys (used during the joining process), and session keys (associated to each end-to-end communication).

## 31.8 Wi-Analys Tool

---

The Wi-Analys tool is a wireless traffic analyzer (*sniffer*) available from the Hart Communication Foundation (HCF) consortium (HCF\_KIT-190), that is, the same task force that also maintains HART and WirelessHART specifications. It consists of a multiple-channel receiver (capable to hear all the 16 IEEE 802.15.4 channels) and is a purposely designed software able to capture packets with a maximum speed of 1000 messages per second (see Figure 31.13). These messages can be filtered according to different stack layer fields and organized and shown in order to easily detect anomalies and errors.

Furthermore, if both the join key and the network ID are known, the Wi-Analys tool is capable to decrypt encrypted packets collected over the air, showing to the user the HART commands actually exchanged and their conformance with the specifications.

Viewing and filtering are implemented by means of a top-down menu whose fields are divided according to the ISO/OSI model, as shown in Figure 31.14.

## 31.9 Designing a New WirelessHART Network

---

Designing a new network may be a cumbersome task, even if following some *rule of thumb* allows to minimize troubleshooting during the commissioning phase. As for any other industrial network installation, three stages are needed: scope (i.e., divide the network[s] according to single process unit or subsection of a process unit), design (i.e., apply guidelines to ensure optimum connectivity), and fortify (i.e., troubleshooting to maximize network availability and reliability).

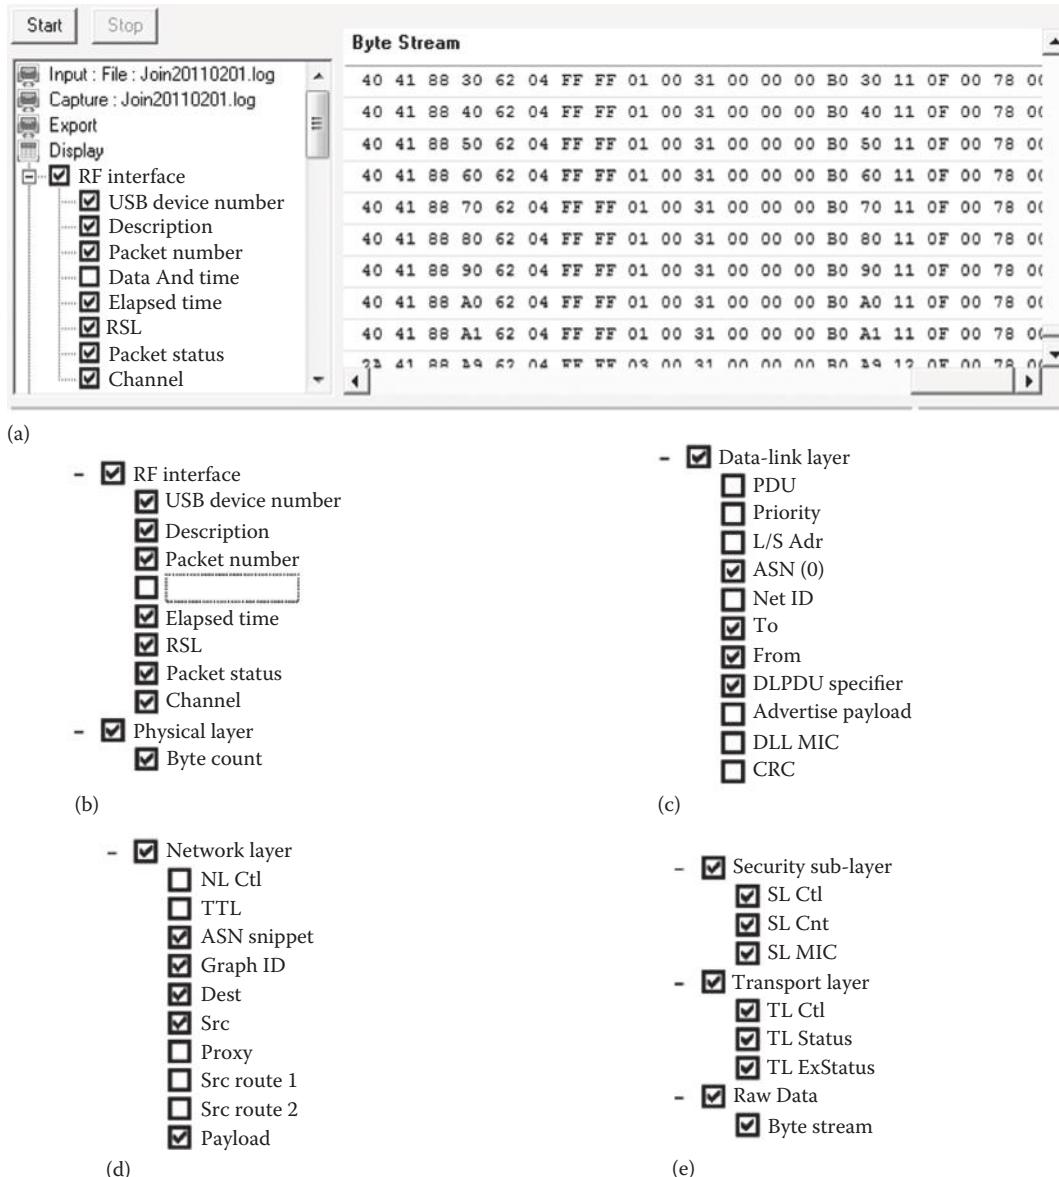

FIGURE 31.13 Wi-Analys network analyzer.

First of all, the number of field devices (including spare parts) must be evaluated, so that the number of gateways can be estimated as a trade-off between the required end-to-end delay and the maximum hop number in the network.

Regarding the design phase, obstructions must be evaluated (in particular, as a function of their distance and their height). Obviously, the LOS scenario must be preferred and if LOS is not possible, additional attenuation, multipath, diffraction, and reflection effects must be taken into account. For the same reasons, moving objects (e.g., people going in and out) have to be considered. It must be also remembered that the antenna is probably the most important component to be considered for correct installation. Since the ground or the floor is somehow conductive (i.e., it may cause reflections), wireless device antenna should be installed at least 1 m above it. Similarly, antennas must be placed as far away as possible from any conductive wall and/or material (e.g., at least 6 cm away from metallic walls running parallel to it). The radiation pattern should be known and the device's antenna has to be aligned accordingly for best results. For instance, do not position WirelessHART devices directly below or above each other since they would be outside each other's antenna range. Performance could be improved connecting a remote antenna to the antenna terminal and mounting the remote antenna as high as possible so that LOS situations are maximized. Also, the use of high-gain (i.e., directional) antennas may improve performance, at the cost of larger dimensions.

In order to exploit intrinsic redundancy of the mesh networking, the number of devices in the effective range of each node must be maximized. As a rule of thumb, each WirelessHART network should have a minimum of five devices in the effective range of the access points (usually placed in the gateway), and every device should have at least three neighbors in its coverage area (thus balancing also the load). Regarding the throughput, it is a good practice to reduce as much as possible the

**FIGURE 31.14** Graphical user interface of the Wi-Analys software. (a) Example of raw data collection, (b–e) messages filter options.

network depth; in particular, experiments show that at least 25% of the overall devices should be in the effective area of the gateway.

Regarding fixing the troubles, key performance indicators furnished by all commercially available network manager, as the device received signal strength indication (RSSI) or the average packet error rate (PER), should be used to detect anomalies. The simplest (despite not the cheapest) solution to improve network reliability is to increase the node density, that is, add additional routing devices, for example, placing additional instruments not for measuring process variables but specifically to act as routers.

## 31.10 Example of Platform Providers

Despite the few years since the standardization of the WirelessHART solutions, the market already offers a quite large number of devices, development platforms, and conformance testing tools. In particular, the availability of the previously described *Wi-Analys* tool, together with a Linux box (called Wi-HTest) that automates the execution of device testing scripts, helps in the conformance and interoperability tests. The HCF consortium simplifies testing operations by providing a test specification to developers that clearly explains test requirements and clarifies possible ambiguities in the protocol specifications. These test specifications can be used both in the development phase and in the field device enhancement process. Starting from these test specifications, test scripts for each test case are realized and used as input to feed in the Wi-HTest for establishing the test environments and generating proper test packets. The heart of the Wi-HTest Linux box is the Wi-HTest engine, which is a C++ program executed in the CINT environment, a C/C++ interpreter aimed at processing C/C++ test scripts interactively. A radio module is included to implement the wireless interface with the device under test. On the other hand, the *Wi-Analys* tool is used to validate the compliance with tests.

The HCF consortium also maintains a list of registered devices on its website (<http://www.hart-comm.org/>), where almost 50 compliant devices are described. Main manufacturers of gateways (which usually implement gateway, network, and security manager functionalities) and/or transmitters are Rosemount, Emerson Process Management, Aiwa, Dresser, ABB, MACTek, Phoenix Contact, Siemens, Endress+Hauser, Dust Networks, P+F, Softing, and Cooper and Spirax, just to mention some of them.

As an example of multiplatform providers, consider Nivis, a company launched in 1998, which is specialized in sensor networks, supporting an array of standard sensing and control protocols including not only WirelessHART™ but also ISA100.11a and 6LoWPAN. The company supplies wireless sensors, edge routers, a management appliance and application, and a gateway to plant or other enterprise networks.

From the developer perspective, most of the difficulties in realizing an error-free WirelessHART device are, obviously, in the implementation of the protocol stack; to speed up the process, the Wireless Industrial Technology Konsortium (WiTECK) was founded. It was an open, nonprofit membership organization whose mission was to provide a reliable, cost-effective, high-quality portfolio of core enabling system software for industrial wireless sensing applications, under a company- and platform-neutral umbrella. They started working on the realization of a WirelessHART stack, whose development process has now completed by Softing AG, which has made the stack now commercially available.

### 32.1 Introduction

The first decade of the new millennium has been the stage for the rapid development of wireless communication technologies for low-cost, low-power wireless solutions capable of robust and reliable communication [1,2]. The Institute of Electrical and Electronics Engineers (IEEE) Std. 802.15.4 for low-rate wireless personal area networks has been the enabling technology for numerous applications within the field of wireless sensor networks (WSNs) [3] and, more recently, wireless instrumentation.

Defined as the merger of WSN technologies and industrial field instruments, wireless instrumentation has become increasingly popular in the process industries since the recent ratifications of the WirelessHART [4] and ISA100.11a specifications [5]. By providing secure and reliable self-configuring and self-healing wireless mesh networks, these standards offer a cost-efficient alternative to traditional wired field instrumentation. Eliminating the need for cables also enables wireless instrumentation to be deployed in remote and hostile areas, as well as provides the opportunity for scalable, flexible, and mobile installations [6].

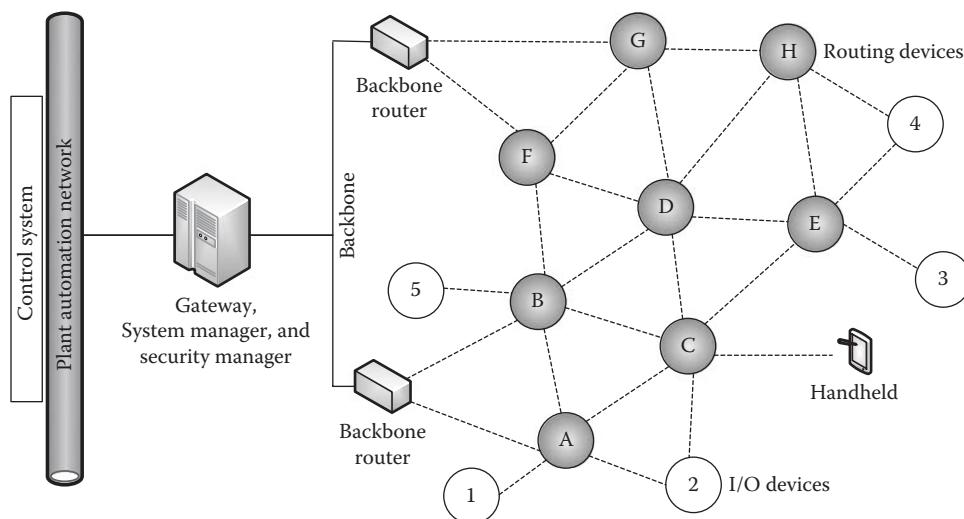

The ISA100.11a specification is the first standard to emerge from the ISA100 standards committee's work to deliver a family of standards for wireless systems for industrial automation. ISA100.11a was ratified in October 2009, and it is designed to offer secure and robust wireless connectivity for industrial automation applications. It is primarily intended to address noncritical monitoring and control applications, with the goal of targeting control and safety applications in future releases.

## 32.2 System Overview

In ISA100.11a, devices are defined as the physical embodiment of the behaviors, configuration settings, and capabilities that are necessary to implement and operate a network [5]. Further, a *role* defines a collection of function and capabilities, and all ISA100.11a devices shall implement at least one role. The following roles and their functions are defined [5]:

- *Input/output (I/O)*: An I/O device provides data to and/or utilizes data from other devices, that is, field sensors and/or actuators. An I/O device implements the minimum characteristics required to participate in an ISA100.11a-compliant network, but it has no message forwarding or routing capabilities.
- *Router*: A router device is capable of forwarding and routing messages from other devices in the network. It also has a clock propagation capability and can act as a proxy.
- *Provisioning*: A provisioning device is able to provision other devices to join the network.
- *Backbone router*: A backbone router is capable of routing messages via the backbone network.
- *Gateway*: The gateway device provides an interface between the wireless instrumentation network and the plant network.
- *System manager*: The system manager is responsible for governing the network, devices, and communications.
- *Security manager*: The security manager is a function that works in conjunction with the system manager to enable secure system operation.
- *System time source*: The system time source is the master time source for the system. The common sense of time is used to manage device operation.

A typical ISA100.11a network configuration with a diverse range of roles and devices is illustrated in Figure 32.1. Since the I/O role is separated from the router role, field instruments conforming to the specification can be defined either as router nodes with routing and forwarding capability or as end nodes with no routing capability. This enables ISA100.11a networks to employ star, star-mesh (as shown in Figure 32.1), or full mesh network topologies depending on the roles of the field devices present in a given network.

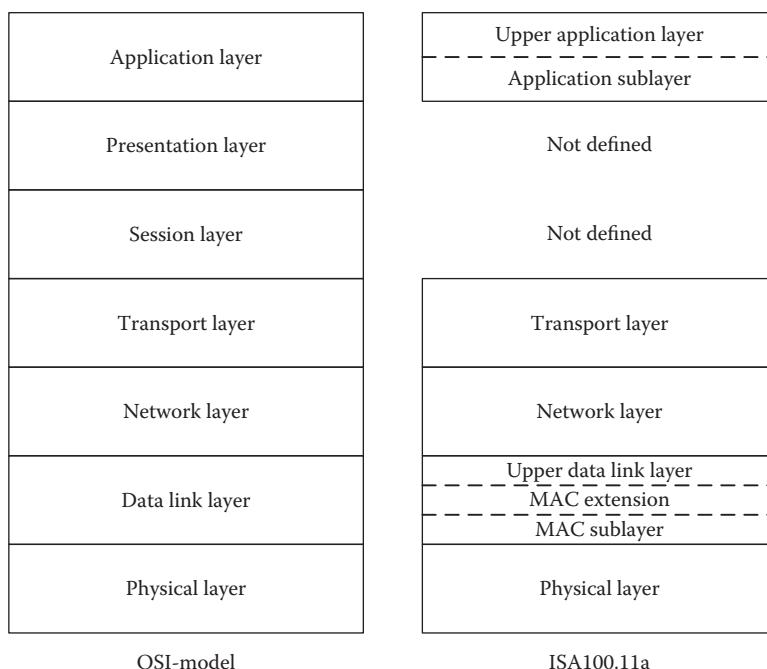

**FIGURE 32.1** Typical ISA100.11a network configuration. (From ISA100.11a-2011 Standard, Wireless systems for industrial automation: Process control and related applications, 2011.)

When it comes to the possible number of devices in an ISA100.11a, there are both theoretical and practical limitations. In theory, the protocol addressing space is capable of handling thousands of devices, but for large mesh networks, the network latency and device power consumption will increase to accommodate the communication links in the network. In a growing network, choke points will arise at the devices closest to the backbone router (such as devices A, B, F, and G in Figure 32.1) as these devices have to forward packets from nearly all of the other devices in the network. For large-scale networks, this can lead to a substantial increase in data traffic and, hence, an increase in power consumption. In addition, the maximum achievable sensor sample rate is proportional to the number of devices in the network, as communication bandwidth must be reserved to accommodate the need for sensor data message exchange. Due to these issues with network scalability, currently available ISA100.11a solutions have an upper limit to the number of devices in a network, typically in the range of 50–100.

### 32.3 Communication Protocol

Most communication protocols use *stacks* to give a layered and abstract description of the network protocol design. A stack consists of different *layers*, where a layer is a collection of related functions needed to perform its defined tasks. Each layer is responsible for providing services to the layer above and, similarly, utilizing services from the layer below. The information and service exchange between layers is performed according to a well-defined message exchange format.

ISA100.11a uses a simplified version of the seven-layered open systems interconnection (OSI) basic reference model [7]. The ISA100.11a stack model is illustrated in Figure 32.2.

**FIGURE 32.2** ISA100.11a stack model. (From ISA100.11a-2011 Standard, Wireless systems for industrial automation: Process control and related applications, 2011; Information Technology, Open systems interconnection—Basic reference model: The basic model, ITU-T X.200 (07/94), 1994.)

### 32.3.1 Physical Layer

The physical layer (PHY) is responsible for the interface to the physical medium, and it handles the transmission and reception of raw data packets. In addition, it offers mechanisms for selecting operating channels and performing clear channel assessment (CCA) and energy detection. ISA100.11a inherits its PHY from IEEE Std. 802.15.4 [8], with some modifications.

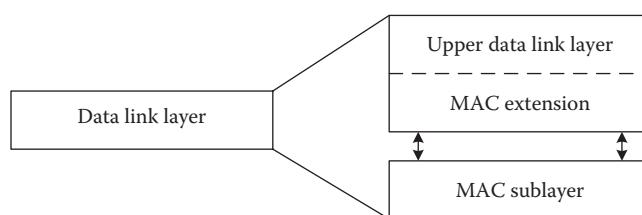

ISA100.11a operation is only defined in the globally available 2.4 GHz band, using channels 11–25 as defined by IEEE Std. 802.15.4. Channel 26 is defined as optional, as it is not available in some countries. Direct sequence spread spectrum (DSSS) is used as the modulation technique, and in combination with offset quadrature phase-shift keying (O-QPSK), this allows for a raw over-the-air data rate of 250 kbps. The maximum transmit power is limited to 10 mW by regulatory authorities, which gives most devices a transmission range of approximately 100 m with direct line of sight, depending on the sensitivity of the radio receiver.

### 32.3.2 Data Link Layer

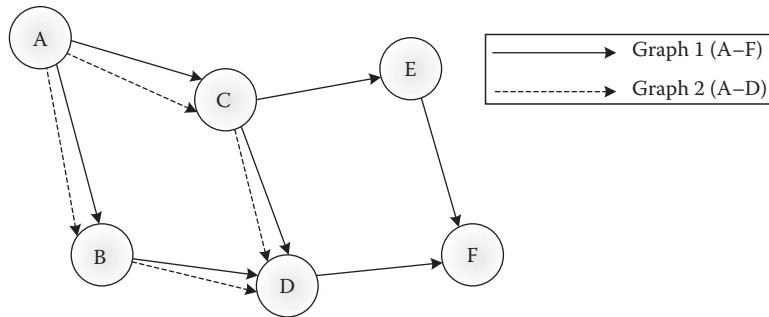

The data link layer (DLL) as defined in the OSI model typically encompasses communication between two peer devices in a network. It offers mechanisms for radio channel access, radio synchronization while handling acknowledgement frames, and security control. However, contrary to common definitions, the ISA100.11a DLL also comprises message forwarding and routing within a subnetwork, which is normally defined and handled by the network layer (NL). The ISA100.11a NL on the other hand is responsible for backbone routing.

The ISA100.11a DLL is divided into a media access control (MAC) sublayer, a MAC extension layer, and an upper DLL, as illustrated in Figure 32.3. The MAC sublayer is a subset of the IEEE Std. 802.15.4 MAC, defining transmission and reception of individual data frames. The MAC extension adds extra features not supported by the IEEE Std. 802.15.4 MAC, more specifically changes to the carrier sense multiple access with collision avoidance (CSMA-CA) mechanisms by including spatial, frequency, and time diversity. The upper DLL handles mesh networking above the MAC layer, including routing within a data link (DL) subnet. A DL subnet consists of one or more groups of field devices with a shared system manager (and backbone network). The DL subnet stops at the backbone router, but ISA100.11a messages may be routed into the plant network. The ISA100.11a NL handles routing beyond the backbone router.

Every field device participating in a DL subnet is assigned a short DL subnet address by the system manager. This short address is used for local addressing within the DL subnet. To enable mesh routing, ISA100.11a supports both graph and source routing algorithms. A graph route is a list of paths that connect end points within a network. A single network may have multiple and overlapping graphs, and a device may have multiple graphs going through it. An example illustration of graph routing can be found in Figure 32.4. In the figure, end-to-end communication between device A and device F is enabled by graph 1. To send a message to device F, device A can transmit to either device B or device C. Device B or C will then in turn forward the message towards device F according to their own graph routing configuration. Using graph 1, the following routes between device A and F are possible: A-B-D-F, A-C-D-F, or A-C-E-F. Similarly, graph 2 is used by device A to send messages to device D.

**FIGURE 32.3** ISA100.11a DLL structure.

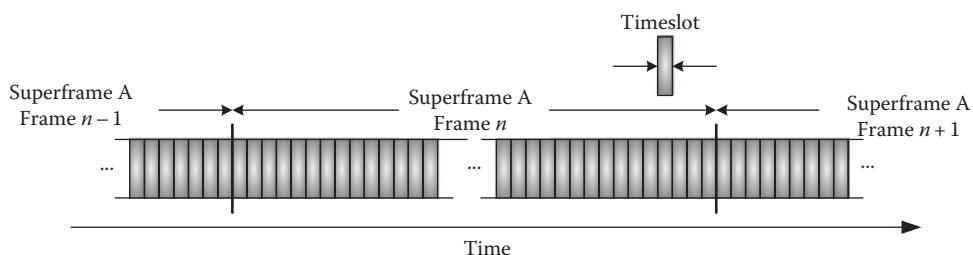

**FIGURE 32.4** Illustration of graph routing. (From ISA100.11a-2011 Standard, Wireless systems for industrial automation: Process control and related applications, 2011.)

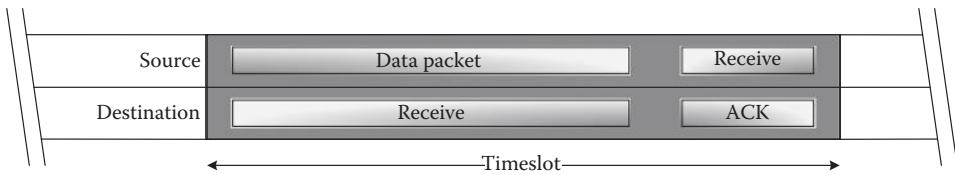

A source route is a single, unidirectional route between two devices, where one device is defined as the source and the other as the destination. A source route defines the specific path a message must take when traversing from the source to the destination. If a single link in a source route should fail, the message will be lost, while in a graph route, each device will have multiple associated neighbors to which they may transmit messages. Compared to source routing, this enhances both reliability and redundancy. The ISA100.11a DL subnet routes are configured by the system manager based on periodic network health reports from devices, which indicates the quality of the wireless connectivity to their immediate neighbors.

ISA100.11a uses time division multiple access (TDMA) as its main channel access mechanism. Communication is divided into distinct timeslots of configurable duration (typically 10 ms). The timeslot length is set to a specific value by the system manager when a device joins the network. A collection of timeslots forms a superframe that repeats in time throughout the entire lifetime of the network. The term frame is used to separate instances in time of a specific superframe, as illustrated in Figure 32.5. ISA100.11a supports multiple superframes of variable lengths, and one superframe must always be enabled. Superframes can be added and removed by the system manager while the network is operational.

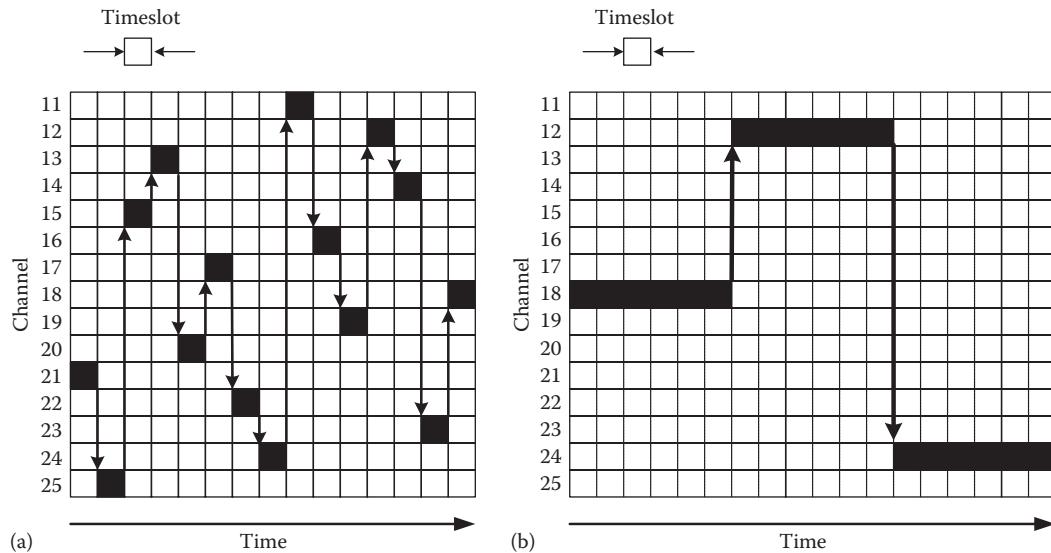

To supervise the communication within a network, the system manager typically assigns two devices to a timeslot, one as a source (transmitter) and the other as the destination (receiver). An exception to this is broadcast messages where multiple devices are assigned as receivers in the same timeslot. Within a timeslot, the source device may transmit a data packet to the destination device. Upon successful reception of a data packet, the destination device will transmit an acknowledgment packet (ACK) to the source device, as depicted in Figure 32.6. If the source device fails to receive an ACK, the data packet will be retransmitted in the next available timeslot. Note that an ACK is not transmitted upon reception of a broadcast message.

**FIGURE 32.5** Structure of TDMA timeslots and superframes.

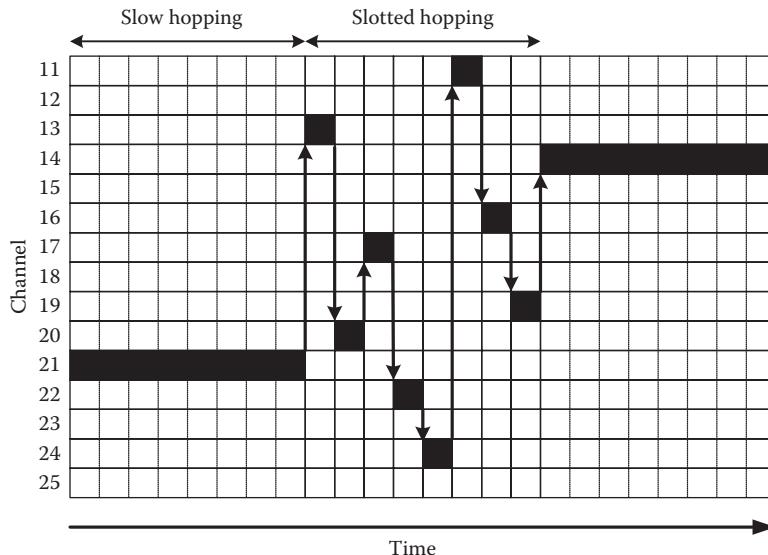

**FIGURE 32.6** Data transmission within a timeslot. (From ISA100.11a-2011 Standard, Wireless systems for industrial automation: Process control and related applications, 2011.)

**FIGURE 32.7** Frequency hopping patterns: (a) slotted and (b) slow. (From ISA100.11a-2011 Standard, Wireless systems for industrial automation: Process control and related applications, 2011.)

Combined with these TDMA mechanisms, ISA100.11a also employs two types of frequency hopping called *slotted* and *slow* hopping. In slotted hopping, communication is divided into a 2D matrix consisting of timeslot and the 16 available channels. A *link* is thus specified by a superframe, timeslot offset (relative to the first timeslot of the superframe), and channel offset, as illustrated in Figure 32.7a. In consecutive superframes, a link will always have the same timeslot offset, while the communication channel will change according to a pseudorandom hop sequence. As an example, for a given link, communication may occur on channel 19 in timeslot  $k$  in frame  $n$  of superframe A and on channel 13 in timeslot  $k$  in frame  $n + 1$  of the same superframe. Combining TDMA and frequency hopping in this manner allows for multiple devices to transmit data at the same time on different channels without generating intranetwork interference. Note, however, that a single device may only participate in communication on one channel (link) per timeslot.

For slow channel hopping, a collection of contiguous timeslot is grouped on a single channel. Each collection is treated as a single slow hopping period, and it will be subjected to channel hopping as for slotted channel hopping, but at a slower rate (see Figure 32.7b). The duration of a slow hopping period is configurable. A slow hopping period is generally used to provide immediate, contention-based channel bandwidth on demand to a group of devices. Transmissions in a slow hopping period are thus not driven by a TDMA scheme; the channel is left open for nondeterministic CSMA-CA-based access. Although the TDMA scheme is not used internally in each slow hopping period, the device must still follow the

**FIGURE 32.8** Hybrid frequency hopping pattern.

overlaying timeslot synchronization and frequency hopping patterns of the network. The slow hopping mechanism enables improved support for event-based and time critical traffic where the occurrence of a given event/alarm may trigger the need for a device to immediately transmit a data packet. With slotted channel hopping, the device would be forced to wait for the next available scheduled timeslot where it is assigned as a transmitter, thereby increasing the communication latency. The drawback of the slow channel hopping method is that the devices designated as receivers in a slow hopping period must continuously listen for incoming traffic, which increases their power consumption compared to slotted channel hopping.

ISA100.11a can also employ a hybrid slotted and slow hopping configuration, where the network will change between periods of slow hopping and periods with slotted hopping as illustrated in Figure 32.8. The order in which slotted and slow hopping are combined is flexible and governed by the system manager.

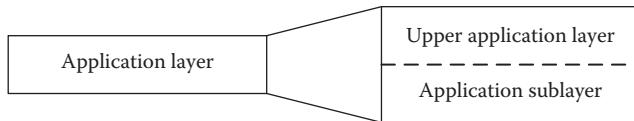

Five preprogrammed hopping patterns that shall be supported by all field devices (I/O and routers) are defined [5]:

- Pattern 1: 19, 12, 20, 24, 16, 23, 18, 25, 14, 21, 11, 15, 22, 17, 13 (,26)
- Pattern 2: pattern 1 in reverse
- Pattern 3: 15, 20, 25
- Pattern 4: pattern 3 in reverse
- Pattern 5: 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25 (,26)

Pattern 3 and 4 are intended for slow hopping channels, while pattern 5 is intended to facilitate coexistence with WirelessHART. The system manager can configure a device to use any of the five patterns for either slotted, slow, or hybrid hopping.

### 32.3.3 Network Layer

Traditionally, the main responsibilities of the NL are to route packets across the network and to discover and maintain routing tables. However, the mesh-level routing within a DL subnet is handled by the ISA100.11a DLL. The DL subnet stops at the backbone router (see Figure 32.1), and it is the routing

**FIGURE 32.9** ISA100.11a AL structure.

beyond the backbone router that is the responsibility of the ISA100.11a NL. The specification of the backbone and plant networks is, on the other hand, outside the scope of ISA100.11a, so the details on how to route traffic over a backbone or plant network are not clearly specified.

The ISA100.11a NL is influenced by the IPv6 over low power wireless personal networks (6LoWPAN) specification [9] of the Internet Engineering Task Force (IETF), with the main goal of facilitating future compatibility with IPv6 [10]. The NL is responsible for determining the appropriate address information, either a 16-bit short address for DL subnets or a 128-bit long address for backbone networks and application end points. The NL must handle translations between the two address types, and all devices shall maintain an address translation table to facilitate these translations. The ISA100.11a NL also fragments and reassembles data packets that exceed the maximum length allowed by the DLL.

### 32.3.4 Transport Layer

The transport layer (TL) is responsible for end-to-end communication, possibly across several devices, and operates in the communication end points, that is, not on the intermediate routers. The ISA100.11a TL provides connectionless services, which extends the User Datagram Protocol (UDP) [11] over IPv6 with optional compression as defined by the IETF 6LoWPAN specification. The extension to UDP includes better data integrity checks and additional authentication and encryption mechanisms. Acknowledged transactions are not supported by the ISA100.11a TL.

### 32.3.5 Application Layer

The application layer (AL) provides services to user-defined application processes, and it defines the necessary communication services to enable object-to-object communication between distributed applications. In the ISA100.11a AL, software objects are used to model real-world objects. The AL is divided into two sublayers: the upper AL (UAL) and the application sublayer (ASL), as illustrated in Figure 32.9. The UAL contains the application processes for a device, and it may be used to handle input and/or output hardware, perform a computational function, or support protocol tunneling. The ASL provides the services needed for the UAL to perform its functions, such as object-oriented communication and routing to objects within a user application process across the network.

## 32.4 Security

When introducing wireless technology in process automation industries, it is important that the communication protocols employ sufficient security mechanisms and algorithms for protection against potential cyber attacks. Data confidentiality, authenticity, and integrity must be maintained, and the networks must be able to prevent the following security issues that wireless systems are susceptible to [12]:

- *Accidental association:* Unintentional access to a wireless network by a foreign computer or device.
- *Malicious association:* Access to a wireless network is obtained by hackers in order to steal user information, passwords, or data or to launch other attacks and install malicious software.
- *Identity theft:* Hacker that is able to impersonate an authorized device or user by listening to credential traffic.

- *Man-in-the-middle attacks*: Hackers gaining access to a network with malicious association and transparently monitor network traffic and/or provide false information and data to other network users.
- *Denial of service*: A target device or gateway is flooded with bogus protocol messages and data in an attempt to reduce or suspend its responsiveness and ability to perform regular functions. Intentional jamming of a wireless communication channel falls under this category.
- *Network injection*: Accessing access points/gateways to introduce bogus network configuration commands that may affect routers, switches, and intelligent hubs. The network devices may crash, shut down, restart, or even require reprogramming.
- *Byzantine attack*: Attack where an intruder reprograms a collection of compromised sensors, whereby they send fictitious sensor readings to the control room.
- *Radio interference*: Interference from other wireless networks operating in the same frequency bands.

ISA100.11a employs payload encryption and message authentication to prevent security breaches, along with a model for distribution and maintenance of encryption keys.

### 32.4.1 Payload Encryption and Message Authentication

ISA100.11a employs payload encryption and message authentication for both single hop messages and end-to-end messages (multihop). The single hop protection is handled by the DLL, while end-to-end message protection is handled by the TL. The DLL security defends against attackers who are outside the system, while the TL security defends against attackers who may be on the network path between the source and destination devices.

ISA100.11a supports counter with cipher block chaining message authentication code (CCM) mode in conjunction with AES-128 (advanced encryption standard with 128-bit block size) block cipher using symmetric keys for message authentication and encryption. This authenticated encryption algorithm is designed to provide both data authentication and privacy.

### 32.4.2 Security Key Model

ISA100.11a defines a set of security keys that are used to ensure secure communication in the network. The standard supports both symmetric and asymmetric cryptography.

Symmetric cryptography relies on both communication end points using the same security key when communicating securely. Attackers that do not have access to the security keys cannot modify messages without being detected, and they cannot decrypt the encrypted payload information.

A new device can be provisioned with a join key before it attempts to join a network. The join key is used to authenticate the device for a specific network. Once the device has successfully joined the network, the security manager will provide it with keys for further communication. The use of the join key is optional. A global key, a well-known key with no security guarantees, may also be used in the join process for devices not supporting symmetric keys.

Devices are issued a master key, DL key, and a session key upon joining a network (if the device supports these security features). The master key is used for communication between the security manager and the device, the DL key is used by the DLL to compute the message integrity code (MMIC), and the session key is an optional key used to encrypt and/or authenticate TL messages. The keys are limited in time and need to be periodically updated.

ISA100.11a also supports optional asymmetrical keys. In asymmetric cryptography, different keys are used to encrypt and decrypt a message. Each device has a pair of keys: a public and a private key. The private key is kept secret, while the public key may be freely and openly distributed. Messages encrypted with the public key can be decrypted only with the private key. Unlike symmetric

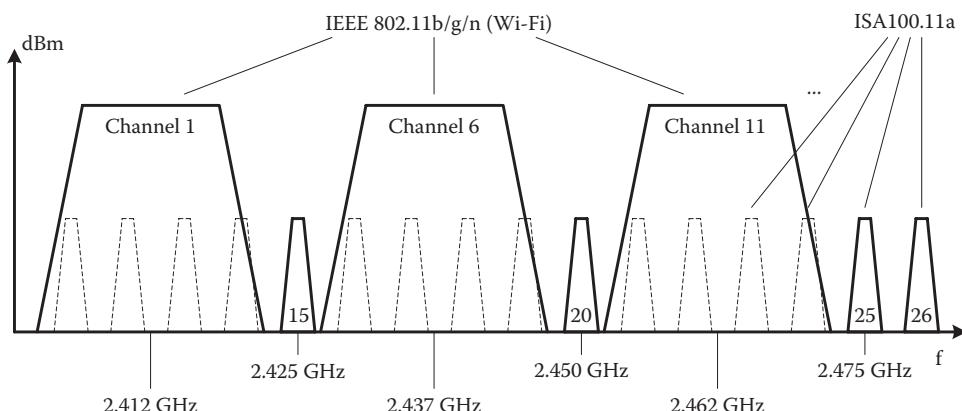

cryptography, this does not require a secure initial exchange of one or more secret keys to the transmitter and receiver. Two asymmetrical keys are defined: CA-root and Cert-A. CA-root is the public key of a certificate authority that signed a device's asymmetric key certificate. It is used to assist in verifying the true identity of the device communicating the certificate. Cert-A is the asymmetric key certificate of device A, used to evidence the true identity of the device during execution of an authenticated asymmetric key establishment protocol.

When joining a network, an ISA100.11a device shall use either symmetric keys, public keys, or no security. The no security option uses the global key, and the MIC will then be the equivalent of a cyclic redundancy check (CRC) with no security guarantees. For these devices, no end-to-end security transmissions are allowed.

## 32.5 Coexistence

ISA100.11a operates in the 2.4 GHz band, one of the very few open frequency bands with near worldwide availability. To ensure a successful adoption in the process industries, it is therefore imperative that ISA100.11a networks are able to peacefully coexist with other wireless networks operating on the same frequency. Examples of such networks are IEEE 802.11-based local area networks (commonly referred to as Wi-Fi), Bluetooth, and cordless telephones. As the widespread adoption of Wi-Fi networks has also reached process and manufacturing plants, it is expected that most ISA100.11a deployments will have to share and contend for the frequency spectrum with nearby Wi-Fi infrastructure.

The 802.11 specifications [13] define 14 overlapping channels in the 2.4 GHz band, each channel being 22 MHz wide and spaced 5 MHz apart. Channel 14 is only available in Japan, while channels 12 and 3 are prohibited in North America and some Central and South American countries. As neighboring channels in Wi-Fi are overlapping, it has become commonplace in industrial deployments to configure Wi-Fi access point to use the nonoverlapping channels 1, 6, and 11 to prevent interference. The frequency distribution of these three channels along with the ISA100.11a channels is illustrated in Figure 32.10. Interference between wireless systems only occurs when they operate at the same frequency, in the same location, and at the same time. As a result, relatively interference-free operation for ISA100.11a can only be achieved in channels 15, 20, 25, and 26 if the network is collocated with a typical industrial Wi-Fi deployment.

**FIGURE 32.10** Wi-Fi and ISA100.11a frequency utilization in the 2.4 GHz band.

### 32.5.1 Spectrum Management

ISA100.11a employs a set of spectrum management techniques to better cope with coexistence and interference issues. Prior to data transmission, a CCA is performed to ensure that the channel is free to use. Four CCA modes are defined, where modes 1–3 are inherited from the IEEE 802.15.4 PHY [5]:

- 0—*Disabled*: CCA is not performed prior to data transmission.
- 1—*Energy above threshold*: CCA reports busy medium upon detecting any energy above a configurable threshold.
- 2—*Carrier sense only*: CCA reports a busy medium if a signal compliant with IEEE Std. 802.15.4 PHY modulation and spreading characteristics is detected.
- 3—*Carrier sense with energy above threshold*: CCA reports a busy medium using a logical AND/OR combination of Mode 1 and Mode 2.

To avoid the use of channels with high levels of noise and/or interference, channel blacklisting may be used. If one or more channels are blacklisted, the device will change its hop pattern to not include the blacklisted channel(s). The blacklisting feature is adaptive, giving each device the capability of autonomously blacklisting problematic channels. However, the system manager may disable the adaptive blacklisting mechanisms of any device in the network.

## 32.6 Implementations and Equipment

---

### 32.6.1 Field Devices

A wireless field instrument can be a traditional industrial sensor or actuator equipped with a radio transmitter, antenna, and a power supply (battery), thus eliminating the need for cables. It consists of five main components:

1. *Sensing (or actuator) element*: A sensor element measures a physical phenomenon such as temperature, pressure, or flow, while an actuator element is used for, for example, opening and closing valves.
2. *Microcontroller*: The microcontroller typically runs both the application program for handling and controlling the sensor or actuator, in addition to the software stack for the wireless communication.
3. *Memory/storage*: Temporary and permanent memory and storage elements are used for program code and execution and storing configuration parameters and application data.
4. *Communication*: The communication module consists of an antenna and the radio-frequency (RF) front end and is responsible for transmitting and receiving raw data over the wireless channel.
5. *Power*: To eliminate the need for cables, a wireless sensor typically uses a high-capacity battery as a power source.

The sensor or actuator elements are identical to the wired counterparts, so a wireless field instrument provides the same measurements with regard to characteristics such as precision, range, and dependency. An integrated ISA100.11a field device is illustrated in Figure 32.11.

As described in Section 32.3, stacks are used to aid in the description of network protocol design. The PHY is implemented in hardware, and as ISA100.11a inherits its PHY from the IEEE 802.15.4 specification, any available IEEE 802.15.4 radio module can be used as an ISA100.11a radio. The stack layers above the PHY (from the DLL to the AL) are implemented in software and are commonly referred to as a software stack. This is illustrated in Figure 32.12.

The value chain for ISA100.11a field devices does thus typically consist of three components: IEEE 802.15.4 radio providers, ISA100.11a radio module providers, and ISA100.11a field device providers.

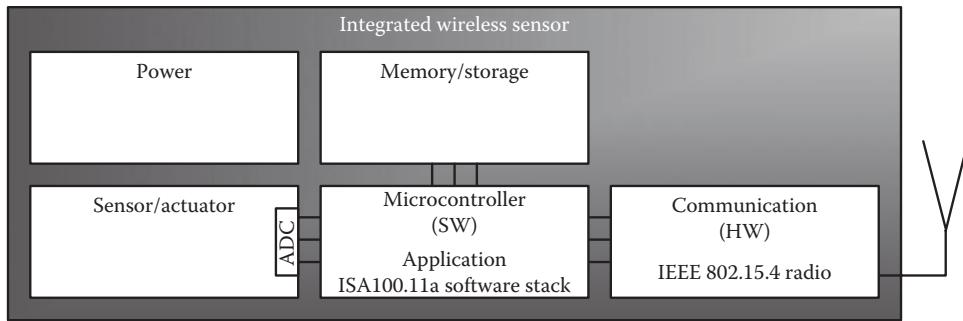

FIGURE 32.11 ISA100.11a field device.

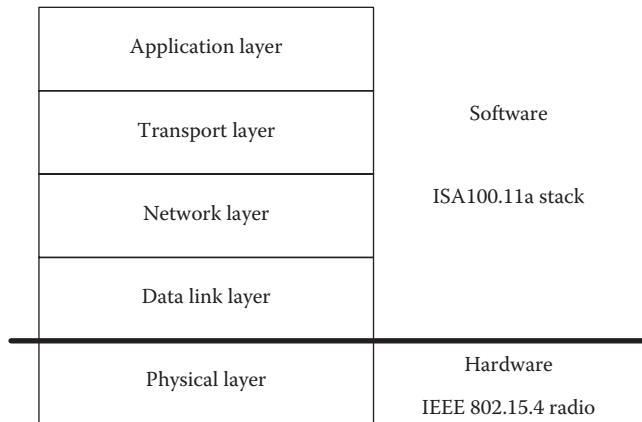

FIGURE 32.12 ISA100.11a radio and software stack structure.

### 32.6.1.1 IEEE 802.15.4 Radios

An IEEE 802.15.4 radio is an implementation of the IEEE 802.15.4 PHY, which defines frequency, channels, modulation, coding, and transmission power levels. The design and implementation of an IEEE 802.15.4 radio affects the power consumption, transmission range, and receiver sensitivity, and radios from different providers will have (slightly) different performance.

There are numerous providers of IEEE 802.15.4 radios, for example, Atmel, Energy Micro, Freescale, Linear Technologies, and Texas Instruments.

### 32.6.1.2 ISA100.11a Radio Module Providers and Software Stacks

An ISA100.11a radio module is an integration of an ISA100.11a software stack and IEEE 802.15.4 radio on the same hardware board. All software stacks must adhere strictly to the ISA100.11a specification, and the ISA100.11a Wireless Compliance Institute performs compliance testing to ensure that the behavior of a software stack is according to the specification. For the software stacks, there is little to no room for vendor-specific implementations, with the exception of potential small variations in optional features and parameters.

At the time of writing, Nivis is the only independent vendor for ISA100.11a software stacks and radio modules. Their radio module is based on an IEEE 802.15.4 radio from Freescale. In addition, Honeywell has their own in-house developed ISA100.11a software stack and radio module, running

on an IEEE 802.15.4 radio from Texas Instruments. Yokogawa has also developed their own in-house ISA100.11a software stack, which is currently being used for their backbone routers.

### 32.6.1.3 ISA100.11a Field Device Provider

An ISA100.11a field device is an integrated field instrument with a sensor or actuator element, power, memory/storage, and an ISA100.11a radio module. The wireless performance will, as mentioned in the previous sections, be slightly dependent on the choice of IEEE 802.15.4 radio used with the ISA100.11a radio module.

At the time of writing, the following companies offer certified ISA100.11a field devices (with the ISA100.11a radio module provider in parenthesis): Flowserve (Nivis), GasSecure (Nivis), GE (Nivis), Honeywell (in-house), and Yokogawa (Nivis).

### 32.6.2 System Manager and Wireless Gateway

The functions of the system manager include security management, address allocation, system performance monitoring, device management, system time services, and communication configuration including contract services and redundancy management [5].

The system manager is responsible for creating and maintaining the routing tables and link distributions (timeslot and channel offsets) for all devices in the network, based on periodic network health reports from the devices. However, the ISA100.11a specification does not define how to actually implement and perform the radio resource management. This means that different implementations of ISA100.11a system managers will have different performances regarding power consumption (of field devices), latency, and reliability.

In the early implementations of ISA100.11a systems, the system manager, security manager, gateway, and backbone router resided encapsulated into the same physical enclosure, which was typically referred to as the network gateway. A schematic of such a network gateway is shown in Figure 32.13. Newer releases of ISA100.11a solutions have enabled the possibility of separating the backbone router from the gateway, system manager, and security manager. This allows for the backbone router to operate in hazardous areas with stricter Atmospheres Explosibles (ATEX) requirements.

At the time of writing, ISA100.11a wireless gateways are available from GasSecure (based on Nivis gateway), Honeywell, Nivis, and Yokogawa.

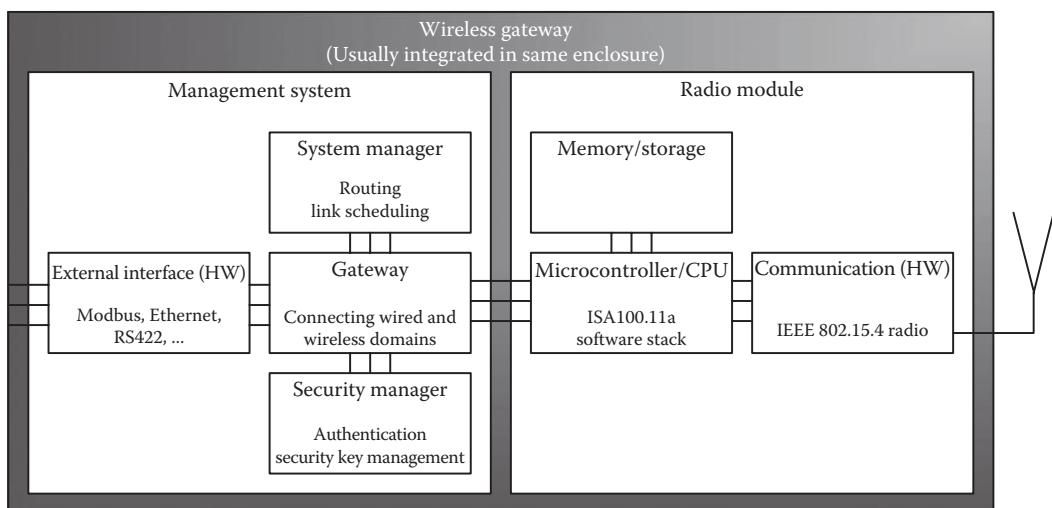

FIGURE 32.13 ISA100.11a wireless gateway.

## 32.7 Conclusion

---

This chapter has provided an overview of the ISA100.11a specification and its implementations. Since its release in October 2009, ISA100.11a networks have been successfully deployed in numerous process plants and facilities, providing adequate network performance for noncritical monitoring applications in harsh and hazardous industrial environments [14]. In addition, with the recent development of the wireless hydrocarbon gas detection system from GasSecure, ISA100.11a is also starting to address critical safety applications [14].

As there are currently three competing standards addressing wireless instrumentation for the process automation industries (WirelessHART, ISA100.11a, and WIA-PA), all backed by different groups of automation companies, it will be interesting to follow their *battle* to become the de facto standard for wireless instrumentation in the coming years.

### 33.1 Introduction

---

Wireless instrumentation, defined as the merger of wireless sensor network (WSN) technologies and industrial process automation systems, has become increasingly popular in the process industries in recent years. WSN, the foundation for wireless instrumentation, is a rather new technology, with its origins tracing back to the early 1980s through the distributed sensor networks (DSNs) program at the Defense Advanced Research Project Agency (DARPA) of the US Department of Defense [1]. DSNs were imagined to consist of many spatially distributed, autonomous, and low-cost sensing nodes that collaborated to gather various information about their surroundings. However, in the 1980s, the technology was not quite ready for this application. The sensors were too large and expensive, and the communication was not yet associated with wireless connectivity.

In the late 1990s, advances in computing, communication, and microelectromechanical technologies caused a shift in DSN research, bringing it closer to achieving the original vision. The *second wave* of DSN activities started in 1998, and it attracted large international involvement and attention. New networking techniques and networked information processing suitable for the dynamic ad hoc environments found in sensor networks were the initial focus, with the goal of enabling the required complex applications to run on resource-constrained sensors [1]. The sensors themselves also evolved with new technology, reducing both their cost and size. In addition, advances in wireless technology enabled robust and reliable wireless communication ideally suited for wireless DSNs. DARPA was again the pioneer, leading the efforts of sensor network research. They initiated a research program that provided

new insights into ad hoc networking, dynamic querying and tasking, reprogramming, and multi-tasking [1]. At the same time, Institute of Electrical and Electronics Engineers (IEEE) had started to note the potential of WSNs and had begun to work on a specification for low-rate wireless personal area networks (LR-WPAN).

The work of IEEE was finalized in 2003, when the IEEE Std. 802.15.4 specification [2] was ratified, defining the physical layer (PHY) and media access control (MAC) layer for LR-WPAN. The higher layers of the protocol stack are out of scope of the specification. Offering features such as low power, low complexity, and low cost is ideally suited for WSN applications. With a growing number of solutions, both standardized and proprietary, based on the IEEE Std. 802.15.4 appearing in the years since its release, it has become the de facto standard for WSNs.

The ZigBee specification [3], originally released in 2004, was the first full standard to appear based on the IEEE Std. 802.15.4. ZigBee defines the network layer (NL) and application layer on top of the IEEE Std. 802.15.4 PHY and MAC.

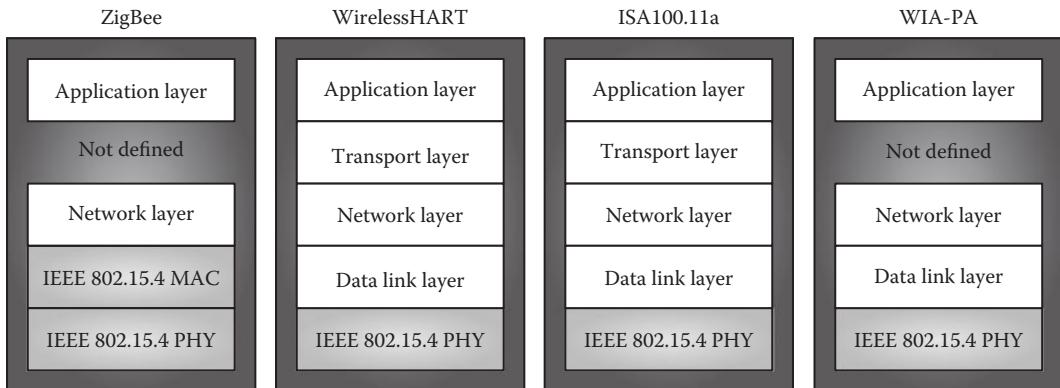

Early research and evaluation of the IEEE Std. 802.15.4 identified several potential issues related to information security, in addition to other minor bugs and errors. A new version of the standard was released in 2006, referred to as IEEE Std. 802.15.4-2006 [4], which addressed these shortcomings. The original standard from 2003 is referred to as IEEE Std. 802.15.4-2003, to distinguish the two versions. Shortly after the ratification of IEEE Std. 802.15.4-2006, the ZigBee Alliance released a new version of the ZigBee standard, ZigBee-2006 [5]. The original ZigBee standard is referred to as ZigBee-2004. ZigBee-2006 included improvements for, among other things, addressing issues leading to scalability problems for large networks. It is important to note, however, that ZigBee-2006 was still based on IEEE Std. 802.15.4-2003, and not on the new IEEE Std. 802.15.4-2006. This means that the security issues of IEEE Std. 802.15.4-2003 were still present in ZigBee-2006.

In 2007, the Highway Addressable Remote Transducer (HART) Communication Foundation (HCF) released the HART Field Communication Protocol Specification, Revision 7.0 [6], which included a definition of a wireless interface to field devices, referred to as WirelessHART. WirelessHART was the first specification to be released that was specifically designed for process automation applications. With features such as self-healing and self-configuring multihop mesh networks, WirelessHART offers a viable wireless alternative for the traditionally wired industrial field instrumentation. WirelessHART was approved by the International Electrotechnical Commission (IEC) as international standard IEC 62591 Ed. 1.0 for wireless communication in process automation [7] in March 2010.

The ZigBee specification was initially designed to address applications within home automation and consumer electronics. A ZigBee network operates on the same, user-defined channel throughout its entire lifetime. This makes it susceptible both to interference from other networks operating on the same frequency and to noise from electrical equipment and machinery in the environment. As a result, ZigBee has not been regarded as robust enough for harsh industrial environments [8]. To combat this shortcoming, the ZigBee Alliance released the ZigBee PRO specification [9] in 2007. ZigBee PRO is specifically aimed at the industrial market, having enhanced security features and a frequency agility concept where the entire network may change its operating channel when faced with large amounts of noise and/or interference. Despite these innovations, ZigBee has still not been embraced by the industry.

Parallel to HCF's work on WirelessHART, the International Society of Automation (ISA) initiated work on a family of standards for wireless systems for industrial automation applications. This resulted in the ratification of the ISA100.11a standard in September 2009 [10]. Like WirelessHART, ISA100.11a aims to provide secure and reliable wireless communication for noncritical monitoring and control applications in the process automation industries. A new version of the ISA100.11a was released in 2011 [11], addressing minor faults and errors in the initial specification.

A third specification addressing wireless communication for the process automation industries, WIA-PA, was accepted by the IEC in 2009 as IEC 62601 [12]. WIA-PA was developed by the Chinese Industrial Wireless Alliance (CIWA) under the urgent requirements of process automation. In 2007, CIWA was established by Shenyang Institute of Automation, along with more than 10 universities,

**FIGURE 33.1** Wireless instrumentation protocol stacks.

academies, and companies. The scope of WIA-PA is to provide a system architecture and protocol stack for use in industrial monitoring, measurement, and control applications. However, at the time of writing, no products supporting WIA-PA are readily available on the market.

In April 2012, the IEEE Std. 802.15.4e [13] was released as an amendment to the IEEE Std. 802.15.4 specification. It provides additional MAC behavior and frame formats that allow IEEE Std. 802.15.4 devices to support applications within industrial applications such as process control and factory automation. At the time of writing, no devices supporting IEEE Std. 802.15.4e have yet been released.

ZigBee, WirelessHART, ISA100.11a, and WIA-PA are all based on the IEEE Std. 802.15.4 PHY. ZigBee uses the IEEE Std. 802.15.4 MAC as well, while the three industrial standards have made modifications to the IEEE Std. 802.15.4 MAC to allow for frequency hopping and extended security mechanisms (see Figure 33.1). With the current status of ZigBee not being considered robust enough, while WIA-PA products seem to be unavailable, the process industries are now faced with two independent and competing standards specifically designed for wireless instrumentation, each supported by different industry players. The process and automation industry as a whole would benefit more from having one global, wireless standard, but with the current situation, this is unlikely to happen in the near future.

This chapter contains a theoretical and analytical comparison of WirelessHART and ISA100.11a, from a technical and systematical point of view. With two available standards for wireless instrumentation, it is important for the end users to be able to understand the inherent strengths and limitations of the two and how these influence their suitability for different automation applications and usage areas.

Note that two separate chapters in this book are devoted for a more detailed description of WirelessHART and ISA100.11a.

## 33.2 System Overview

A typical WirelessHART or ISA100.11a installation consists of a collection of components, including physical devices and software modules, each fulfilling one or more defined functions or roles. The following devices and components are defined in WirelessHART [6]:

- Field device
- Adapter
- Handheld
- Gateway
- Network manager
- Security manager

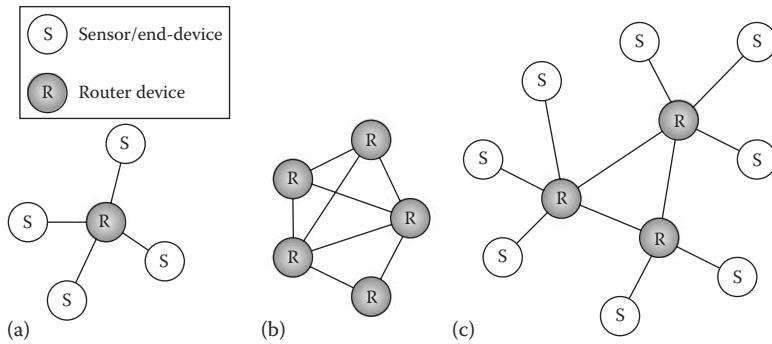

FIGURE 33.2 Network topologies: (a) star, (b) mesh, and (c) hybrid star–mesh.

In ISA100.11a, a set of roles are used to describe the capabilities of a device. The following roles are defined in ISA100.11a [11]:

- Input/output (I/O)
- Router
- Provisioning
- Backbone router
- Gateway
- System manager
- Security manager
- System time source

A more detailed description of the function of each of these components and roles can be found in Chapters 31 and 32.

WirelessHART and ISA100.11a have a fundamental difference on the field device level that influences the possible network topologies for the two standards. In WSNs, the typical network topologies are either star, mesh, or a hybrid combination of the two called star–mesh. These three network topologies are illustrated in Figure 33.2. In WirelessHART, all field devices (and adapters) are required to be routers with the capability of routing packets on behalf of other devices in the networks, enabling a full mesh network topology. In ISA100.11a on the other hand, the sensor and actuator (I/O) role is separated from the router role. An ISA100.11a field device can thus be configured either as end node with no routing capability or as router nodes with routing capacity. As a result, an ISA100.11a network can employ star, mesh, and star–mesh network topologies depending on the defined roles of the devices in a network.

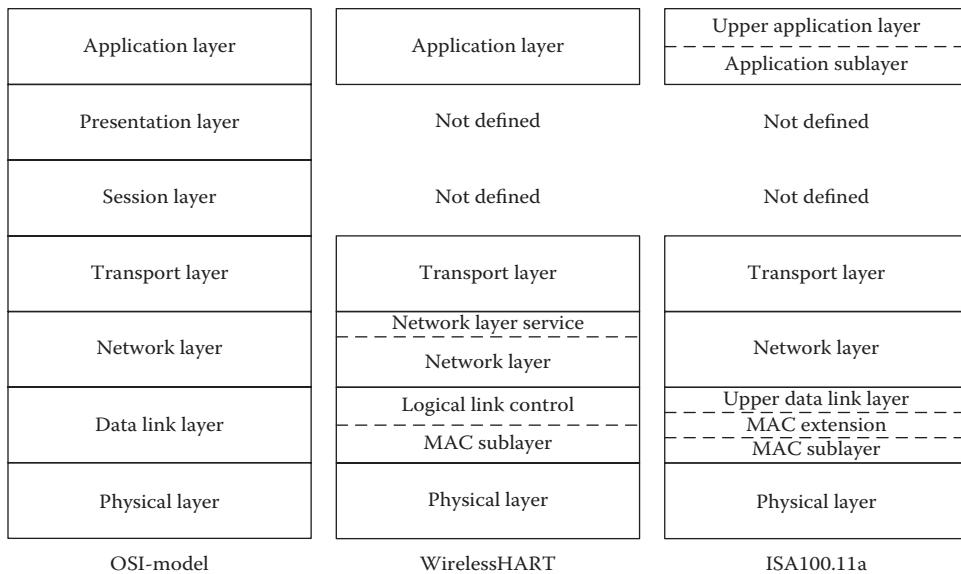

### 33.3 Communication Protocols

WirelessHART and ISA100.11a use a simplified version of the seven-layered open systems interconnection (OSI) basic reference model, as illustrated in Figure 33.3.

The following section gives a comparison of the different protocol stack layers of WirelessHART and ISA100.11a.

#### 33.3.1 Physical Layer

WirelessHART and ISA100.11a implement the PHY of the IEEE Std. 802.15.4 specification [4], with operational frequency being limited to the 2.4 GHz band. The only difference between the WirelessHART

**FIGURE 33.3** WirelessHART and ISA100.11a stack structures.

PHY and the ISA100.11a PHY is related to the usage of channel 26, which is not legal to use in some countries. The channel is not included in WirelessHART, while it is defined as optional in ISA100.11a.

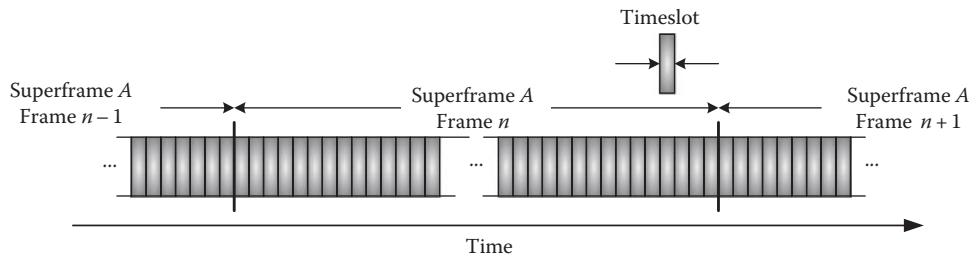

### 33.3.2 Data Link Layer

WirelessHART divides the data link layer (DLL) into a logical link control layer and a MAC (see Figure 33.3). The scope of the WirelessHART DLL is communication between neighboring devices on a one-hop level. Any responsibilities to the network beyond a device's immediate neighbors are allocated to the WirelessHART NL.

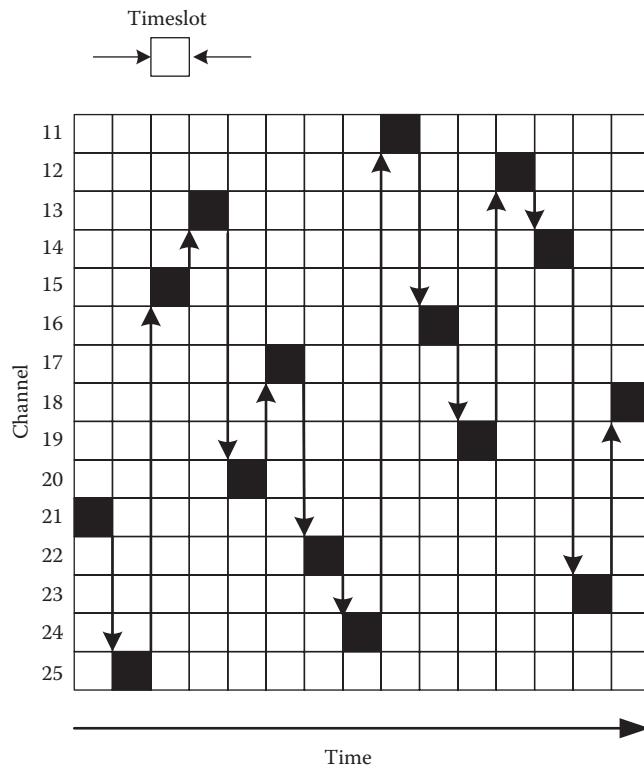

ISA100.11a divides the DLL into a MAC sublayer, a MAC extension, and an upper DLL. Unlike WirelessHART and contrary to the DLL definition in the OSI model, the ISA100.11a DLL handles mesh routing within a data link (DL) subnet. An ISA100.11a DL subnet comprises one or more groups of field devices with a shared system manager and backbone network. The DL subnet stops at the backbone router, and network routing beyond the backbone router and into the backbone and plant network is handled by the ISA100.11a NL. More information about the graph and source routing mechanisms employed by ISA100.11a can be found in the separate section on the specification.

Both WirelessHART and ISA100.11a use a combination of time division multiple access (TDMA) and frequency hopping for medium access. Communication is divided into a 2D matrix consisting of timeslots and channels. In WirelessHART, the duration of a timeslot is fixed at 10 ms, while in ISA100.11a, it is configurable (with a typical and default duration of 10 ms). A collection of timeslots is called a superframe, and the superframes repeat continuously throughout the lifetime of the network. The term frame is used to separate different instances in time of a given superframe, as illustrated in Figure 33.4.

The channel used for communication between devices in a given timeslot in a superframe will change in each consecutive frame according to a pseudorandom hop pattern, as illustrated in Figure 33.5. This channel hopping mechanism is called slotted hopping in ISA100.11a, and in addition to slotted hopping, ISA100.11a also supports slow hopping and hybrid combinations of slotted and slow hopping. In slow hopping, a collection of contiguous timeslots are grouped on a single channel, as illustrated

**FIGURE 33.4** Structure of TDMA timeslots, superframes, and frames.

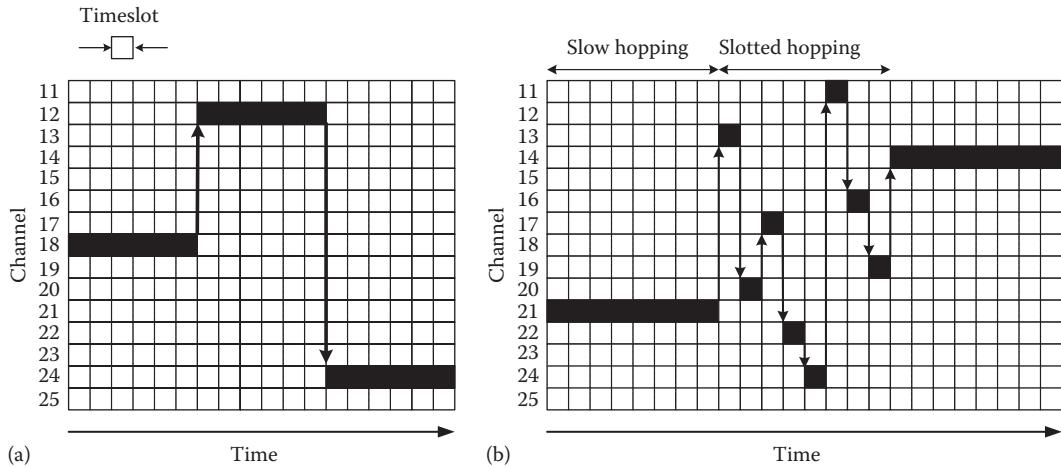

**FIGURE 33.5** WirelessHART and ISA100.11a (slotted) frequency hopping.

in Figure 33.6a. The length of a slow hopping period is configurable, and it is intended to be shared by a group of devices that may require immediate and contention-based channel bandwidth on demand. In hybrid slotted and slow hopping configuration, the network will change between periods of slow hopping and periods of slotted hopping. An example of hybrid slotted and slow hopping is shown in Figure 33.6b.

### 33.3.3 Network Layer

For the HART Field Communication Protocol, the NL is the point of convergence for traditional wired HART token-passing networks and WirelessHART TDMA-based networks. The WirelessHART NL is responsible for routing packets from their initial source to their final destination, similar to the

**FIGURE 33.6** ISA100.11a frequency hopping mechanisms: (a) slow and (b) hybrid slow and slotted.

ISA100.11a DLL described in the previous section. WirelessHART supports both graph and source routing, and all devices in a WirelessHART network maintain a series of routing tables that control the communications performed by the device. The assignment of routing tables is handled by the network manager.

The ISA100.11a NL is used for backbone routing and has support for IPv6 [14] traffic through inclusion of the IETF 6LoWPAN specification [15]. The ISA100.11a NL is responsible for determining the appropriate address information for data messages, either a 16-bit short address for DL subnets or a 128-bit long address for application end points and backbone networks.

### 33.3.4 Transport Layer

The WirelessHART transport layer (TL) supports both acknowledged and unacknowledged transactions between devices, allowing the end application to decide whether it is desirable to send packets with or without end-to-end acknowledgment receipts.

The ISA100.11a TL is an extension of the connectionless User Datagram Protocol [16], with optional compression as defined by 6LoWPAN. ISA100.11a does not support acknowledged TL transactions.

### 33.3.5 Application Layer

WirelessHART inherits its application layer from the wired HART AL. The HART AL defines the commands, responses, data types, and status reporting supported by the HART Field Communication Protocol Specification. All communication between devices on the AL level is through a set of defined commands. The commands are divided into four groups:

1. Universal commands
2. Common practice commands
3. Device families commands
4. Device-specific commands

The ISA100.11a AL is object oriented and has support for handling I/O hardware, protocol tunneling, and execution of computational functions.

## 33.4 Main Differences

Although WirelessHART and ISA100.11a have many more similarities than differences, there are still some key technical properties that are different in the two standards. In the following sections, a breakdown of some of the most prominent features that separate WirelessHART and ISA100.11a is presented.

### 33.4.1 Flexibility

WirelessHART and ISA100.11a are inherently different regarding the operational flexibility and configuration possibilities that the specifications allow for. WirelessHART is a rather *simple* specification with very few optional or configurable parameters. ISA100.11a on the other hand is a complex and comprehensive specification with many configurable and optional parameters found in different stack layers. These features are both strengths and weaknesses depending on the specific needs and requirements of the target applications and usage scenarios.

The strict and limited approach of WirelessHART ensures that practically all WirelessHART devices will have identical behavior, regardless of design and implementation choices made by the equipment providers. This should easily facilitate interoperability between multiple vendors, as all products adhering to the standard should be equal. This naturally comes at the cost of a lack of possibility to adapt and tailor the device and network behavior to specific application requirements.

The wide range of available optional and configurable parameters in ISA100.11a allows for great flexibility for adapting network behavior to various application requirements. However, it may lead to interoperability issues if different vendors choose to implement different features of the standard. To combat this, ISA100.11a must define application profiles. A profile is a cross-layer specification that defines which options are mandatory in the different protocol layers. Although profile definitions help with possible interoperability issues, it still requires extensive compliance testing and verification to achieve full vendor flexibility.

### 33.4.2 Protocol Support

WirelessHART is a wireless extension of the wired HART Field Communication Protocol Specification and is naturally confined to using the command-based HART protocol for message exchange. All information and data in a WirelessHART network must be transmitted in the shape of HART commands.

The ISA100.11a application layer is object oriented and implements tunneling features that allow devices to encapsulate foreign protocols and transport them through the network. Although successful tunneling of protocols depends upon how well ISA100.11a meets the technical requirements of the foreign protocol, it still opens up the possibility of transferring a multitude of wired protocols over an ISA100.11a network.

### 33.4.3 Coexistence

Since WirelessHART and ISA100.11a operate in the crowded 2.4 GHz band, they are likely to be subjected to interference from other wireless networks operating in the same frequency band. In recent years, IEEE 802.11-based infrastructure has become commonplace in many process plants and facilities, and it is expected that most wireless instrumentation deployments will share the frequency spectrum with IEEE 802.11-based access points and mobile devices. Practical experiments have shown that the performance of IEEE Std. 802.15.4-based networks will be degraded when coexisting with IEEE 802.11 networks [17], and since WirelessHART and ISA100.11a inherit their PHY from IEEE Std. 802.15.4, they will be subjected to such interference as well.

To mitigate the effects of interference, wireless protocols may employ various coexistence mechanisms. In WirelessHART and ISA100.11a, clear channel assessment (CCA) and channel blacklisting

are the weapons of choice to combat the degrading influence from other wireless networks. However, the two standards have chosen to implement the two features in slightly different ways. WirelessHART employs manual channel blacklisting, where a network operator must manually configure which channels are available and which channels are blocked. ISA100.11a has an adaptive blacklisting mechanism, where each device in a network may autonomously blacklist channels that suffer from noise and/or interference. Furthermore, ISA100.11a defines four different CCA modes, where modes 1–3 are defined by IEEE Std. 802.15.4:

- 0—*No CCA*: CCA is disabled and not conducted prior to transmission.
- 1—*Energy above threshold*: CCA reports a busy medium upon detecting any energy above a configurable threshold.
- 2—*Carrier sense only*: CCA reports a busy medium if a signal compliant with IEEE Std. 802.15.4 PHY modulation and spreading characteristics is detected.
- 3—*Carrier sense with energy above threshold*: CCA reports a busy medium using a logical and/or combination of modes 1 and 2.

WirelessHART on the other hand has fixed its CCA mechanism to mode 2.

With the correct configuration, ISA100.11a should be somewhat better equipped to handle coexistence with IEEE 802.11 networks. While WirelessHART only listens to activity from other IEEE Std. 802.15.4 networks, ISA100.11a will by employing CCA modes either 1 or 3 report a busy medium if any energy above a threshold is detected. If there is activity from a nearby IEEE 802.11 access point or client, the ISA100.11a device will back off and delay its transmission to the next available timeslot. This will naturally result in increased latency, but no power is wasted trying to transmit a message that will most likely not be received correctly by the destination device. In addition, the adaptive channel blacklisting mechanism of ISA100.11a can dynamically remove this problem completely by not using channels that show high IEEE 802.11 activity.

### 33.4.4 Security

Even though WirelessHART and ISA100.11a define a series of security mechanisms to ensure the integrity of the networks, some potential minor security weaknesses have been identified.

In WirelessHART, all security features are mandatory, while ISA100.11a defines many security mechanisms as optional. Considering that security algorithms require additional processing time, memory, and power, making them mandatory means that devices that may not require strict security policies cannot disable them to achieve benefits such as extended battery life. On the other hand, the ISA100.11a concept of having optional security features may be a security threat in itself and also an issue when it comes to interoperability. Vendors might not choose to implement the full security suite, and different vendors might choose to implement different parts of the optional security features.

Both WirelessHART and ISA100.11a rely on a centralized security manager for the authentication of new devices and the generation and management of security keys throughout the lifetime of the network. This means that the loss of the security manager will cause the loss of security mechanisms in the network. New releases of WirelessHART and ISA100.11a are combating this issue by offering redundant network and security manager solutions with automatic and transparent handover from the primary to the secondary system in case of failure.

### 33.4.5 Quality of Service

Although Quality of Service (QoS) is a term with various meanings and interpretations depending on the context, it can here be accepted as a measure of the service quality that a network offers to applications and/or users [18]. With QoS comes the ability to control the resource sharing of a network by giving different priorities to various applications and data packets depending on their requirements.

Higher performance levels can then be provided to specific applications and data packets through a set of measureable service parameters such as latency, jitter, packet loss, reliability, and availability [19].

Support for QoS in wired networks is generally obtained by overprovisioning and/or traffic engineering [18]. With overprovisioning, extra resources are added to the network so that it is able to provide satisfactory services to all applications. As all users are served at the same service class, overprovisioning may become unpredictable during peak traffic. For resource-constrained WSNs, overprovisioning is not an ideal QoS method as the network often does not have the capacity to provide the required resources. In traffic engineering, users and applications are assigned a different priority through a set of defined service classes. This method is also called service differentiation, and it is a widely adopted scheme for both wired and wireless networks to provide QoS guarantees [19]. For traditional wired computer networks, there are two main models for service differentiation: integrated services (IntServ) [20] and differentiated services (DiffServ) [21]. The IntServ model maintains service on a per-flow basis, while the DiffServ model maintains service on a per-packet basis. For the packet-based nature of WSNs, DiffServ is the best suited mechanism for service differentiation [22]. In the DiffServ model, the source devices know the criticality of the data packets it is sending, and this criticality is translated into predefined priority levels. Other devices in the network also select the appropriate service level for data packets based on their priority.

WirelessHART defines four different priority levels on the DLL [6]:

1. *Command* (highest priority). The command priority is used for packets containing network-related diagnostics, configuration, or control information.
2. *Process data*. Packets containing either process data or network statistics shall be classified as process data priority. Only the control of the network is more important than the delivery of sensor data measurements from field transmitters or set point information to actuators.
3. *Normal*. If a data link protocol data units (DLPDU) do not meet the criteria for any of the other three priority levels (command, process data, or alarm), it shall be classified with normal priority.
4. *Alarm* (lowest priority). Packets containing only network alarm and network event information shall have a priority of alarm.

These priority levels are primarily used for flow control and to mitigate potential network congestion points in the event of either a process upset or noise/interference deteriorating the radio frequency (RF) channel(s). With the aforementioned mechanisms, network management packets have full priority while propagated through the network, allowing the network manager to keep the network operational. Network-induced alarms have a restricted flow through the network, ensuring that alarm floods do not disrupt or hinder the network operation. All other network traffic flows through the network as bandwidth and internal buffer spaces on the devices allow. Unfortunately, there is only one priority level reserved for process data, which means that all sensors and/or actuators in a WirelessHART network share the same priority level, regardless of the requirements and criticality of the application they are serving.

ISA100.11a uses contracts to define the setup and requirement of communication between two devices in a network. A contract is an agreement between the system manager and a device in the network that involves the allocation of network resources by the system manager to support the communication requirements of the device. All contracts are unidirectional, and they are established by the system manager upon reception of a contract request. ISA100.11a supports two priority levels, contract priority and message priority. The contract priority is the base priority for all messages sent using a specific contract. Four contract priorities are supported:

1. *Network control* (highest priority): may be used for critical management of the network by the system manager
2. *Real-time buffer*: may be used for periodic communications in which the message buffer is overwritten whenever a newer message is generated

3. *Real-time sequential*: may be used for applications such as voice or video that needs sequential delivery of messages
4. *Best effort queued* (lowest priority): may be used for client–server communications

The message priority establishes priority within a contract using two message priorities: high and low. The contract priority is specified by the application, during contract establishment time, in its contract request. It may be used by the system manager to establish preferred routes for high-priority contracts and for load balancing the network. The combined contract/message priority is used to resolve contention for scarce resources when these messages are forwarded through the network.

### 33.4.6 Application Potential

The performance requirements of an industrial field instrument depend upon the nature and criticality of the application it is serving. NAMUR, a user association for automation technologies in the process industries, defines the following three applications classes for wireless instrumentation in their recommendation document NAMUR NE 124 *Wireless Automation Requirements* [23]:

- Application class A—functional safety
- Application class B—process management and control
- Application class C—display and monitoring

Similarly, the ISA has defined six usage classes for wireless instrumentation through their work on the ISA100.11a specification for wireless field devices [11]:

- Application class 0—emergency action
- Application class 1—closed-loop regulatory control
- Application class 2—closed-loop supervisory control
- Application class 3—open-loop control
- Application class 4—alerting and flagging
- Application class 5—logging and downloading/uploading

A mapping between the NAMUR and the ISA application classes is shown in Table 33.1. For simplicity, the three NAMUR application classes will be used in further discussions, referred to as monitoring (C), control (B), and safety (A), respectively.

#### 33.4.6.1 Monitoring

Monitoring applications cover tasks that, by definition, are not of any immediate operational consequence. In addition, they do not affect plant safety in any regard. As a result, the performance

**TABLE 33.1** Wireless Instrumentation Usage Classes

Application	NAMUR	ISA
Safety	Class A	Class 0
	Functional safety	Emergency action
Control	Class B	Class 1
	Process management and Control	Closed-loop regulatory control
		Class 2 Closed-loop supervisory control
Monitoring		Class 3 Open-loop control
	Class C	Class 4
	Display and monitoring	Alerting and flagging Class 5 Logging and downloading/uploading

requirements for field instruments in this category are somewhat relaxed, but it is still of interest to maintain a certain level of service quality in order for the application to be of any operational value. Monitoring applications typically use continuous data delivery, where sensors measure and transmit data to the control system at periodic intervals.

Most industrial deployments of wireless instrumentation to date have been limited to noncritical monitoring applications, and fulfilling the requirements for this application class has been the initial focus of the WirelessHART and ISA100.11a specifications, as well as the vendor-specific implementations of the specifications. Both WirelessHART and ISA100.11a have been qualified for use by many process industry end users [24]. This is backed by results from extensive laboratory experiments, pilot installations, and deployment in live production environments, which show that both solutions are fully capable of providing adequate application performance for noncritical monitoring applications [24]. For these applications, there should be minimal performance deviations between the two standards.

### 33.4.6.2 Control

For control applications, sensor data and actuator set points must be provided in a timely and regular manner. Most control algorithms are not designed to handle a periodic reception of sensor data and thus require bounded latency and bounded jitter, where jitter is defined as the variance in latency of consecutive sensor data. Control applications are typically continuous by nature where sensor data and actuator set points are transmitted at periodic intervals. Event-driven control, where sensor data are transmitted only when a measurement exceeds a predefined threshold, is still not very common in the process industries.

Another requirement for many control applications is to have a common timing domain for all components in the system. This means that the clocks of wireless sensors and actuators and the wireless gateway should be synchronized with the clocks of the controllers and control system. Propagating time information through the wireless network should be possible, as a clock accuracy of 1 ms is already required for all wireless devices in order for the TDMA timeslot structure to work properly according to today's wireless standards.

To achieve low latency and jitter, it is recommended to implement proper fieldbus interfaces (e.g., PROFIBUS or Foundation Fieldbus) on the wired side of the wireless gateway and on the instrumentation backbone networks [24]. The definition of these interfaces is beyond the scope of both WirelessHART and ISA100.11a and left open for the implementers to decide what they find most suitable for their systems.

For open-loop control, WirelessHART and ISA100.11a should be able to deliver the low latency and high reliability as required by the applications. However, recent research has shown that latency and determinism issues make WirelessHART less suitable for control applications where bounded and low latency and jitter are the main requirements [25]. Such experiments have at the time of writing not yet been conducted for ISA100.11a, but the results are expected to be quite similar. However, as described in Section 33.4.5, the lack of multiple message priority levels for process data in WirelessHART will most likely hinder future developments in the direction of control applications. ISA100.11a on the other hand has through its contract-based priority levels access to a mechanism for distinguishing between messages of different criticality based on the nature and requirements of the application it is serving.

### 33.4.6.3 Safety

In safety applications, reliability and timeliness are the main requirements for the communication between sensors and the safety system. As opposed to control loops, rapid update rates are normally not required, but safety communication must have mechanisms that ensure that data packets arrive within a specific deadline. For most safety systems, a query-based data delivery model is used where the safety controller periodically requests data from the sensors.

Safety systems in the process industries are subject to comply with a certain Safety Integrity Levels (SIL). The standard IEC 61508 [26] defines SIL from a set of requirements that accomplish both hardware safety integrity and system safety integrity. There are four SIL levels (1–4), where SIL4 is defined as the most dependable and SIL1 as the least. Neither WirelessHART nor ISA100.11a directly supports the necessary certified SIL safety mechanisms as an integrated part of their specifications. A work-around for this is to use an already established and certified end-to-end communication protocol, such as the SIL2-rated PROFIsafe [27], which is designed to be implemented on top of the PROFINet fieldbus [28].

The recent development of the world's first wireless hydrocarbon gas detection system has proven that it is possible to achieve SIL2 end-to-end communication between a safety controller and a wireless sensor by tunneling PROFI safe over ISA100.11a [24]. For WirelessHART on the other hand, limitations in currently available HART commands at the application layer make it impossible to implement the tunneling mechanisms needed for full PROFI safe support. PROFI safe over WirelessHART will thus not be available before a potential modification and new release of the HART Field Communication Protocol Specification.

### 33.5 Conclusion

---

WirelessHART and ISA100.11a are both on the quest to become the de facto standard for wireless instrumentation in the process industries, each being backed by different leading automation providers. The theoretical comparison of the two specifications has shown that although they have some key differences, most features regarding the fundamental wireless communication parameters are the same. They are both able to provide satisfactory network performance in harsh industrial environments, and as a result they have been qualified for use in noncritical monitoring applications in the process industries.

For more advanced applications within industrial control and safety domains, the marginal differences between the two specifications become more apparent. Due to the lacking QoS mechanisms for process data packet priorities, combined with a command-based application layer with limited flexibility, WirelessHART is unlikely to be able to address fast closed-loop control and safety applications with SIL requirement without making alterations to the HART Field Communication Protocol Specification. The more comprehensive ISA100.11a standard, on the other hand, has adequate QoS support through its contract priority levels, and the object-oriented application layer has proven to be suitable for tunneling the SIL2-certified PROFI safe protocol.

Regardless of these differences and despite ISA100.11a's better suitability for control and safety, it is still nearly impossible to predict which of the two standards, if any, will emerge as the leading global specification for wireless instrumentation. It is expected that nearly all wireless instrumentation installations and deployments in the near future will be within noncritical monitoring applications, so ISA100.11a current advantage in addressing safety applications might not be significant. The ongoing struggle for domination is thus expected to be more of a marketing and political battle than a pure technical one. With a 2-year lead in availability, the current market share is in favor of WirelessHART, and it remains to be seen if ISA100.11a is able to close this gap.

Despite the ongoing struggle to gain market positions, there are some initiatives to merge the two standards. The ISA100 committee has created an ISA100.12 working group that has the stated goal of investigating long-term possibilities for merging ISA100.11a and WirelessHART. This initiative is currently being conducted by leading automation industries, commonly referred to as the Heathrow group. Furthermore, NAMUR, the international user association of companies in the chemical and pharmaceutical process industries, has published recommendations on the convergence of the standards for industrial WSNs [29]. However, these convergence activities are expected to take time, and it is not certain that they will succeed in creating a unified, global standard for wireless instrumentation. So, for the time being, the process automation end users will have to decide between multiple standards when deploying wireless instruments in their plants and facilities, a situation that is far from ideal.

### 34.1 Introduction

During the fieldbus war (1986–2002), several technologies appeared as de facto standard for industrial networks (Modbus, Fieldbus Foundation, HART, just to name a few) (Sauter, 2010). All these technologies were based on structured cabling and they had as a goal creating a universal protocol to meet all the industrial demands (Decotignie, 2009). Despite the appearance of wireless technologies, the scenario has not been very different. A variety of technologies coexist and others are yet to be seen. Establishing a conservative scenario, only one wireless solution will hardly be the universal standard for the industry. It is wiser to think that several solutions will coexist, each one having its own advantages and disadvantages and its specific niche applications.

The current solutions for the industrial wireless networks are focused on two distinct groups (Willig, 2008). The first group is related to the WLANs (wireless local area networks), whose technologies are variations of the IEEE 802.11 standard. On the other hand, the second group is represented by WPANs (wireless personal area networks), whose solutions are variations developed by the IEEE 802.15 work group and other standardization commissions such as the ISA (International Society of Automation) and the IEC (International Electrotechnical Commission). Each group has its own peculiarities; however, the WPANs have presented themselves as a better solution when analyzed in industrial environments,

**FIGURE 34.1** Wireless communication standards used in the industry.

with special focus on the WirelessHART (IEC-62591, 2010), ISA100.11a (IEC-62734, 2012), and IEC 62601/wireless networks for industrial automation–process automation (WIA-PA) (IEC-62601, 2011) standards, which were created for this kind of environment specifically.

An overview of the main wireless communication standards used in industrial environments is described in Figure 34.1. The chapter mentioned does not have the goal of describing all these standards, shifting the focus to the IEC 62601/WIA-PA standard. In order to have an overall analysis of the standards, it is recommended to read the following references (Silva et al., 2013).

## 34.2 IEC/PAS 62601: WIA-PA

In 2007, the Chinese Industrial Wireless Alliance (CIWA), under the urgent requirements of process automation, approved a new wireless communication standard, the WIA-PA. In 2011, the IEC approved the WIA-PA standard as a publicly available specification named IEC/PAS 62601 (IEC-62601, 2011). In the same year, the Chinese National Standard approved the WIA-PA as a national specification named GB/T 26790.1-2011. For producing valuable social and economic benefits to China, the GB/T 26790.1-2011 specification won the first prize of the China Standard Innovation Award 2013 (Liang et al., 2013).

The WIA-PA standard follows the trends of industrial network technologies to adopt wireless infrastructure. As its counterparts, the WirelessHART and ISA100.11a standards, the WIA-PA adopts similar physical features (Petersen and Carlsen, 2011). However, there are several differences between them. More details will be described later in this chapter. For the sake of understanding, Figure 34.2 gives an overview about the evolution of industrial wireless technologies.

A typical WIA-PA network defines five types of devices as described in Figure 34.3: host configuration computer, gateway device (GW), router device, field device, and handheld. The host configuration computer is used to provide high-level access to operators. The physical access between the plant automation network and the wireless network is conducted by the gateway. In relation to intranetwork communication,

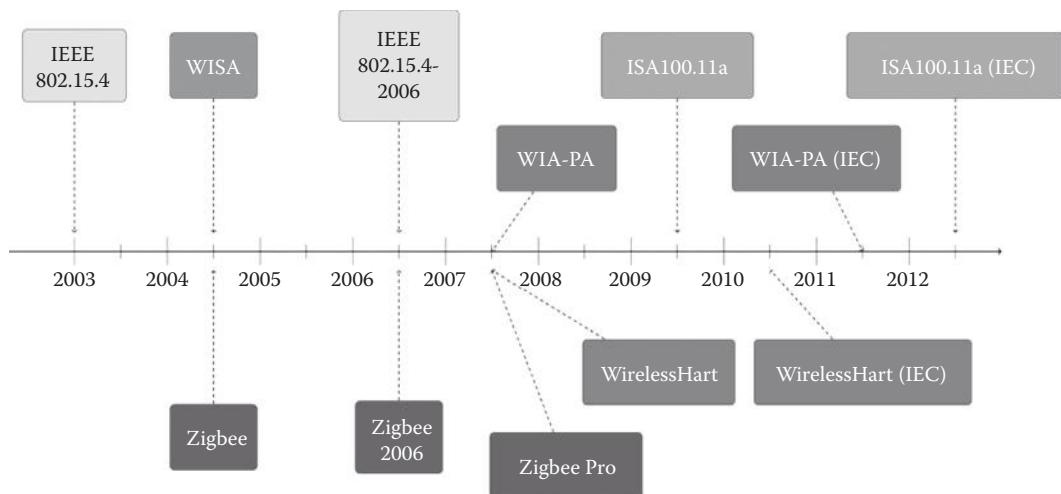

FIGURE 34.2 Evolution of industrial wireless technologies.

routers are responsible for forwarding the messages toward the gateway. The field devices and the hand-held devices are considered the most basic devices. The former ones are responsible for the monitoring of process variables, whereas the latter ones are used during the commissioning of network devices.

Additionally, a WIA-PA network supports redundant gateways and redundant routers. The standard suggests a cold standby redundancy approach, where the start-up of a spare device is not later than the primary device. Periodically, the primary device updates its spare device with the information changed

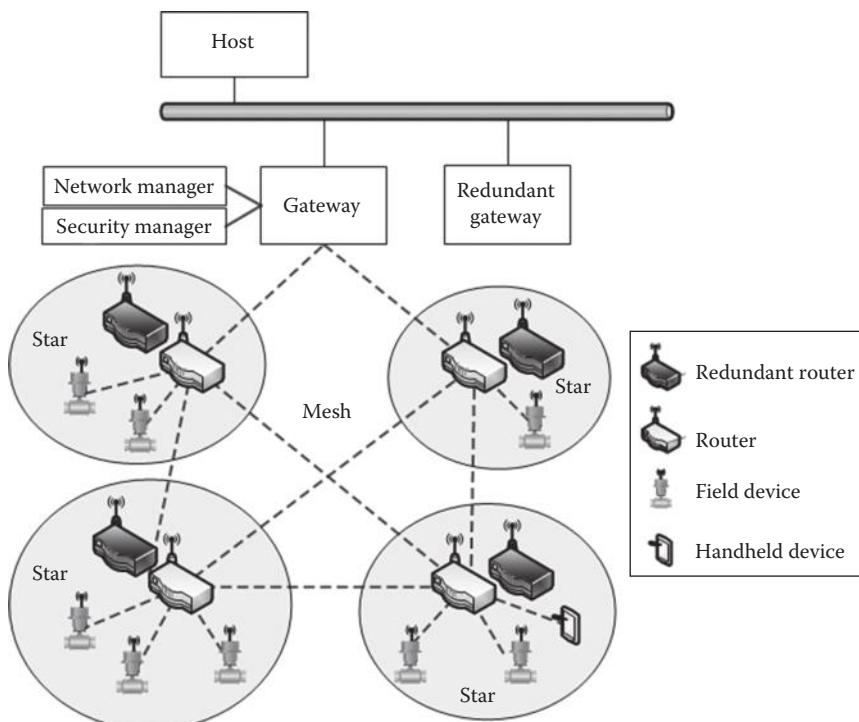

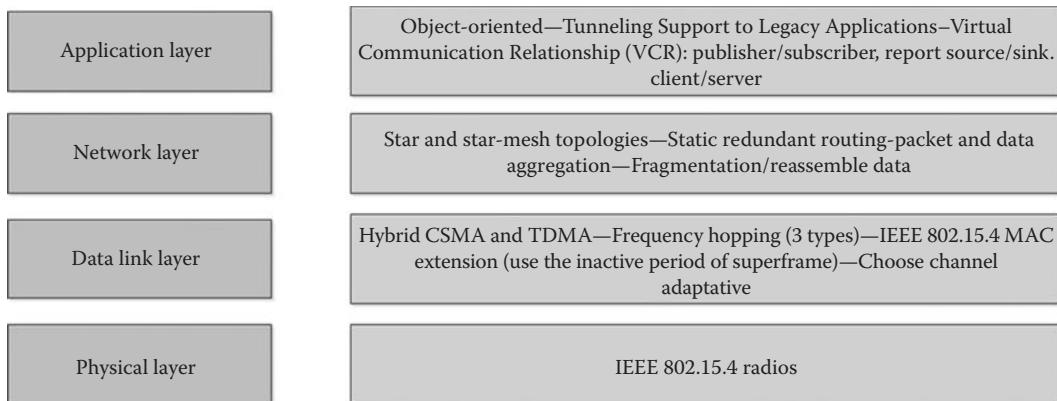

FIGURE 34.3 Typical WIA-PA network.

**FIGURE 34.4** Overview of protocol stack present in the WIA-PA standard.

more recently. The update must occur in a wired manner; however, it is not specified in the WIA-PA standard. This mechanism allows the reliability of the network to be improved (Liang et al., 2011).

The WIA-PA standard supports two types of topologies: star and mesh star. The communication between routers follows a mesh approach, whereas the communication between a router and field devices follows a star approach, similar to a cluster topology. Thus, from a high-level viewpoint, a field device communicates with the gateway through a mesh-star network.

All communication over the network is centralized by two rules generally implemented inside the gateway. The first rule is called the security manager (SM). Its duties are concentrated on all issues related to security (storage of keys, validation of messages, authentication, etc.). On the other hand, the rule called the network manager (NM) is considered the core of the WIA-PA network. This rule is responsible for controlling all the communications over the network, from the scheduling tables to the choice of communication channels. In addition, secondary rules such as the cluster head and the cluster member are responsible for managing the intracluster communication. A field device and the handheld should only act as the rule of cluster member, whereas a router device acts as the rule of cluster head.

As described earlier, the system management in the WIA-PA network is composed of NM and the SM rules. The functions of management are implemented by the device management application process (DMAP) in each device. In spite of this implementation, the control of the network is centralized on the GW. The DMAP implements the following functions: joining and leaving the network, network address allocation, routing configuration, communication resource configuration, time source configuration, performance monitoring, management information base (MIB) maintenance, and firmware upgrading.

All functionalities of a standard are defined in its protocol stack. Similarly to WirelessHART and ISA100.11a standards, the protocol stack defined in the WIA-PA is based on the OSI model. However, only four layers are defined, as illustrated in Figure 34.4. When compared with other industrial wireless standards, the WIA-PA has the following advantages: adaptive frequency hopping (AFH), data and packet aggregation, and flexible routing approaches and application modes. In the next sections, the main features of each WIA-PA layer will be described in more detail.

### 34.3 Physical Layer

The physical layer defined in the WIA-PA standard is based on the IEEE 802.15.4-2006 (IEEE-802.15.4, 2006), and consequently, it is very similar to the WirelessHART and ISA100.11a physical layers.

The IEEE 802.15.4 standard was initially approved in 2003; however, its more recent version was approved in 2006. It is considered a de facto standard for the low-rate WPANs (LR-WPANs). These networks were designed to support devices with limited physical features (low energy consumption,

**TABLE 34.1** Main Features Present in the IEEE 802.15.4-2006 Physical Layer

Features	IEEE 802.15.4 Physical Layer
Frequency bands	868 MHz (1 channel) 915 MHz (10 channels) 2450 MHz (16 channels)
Channel width	2 MHz
Throughput	250, 40, and 20 kbps
Modulation	O-QPSK, BPSK, and ASK
Communication range	100–200 m
Transmission power	0 dBm

a communication range of a few meters, low power processing, and reduced memory), enabling the development of pervasive applications in diverse areas (forest fire and landslide detection, greenhouse and industrial monitoring, passive localization and tracking, etc.). When an LR-WPAN is designed for an industrial environment, it is called an industrial wireless sensor network (IWSN).

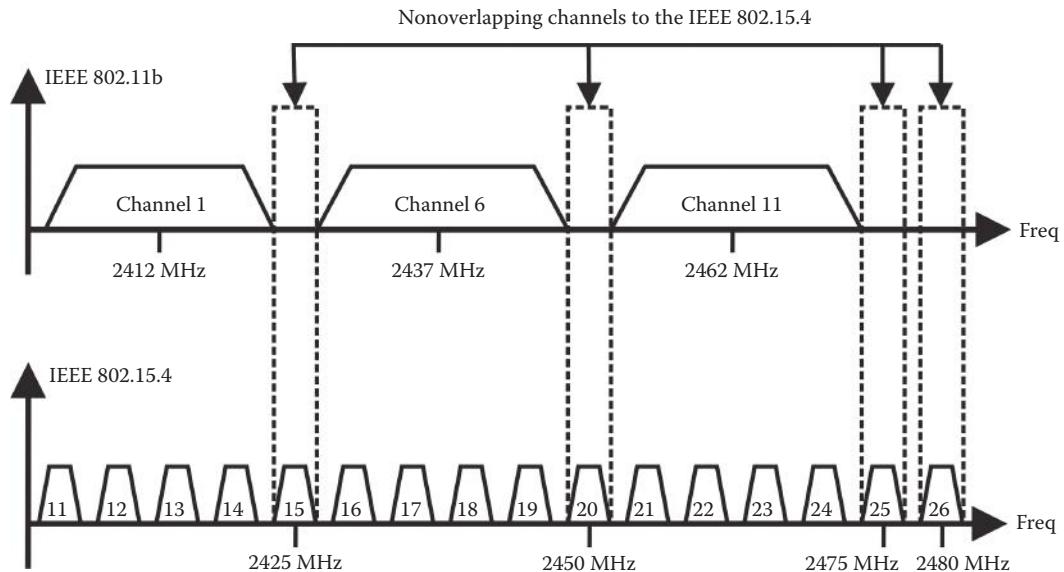

The IEEE 802.15.4-2006 physical layer can operate in three distinct frequency bands: the 2450 MHz ISM band (worldwide) with 16 channels, the 915 MHz band (in the United States only) with 10 channels, and the 868 MHz band with only one channel (European and Japanese standards). All of them use the direct-sequence spread spectrum (DSSS) access mode. Signaling in the 2450 MHz band is based on orthogonal quadrature phase shift keying (O-QPSK), while the 868/915 MHz bands rely on binary phase shift keying (BPSK). The throughputs of the bands are 250, 40, and 20 kbps, respectively. In addition to the management of the physical layer, services include the activation and deactivation of the radio transceiver, energy detection (ED) within the current channel, link quality indication (LQI) for received packets, clear channel assessment (CCA) for carrier sense multiple access with collision avoidance (CSMA-CA), channel frequency selection, and data transmission and reception. The main features present in the IEEE 802.15.4-2006 physical layer are summarized in Table 34.1.

Although the physical layer can support three frequency bands, the 2450 MHz ISM band is by far the most frequently used. The use of this band generates a coexistence problem in the sense that other wireless technologies also employ the same frequency band (e.g., IEEE 802.11 and Bluetooth). In relation to coexistence with the IEEE 802.11 devices, it is possible to carry out configuration until there are four nonoverlapping IEEE 802.15.4 channels as described in Figure 34.5. Obviously, as only four channels are available in this scenario, it is expected that the transmissions have a higher probability of suffering interference than a scenario where 16 channels are available (Angrisani et al., 2008). On the other hand, a minor impact is expected when the coexistence with Bluetooth devices is considered, because in the Bluetooth standard, the frequency band is modified 1600 times per second. Thus, it is more likely that the interferences occur in the first transmission attempts. However, an efficient retransmission mechanism can be implemented in the IEEE 802.15.4 to mitigate this interference (Young et al., 2007).

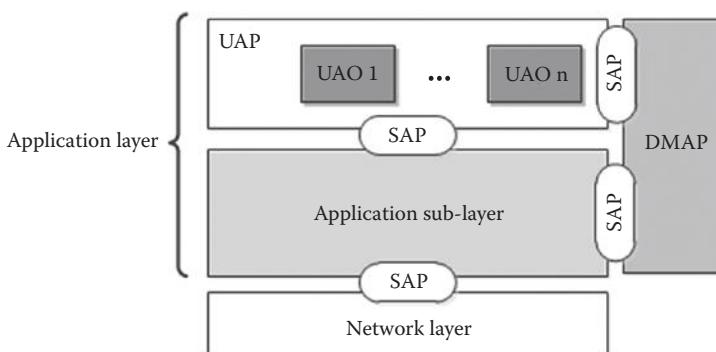

## 34.4 Data Link Layer

The data link layer (DLL) defined in the WIA-PA standard was designed to provide real-time, secure, and reliable communications. It is based on the IEEE 802.15.4 DLL with the improvement of some properties (frequency hopping, retransmission, TDMA, and CSMA). A message integrity code (MIC) mechanism and encryption are also adopted to guarantee the integrity and confidentiality of the data transmitted, respectively.

According to Figure 34.6, the WIA-PA DLL is composed of two sublayers that include the medium access control (MAC) layer and the data link sublayer (DLSL) and service access points (SAPs). The MAC handles the mechanisms for sending and receiving data frames, whereas the DLSL controls the aspects

**FIGURE 34.5** Coexistence of IEEE 802.11 channels and IEEE 802.15.4 channels.

**FIGURE 34.6** WIA-PA DLL.

of communication resource. The management of DLL and the exchange of messages between the layers are provided through SAP. The implementation of an interface to the DMAP in the DLL is also mandatory.

### 34.4.1 Medium Access Control

The MAC layer adopted in the WIA-PA standard is based on the IEEE 802.15.4-2006 MAC layer configured to beacon-enabled mode. The legacy compatibility was necessary to guarantee the following services: generating beacons (only to the gateway and router devices), synchronizing, security and reliability, joining, and maintaining the guaranteed timeslots (GTS).

Another property inherited from the IEEE 802.15.4-2006 MAC layer was the types of devices. According to that standard, the devices are classified as reduced-function devices (RFD) or full-function devices (FFD). In a WIA-PA network, field devices and the handheld act as RFD, whereas router devices and the gateway act as FFD.

One of the most important features implemented in the MAC layer is the synchronization mechanism. In order to guarantee the reliable communication between the devices, it is mandatory that the entire network is synchronized. All devices in a WIA-PA network should synchronize with a time source device. In the intercluster communication, the gateway is time source to the router devices. On the other hand, the router devices are the time sources to the field devices in the intracluster communication. The synchronization is established through beacon (inherited of the IEEE 802.15.4-2006) or synchronization frames. Both use a field of four octets to calibrate the time reference between the devices.

In a similar way to the synchronization mechanism, the devices must implement a mechanism for connection maintenance between neighbor devices. This procedure is implemented through keep-alive messages. Periodically, all devices send keep-alive messages to maintain its connections. The gateway sends keep-alive messages during the intercluster communication, whereas the field devices and the handheld send its keep messages during the intracluster period. Router devices can send keep-alive messages in both periods.

### 34.4.2 Data Link Sublayer

According to Figure 34.6, the WIA-PA DLSL provides an interface between the network layer (NL) and the MAC layer. Its main duties include the following: avoiding collisions; improving throughput; increasing bandwidth utilization, coexistence, timeslot, and superframe management; frequency hopping; transmission of long cycle data; channel conditional monitoring; security; and other management services.

#### 34.4.2.1 Timeslot, Superframe, and Frequency Hopping

The communication unit is the timeslot. The duration of the timeslot is configured according to the limits imposed by the IEEE 802.15.4-2006. The timeslot length is configured by the NM after a device joins the network. Additionally, a tuple composed of time and frequency (link) is used inside the timeslot for communication. There are three types of links: transmit, receive, and shared. The first two types of links allow only two devices (source and destination) to exchange packets (used for intracluster and intercluster communication of periodic data), whereas the latter one allows more than two devices to use the communication channel (used for transmission of aperiodic data).

A collection of timeslots creates a superframe structure. Each superframe is repeated periodically at intervals (from 15.36 ms up to 251 s) proportional to the number of timeslots used. The WIA-PA superframe is described in Figure 34.7. The IEEE 802.15.4-2006 superframe is included in Figure 34.7 to show that the WIA-PA superframe is an extended version of it.

In a pure beacon-mode IEEE 802.15.4-2006 superframe, a device accesses the medium listening for beacon messages sent by the network coordinator. After receiving a beacon message, the device transmits data by using the superframe structure. As described in Figure 34.7, the IEEE 802.15.4-2006 superframe structure is divided into two parts: the active and inactive periods. During the active period,

IEEE 802.15.4-2006 superframe

Beacon	CAP	CFP	Inactive period	
--------	-----	-----	-----------------	--

WIA-PA superframe

Beacon	CAP	Intra-cluster CFP	Intra-cluster Communication	Inter-cluster Communication	Inactive period
--------	-----	-------------------	-----------------------------	-----------------------------	-----------------

FIGURE 34.7 WIA-PA superframe.

the medium can be accessed with or without contention. Devices that wish to communicate during the contention access period (CAP) must compete with other devices using a slotted CSMA-CA mechanism. On the other hand, a contention-free period (CFP) can be used for applications with restrictive requirements. Due to protocol limitations, the CFP has support for only seven timeslots. Finally, the inactive period of the superframe can be used by the devices to configure an operation mode with low energy consumption and consequently increase the network lifetime (assuming that the devices are battery powered).

On the other hand, the WIA-PA superframe added other functions beyond the ones implemented in the IEEE 802.15.4-2006 superframe. In this case, the joining process, intercluster management, and retransmissions occur in the CAP interval of the superframe, where the MAC is based on CSMA-CA. Furthermore, all other communications access the medium using a TDMA approach. During the CFP, mobility devices are authorized to communicate with the cluster head (router). Another important aspect is that part of the inactive period of the IEEE 802.15.4-2006 superframe is used for transmission in the WIA-PA superframe. More specifically, it was designed for intracluster and intercluster communications. The WIA-PA superframe also supports an inactive period when the devices can minimize the energy consumption. However, it has a smaller duration than the IEEE 802.15.4-2006 inactive period.

In order to improve the network reliability, a frequency hopping mechanism was introduced to the WIA-PA network. Basically, three hopping patterns are defined: adaptive frequency switching (AFS), AFH, and timeslot hopping (TH).

The hopping pattern AFS is used during the transmission of beacons and CAP and CFP. In this pattern, all the devices use the same communication channel. If the channel suffers some interference (e.g., the packet loss rate increases), the NM configures the devices to use another channel.

On the other hand, the hopping pattern AFH is used during intracluster communication, where the changes of channels occur irregularly depending on the actual channel condition. A channel is considered bad if the amount of retry times in that channel reaches a threshold. When the sender device identifies that the current channel is bad, it chooses the next channel (immediate) in the channel list. Thus, in the next retry timeslot, the sender notifies the receiver using the same bad channel. If the notification is not received, the receiver device will naturally increment its packet loss rate to that channel. After the threshold of packet loss rate is reached, the receiver device chooses the next channel (immediate) in the channel list. On the other hand, if the receiver device receives the notification (in the next retry timeslot), the channel is changed and an acknowledge packet (ACK) is sent to the sender device. Note that if the number of retry times reaches *macMaxFrameRetries* threshold (range between 0 and 7), the sender discards the current packet and it transmits the next packet using the same bad channel.

Finally, the hopping pattern TH is used during intercluster communication, where the channels are changed per timeslot. This technique is used to combat interference and fading. The sequence used to change the channels is not defined in WIA-PA standard. Table 34.2 summarizes the frequency hopping mechanisms adopted in the WIA-PA network.

**TABLE 34.2** Frequency Hopping Mechanism Adopted in the WIA-PA Network

Portion of the Superframe	MAC	Frequency Hopping
Beacon	TDMA	AFS
CAP	CSMA	AFS
CFP	TDMA	AFS
Intracluster	TDMA	AFH
Intercluster	TDMA	TH
Inactive period	—	—

### 34.4.2.2 Frames Priority and Scheduling Rules

The correct operation of the DLSL is necessary to define priority levels to the different types of frames. According to the WIA-PA standard, four priorities are defined: highest priority (commands), secondary priority (process data), third priority (normal frames), and lowest priority (alarms).

Packets where payload is related to diagnostics, configuration, control information, and emergent alarms must be marked as command (highest priority). On the other hand, any packet where payload contains a process data must be marked as a process data (secondary priority). Nonemergent alarm frames must be marked as alarm priority (lowest priority), whereas a frame that does not meet the previous criteria must be classified as normal priority.

In relation to scheduling rules, the WIA-PA standard suggests the following criteria:

- i. Timeslots for beacon frames and active period should be allocated first.
- ii. Resources for devices with the fastest update rate should be allocated with a secondary priority.
- iii. In a multihop scenario, the packet with the earliest generating time should be allocated first.
- iv. Highest-priority packet should be allocated first than a lower-priority packet.

### 34.4.2.3 Transmission of Long Cycle Data

The long cycle data are scenarios where a device has an update rate greater than the update rate of its cluster head (router device). In a WIA-PA network, the update rate of router devices is configured to the least update rate in cluster. For example, if a cluster has three field devices in which update rates are, respectively, 1s, 4s, and 8s, then the update rate and consequently the superframe duration of cluster head will be 1s. Thus, the field devices with update rates of 4s and 8s will be configured for a long cycle data in that cluster.

The target problem here is to define when a device on a long cycle data will transmit. The WIA-PA standard solves this problem by defining a parameter termed *TransmitFlag* as follows:

$$\text{TransmitFlag} = \frac{\text{ASN} - \text{ActiveSlot} + 1}{\text{NumberSlots}} \% \text{SuperframeMultiple} \quad (34.1)$$

where

*absolute slot number (ASN)* is the number of slots since the beginning of the network

*ActiveSlot* is the ASN at the moment when the superframe is initialized

*NumberSlots* is the superframe size

*SuperframeMultiple* is the ratio between the maximum and the minimum update rate in that superframe

At the beginning of each superframe cycle, beacons are received by the devices and these must decide if they send or not data in this superframe. If a device has a long cycle data, then it must transmit data only if

- i.  $0 < \text{TransmitFlag} < \text{SuperframeMultiple}$  and  $\text{TransmitFlag} = \text{LinkSuperframeNum}$
- ii.  $\text{TransmitFlag} = 0$  and  $\text{LinkSuperframeNum} = \text{SuperframeMultiple}$

The parameter *LinkSuperframeNum* is the ratio between the update ratio of a device and the superframe duration (equal to the minimum update rate).

For the sake of understanding, let us describe the example shown in Figure 34.8. We assume only a router device and a field device, in which update rates are, respectively, 4s and 8s (a timeslot has duration of 1s in the example). Thus, the field device has a long cycle data because its update rate is greater than the cluster head. The problem is to identify the slots where the field device can transmit. For this example, the parameters *SuperframeMultiple* and *LinkSuperframeNum* are equals ( $8/4 = 2$ ). Testing the timeslots where ASN is 8 and 11 and using the Equation 34.1 and the conditions i and ii, then

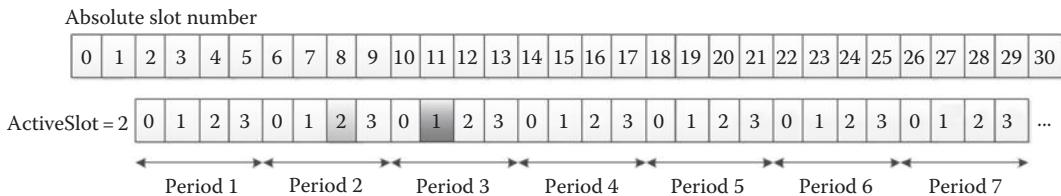

FIGURE 34.8 Transmission of long cycle data assuming an update rate of 8s and a minimum update rate of 4s.

- ASN = 8

$\text{TransmitFlag} = \frac{8-2+1}{4} \% 4 = 2$  and  $\text{TransmitFlag} = \text{LinkSuperframeNum}$  (thus, the field device can transmit in this timeslot)

- ASN = 11

$\text{TransmitFlag} = \frac{11-2+1}{4} \% 4 = 3$  and  $\text{TransmitFlag} \neq \text{LinkSuperframeNum}$  (thus, the field device cannot transmit in this timeslot)

It is possible to see that the field device can only transmit in any timeslot of an even period.

#### 34.4.2.4 Management Service

The management services provided by the WIA-PA DDSL include network discovery, device joining and leaving, channel condition monitoring, and information about neighbors.

The network discovery service can be used by field devices to search beacons sent by cluster heads or gateways. The device scans the channels for *ScanDuration* until reaching a possible path to the network.

In relation to joining services, there are two moments where this service is required: when a field device joins the star network (through a routing) and when a router joins the mesh network (through the gateway). This service requires that the device has been configured previously with security keys. After the join process, the device receives the confirmation with the information about its address and if it is a time source. Similar procedure is required when a device leaves the network.

The DDSL is also responsible for providing channel condition to the DMAP. The reported data include LQI (in which the range varies between 0 and 255), packet loss rate per channel, and the count of retry per channel. Reports about neighbors are also provided, including information about the number of packets received, time of the last communication, and average level of signals received.

## 34.5 Network Layer

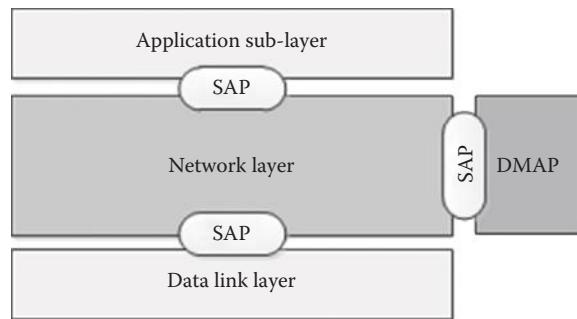

According to Figure 34.9, the WIA-PA NL provides an interface between the DLL and the application sublayer (ASL). The management of NL and the exchange of messages between the layers are provided through SAP. The implementation of an interface to the DMAP in the NL is also mandatory.

The WIA-PA NL is responsible for the following mechanisms: address assignment, routing, communication resource allocation, management of the life cycle of packets, management for device joining and leaving network, fragmentation/reassembly, and end-to-end network monitoring. All the mechanisms are configured by the NM.

### 34.5.1 Addressing

Regarding address assignment, each network device has a 64-bit address in the physical layer, whereas in the NL, the address has only 16 bits. These addresses are used in all communications (unicast, broadcast, intracluster, and intercluster).

During the join process, the devices use the 64-bit address to communicate with other devices. After a device has been properly joined to the network, the 16-bit address is used for communication. The 16-bit

**FIGURE 34.9** WIA-PA NL.

address is composed of two 8-bit address numbers, in which the template is X.Y. The most significant number (X) is the cluster address (0–255), whereas the least significant number (Y) is the intracluster address (0–255). The value 255 is used for broadcasting purpose and the routing device address (cluster head) is always 0. Thus, the WIA-PA standard classifies the 16-bit address as follows:

1. Unicast
  - Gateway address is 0.Y (0–254).
  - Router device address is X.0 (1–254).
  - Field device address is X.Y (1–254).
2. Broadcast
  - Intracluster broadcast address is X.255 (0–254).
  - Intercluster broadcast address is 255.0.
  - Global broadcast is 255.255.
  - GW broadcast is 0.255.

### 34.5.2 Routing, Fragmentation, and Reassembling

The adopted routing approach is based on the network redundancy perspective. The NM generates all routing tables after discovering the complete set of all neighbors from each network router. These tables are used to create a mesh topology where connections between routers and the gateway are made by redundant paths. Each device is configured to periodically transmit information about link failures, battery level, and the status of its neighbors to the gateway. Based on this information, the NM can update the routing table of each device. Thus, the adopted routing approach can guarantee a resilient performance.

Each device maintains its own routing table. This structure is composed of five fields: *RouteID*, *SourceAddress*, *DestinationAddress*, *NextHop*, and *RetryCounter*. The parameter *RouteID* is used to identify a path. The parameters *SourceAddress* and *DestinationAddress* identify the source and destination of path, whereas *NextHop* informs the next hop for the packet. Finally, the parameter *RetryCounter* is used to record the number of retries in the path. In order to ensure redundancy, it is possible to configure a *RouteID* with two *NextHop* values. In this case, the NM should indicate the main and secondary next hop.

Beyond the routing table structure, the information about routing is relayed to the device in the NL packet. As described in Figure 34.10, the routing field is used for this purpose.

Network layer header									Network layer payload	
Control field	Routing field			Time-stamp	Priority	Sequence number	Number of fragment	Fragment sequence number	Payload length	Network layer payload
	Destination address	Source address	RouteID							
1 byte	2 bytes	2 bytes	2 bytes	4 bytes	1 byte	1 byte	0/1 byte	0/1 byte	1 byte	Variable length

**FIGURE 34.10** Common NL packet format.

		Network layer payload						
Network Layer Header	Aggregated number	The first aggregated data			...	The n <sup>th</sup> aggregated data		
		Source address 1	Data length 1	Data 1	...	Source address n	Data length n	Data n
14/16 bytes	1 byte	2 bytes	1 byte	Variable	...	2 bytes	1 byte	Variable

FIGURE 34.11 Aggregated packet format.

Other features are also described in the NL packet. For example, the *control field* is used to indicate the type of packet (data, command, or aggregation) or whether the packet is a fragment packet. Fragmentation is used when the NL packet is longer than the DLL payload. In this case, when all fragments reach the receiver, they are reassembled at the NL. The fields *number of fragment* and *fragment sequence number* are used for this purpose. Additionally, the NL records the generation time of a data to limit the packet life cycle. This procedure is controlled by *time-stamp* field. Finally, the fields *priority* and *sequence number* indicate the priority (0–15) and the sequence number of the packet at the NL, respectively.

### 34.5.3 Aggregation and Disaggregation Services

The WIA-PA standard supports native aggregation services for data and packet. This feature is not present in the WirelessHART and ISA100 standards.

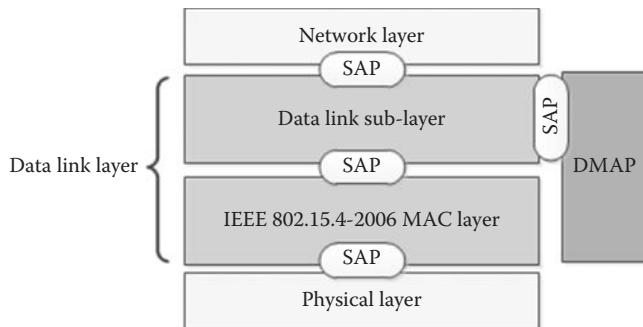

When a field device has many application objects (data) to transmit, it is possible to merge all data into a unique packet. This procedure is known as data aggregation. On the other hand, a router device can receive packets from many cluster members in a given period, being possible to merge all packets for a unique packet. This procedure is known as packet aggregation. Obviously, it is very probable that the merged packet suffers fragmentation because its payload is longer than the standard limit. Data aggregation occurs in the application layer (AL), whereas the packet aggregation occurs in the NL. Both the aggregation procedures try to reduce the number of packet forwarded in order to minimize energy consumption. The drawback of this mechanism is that the longer the packet, the greater is the probability to have interference.

The aggregation service is optional for the field device and the router device. The parameter *AGGSupportFlag* indicates the support for this service. Each device has a device structure table to maintain basic information configured by the NM, including the *AGGSupportFlag* parameter. Another fundamental parameter to the aggregation service is the *AggPeriod*. The NM configures the *AggPeriod* to the minimal update rate of the cluster (if the service is packet aggregation) or the minimal update rate of the field device application object (if the service is data aggregation). The idea is to start a timer right after the first packet or data in order to be received with the aggregation flag active. When the aggregation timer expires, the router device merges all packets previously received, as shown in Figure 34.11 (packet aggregation), or the field device merges all data into a unique packet (data aggregation). The aggregated data format is similar to the one described in Figure 34.10, but in this case, there is not the field *destination address*. The indication about the aggregation service is marked in the *control field* at the NL header.

The process of disaggregation is similar to the aggregation. After receiving a packet, the gateway evaluates whether the HL header indicates an aggregated packet. In an affirmative case, the network payload is disaggregated and right after it is forwarded to the upper layer. If the AL identifies a data aggregation, the payload is fully disaggregated. Nonaggregate packet or data are handled transparently.

## 34.6 Application Layer

According to Figure 34.12, the WIA-PA AL provides an interface to user application objects (UAOs) and industrial process. It has two sublayers: the user application process (UAP) and the ASL. The former one implements the interaction between the distributed applications of industrial processes (collecting

**FIGURE 34.12** WIA-PA AL.

process data, data conversion, linearization, generating alarms, etc.), whereas the latter one provides transparent services of data transmission (end-to-end data services, client/server [C/S], publisher/subscriber [P/S], and report source/sink [R/S]). The SAP manages the communication between the AL and the NL. The implementation of a communication interface (SAP) to the DMAP in the AL is also mandatory.

### 34.6.1 User Application Process

In technical terms, the UAP can be described as an application process defined by network users. According to the WIA-PA standards, the UAP may be defined by either the IEC 61499 or the IEC 61804 standards. Both of them define function block structures that are independent of implementation.

In a typical UAP, several UAOs coexist in the same device. Each UAO may process data of different types of sensors such as temperature, humidity, pressure, level, flow, vacuum, and combustion. The main functions supported by a UAO are the following: range scaling, linearization, compensation (drift), filtering, engineering unit conversion, and time stamp.

### 34.6.2 Application Sublayer

The ASL provides a transparent interface to communicate with distributed applications (UAO). The communication between two UAOs is defined by a virtual communication relationship (VCR). The ASL defines three VCR application modes:

1. P/S: used for periodic data
2. R/S: used for aperiodic events
3. C/S: used for aperiodic and dynamic unicast messages

In the P/S mode, the publisher (e.g., a field device) sends data periodically according to its update rate. The NM and the cluster head are responsible for ensuring enough resource to the publisher. On the other hand, the subscriber (gateway or a router device) has a prior knowledge about the publisher address and occasionally captures new data. Alternatively, in the R/S mode, a report source (field device or a router device) sends aperiodic alarms or events to the sink (gateway). It is mandatory to send an ACK to the report source. Finally, in the C/S mode, the client (field device, routing, and gateway) sends read or write requests to the server (field device, router, and gateway). The latter one should execute the request and send to the client the respective confirmation. The C/S mode is used for end-to-end retransmission (AL), unicast messages in the intercluster communication (NL), and during the CAP (DL).

## 34.7 Security

One of the most important advantages in being an open standard is the flexibility to provide interoperability between several manufacturers. However, this can be a drawback to security, since an open network standard has potential security risks (invasions, data destruction, replay attacks, etc.). Thus, the implementation of techniques to guarantee the dependability requirements (system availability, data integrity and authenticity, confidentiality, key management) is mandatory.

Additionally, being an industrial communication standard, the WIA-PA must guarantee the support for critical applications. In general, such applications have stringent dependability requirements, as a system security failure may result in economic losses, put people in danger, or lead to environmental damages.

Given the context described previously, the WIA-PA implements network security in several levels. The data integrity is provided in the AL and DLSL. MICs are adopted to verify whether the information was compromised. The MIC types are specified in the security header of the protocol data unit (PDU) of AL and DLSL as described in Figure 34.13.

The data confidentiality is also guaranteed in the AL and DLSL. Symmetric keys are used to encrypt and decrypt the payload of packets. MIC and security keys are also adopted to guarantee device authentication, for example, during the join process. The security services in the MAC are provided by the IEEE 802.15.4-2006.

Coordinated by the network security, the management and the maintenance of key are provided in the DMAP module. Each device has an instance of DMAP. According to the WIA-PA standard, the following cryptographic keys are supported:

1. Join key (JK)
  - During the provisioning process, the handheld device configures a temporary key for a device. This key is generated based on the 64-bit-long address of device and it is mandatory for the join process. Eventually, the JK is also necessary to encrypt the key encryption key (KEK) during its first distribution.
2. KEK
  - After the join process, the SM provides for the incoming device a special key to encrypt the transmission of other keys. At the first time, the SM transmits the KEK encrypted by the JK. However, the next transmissions encrypt the new KEK using the old KEK.
3. Data encryption key (DEK)
  - DEK is also distributed (encrypted using the KEK) by the network security after the join process. It is used by the AL and DLSL to protect data during the transmission of packets.

### 34.7.1 Secure Joining Process

The first step to guarantee the dependability features of a network is maintaining the secure join process. Thus, it is mandatory that the incoming device is authenticated. This procedure is conducted by the SM as described in Figure 34.14.

DLPDU				APDU			
Frame control	Security header	Payload	MIC	ASL Header	Security header	Payload	MIC
1 byte	1 byte	Variable	0/4/8/16 bytes	5 bytes	1 byte	Variable	0/4 bytes

FIGURE 34.13 Security structure for DLL and ALs.

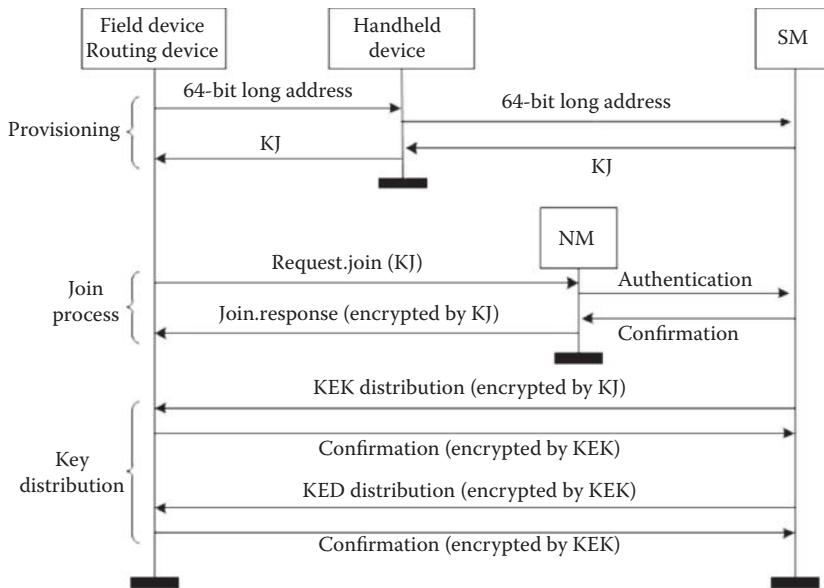

FIGURE 34.14 The secure joining process and the exchange of security keys.

Before joining the network, the incoming device should generate the KJ. The handheld device is responsible for communicating with the SM requesting the generation of the KJ. The parameter of generating function is the 64-bit-long address of incoming device. The join process starts when the incoming device sends the request join (with the JK attached) to the NM. The request is forwarded to the SM where the incoming device is authenticated. A confirmation (encrypted with the JK) is sent to the incoming device acknowledging the secure join.

Right after the join procedure, the SM sends the other security keys to the device. The KEK is the first key to be distributed. Note that the KEK distribution is encrypted with the KJ. Finally, the KED is also sent by the SM to the device; however, the distribution is encrypted with the KEK.

### 34.7.2 Secure Transportation

For the sake of understanding, in this section, the secure procedure used to transfer data from a field device to the end application is described. The procedure depends on the availability of aggregation service. If the field device and router device do not support the aggregation service, the secure procedure to transfer data is as follows:

- Field device
  - The ASL payload is encrypted using the KED, and after that, it generates the AL MIC. The encrypted material is forwarded to the NL.
  - The DLSL encrypts its payload using the KED, and after that, it gets the DLSL MIC.
  - The packet is sent to the router device.
- Router device
  - The router device receives the packet and checks the integrity with the MIC. Then, the packet is decrypted in the DLSL (using the KED).
  - The next hop is verified in the NL.
  - The router device uses the next-hop DLSL KED to encrypt the DLSL payload, and after that, it generates the MIC.
  - The packet is sent to the gateway.

- Gateway
  - The gateway checks the DDSL MIC of incoming packet and decrypts the DDSL payload using the KED. The packet is forwarded to the NL.
  - The AL checks the MIC and decrypts its payload using the KED.
  - Finally, the gateway forwards the data to the end application.

The procedure is very similar if the support to aggregation is enabled. The difference is that the field device must encrypt the payload of data from multiple UAOs. After that, it generates a unique payload in AL. In the router device, after all the packets had been decrypted in the DDSL, all payloads are aggregated and a new NLPDU is obtained. From that point on, the procedure is similar to the previous one.

## 34.8 Conclusion and Discussion

---

Industrial applications are known as a very conservative environment where reliability, interoperability, and security issues are always required. Adoption of new communication paradigms is viewed with great skepticism by plant managers. This context does not differ when considering the emerging industrial wireless technologies. In the last 10 years, this technology has become sufficiently mature to allow its adoption in industrial environments. The main improvements are related to redundant routing protocols, real-time scheduling, and efficient frequency hopping mechanisms. These technologies enable the development of emerging industrial applications where the use of legacy wired technologies is difficult or impracticable, for example, in tank farms, pipelines, distillation columns, wellheads, and rotation equipments (turbines and kilns).

In this chapter, the WIA-PA standard, an emerging Chinese standard for industrial wireless communication, was described in detail. The features described in the chapter can be used to aid the design of applications to develop more resilient networks.

Considering the protocol stack, the WIA-PA supports a physical layer based on the IEEE 802.15.4. However, implementation of the upper layers follows independent approaches. The WIA-PA standard improved the MAC protocol implemented in the IEEE 802.15.4, highlighting the TDMA and frequency hopping approaches with a flexible energy-saving operation. Regarding the routing issues, the WIA-PA network adopts a mesh-star routing approach where the field devices are organized in a cluster. Additionally, there is support to data and packet aggregation. The former one is used by the field devices to aggregate data from multiple processes, whereas the latter one is used by router devices to aggregate multiple packets. Both procedures are adopted to increase the lifetime of devices. Furthermore, the AL provides an interface between the network and the industrial process based on standard application modes (P/S, R/S, and C/S). Finally, security is guaranteed from multiple levels (system availability, data integrity, authenticity, confidentiality, and key management).

From the commercial viewpoint, a wireless battle to establish a communication standard is on the horizon. Currently, various industrial wireless standards coexist. The WirelessHART standard has dominated the marketplace because it was the first standard approved by IEC. However, the ISA100.11a standard has more flexible features than the WirelessHART ones, mainly those related to the tunneling of legacy applications, segregation of network (subnets), and more frequency hopping profiles. On the other hand, in the Chinese market, it is expected that the WIA-PA networks will dominate despite of unannounced Chinese suppliers. To increment the industrial wireless technology competition, the task group IEEE 802.15 (TG4e) is developing a new wireless standard specific to the industrial environment named IEEE 802.15.4e. Another challenge is related to the coexistence of different wireless technologies in the same area. Since the transmission medium is open, there may be situations where different technologies share the same frequency range. Thus, it is important that even when they coexist in the same environment, different technologies can operate without interferences.

### 35.1 Introduction

---

In the last years, wireless networks have become an interesting opportunity for industrial communication systems [1,2] thanks to the indubitable benefits they can bring. Indeed, introducing wireless communications in industrial environments is particularly appealing since, in principle, it increases system flexibility by reducing setup times and costs. Also, it avoids (or, at least, limits) cabling, which turns out to be cumbersome and/or expensive in many real cases. To this regard, it may be observed, for instance, that reliability as well as availability problems could arise with cables used to connect moving parts, as a consequence of mechanical stress and/or attrition.

Several studies have been carried out to assess the suitability of wireless networks for industrial applications since, as it is well known, such networks may be characterized by problems like fading, multipath propagation, shadowing, and interference, which could have a negative impact on the performance of industrial communication systems often characterized by severe requirements in terms of both timeliness and reliability [3].

The obtained results are interesting, since it has been proved that some very popular, general-purpose wireless solutions can be profitably adopted in several industrial applications, too, including real-time communications at the shop-floor. Also, recently, wireless networks explicitly conceived for industrial communications have been designed, and the number of their deployments is rapidly increasing. It is the case, for example, of both WirelessHART [4] and ISA100.11a [5].

Thus, it may be eventually stated that wireless networks are now definitely available for industrial applications along with other communication systems like both the well-settled fieldbuses [6] and

real-time Ethernet (RTE) [7] networks. These three systems, which may be used either in a stand-alone mode or in combination with each other, allow to satisfy the most demanding requirements that may be encountered in factory automation.

As a point on which most experts agree, however, wired solutions will be still massively adopted in the future (to this regard, it is worth observing that the number of RTE installations is progressively increasing [8]). In other words, it is commonly thought that wireless communications are unlikely to replace the wired solutions currently adopted in industrial scenarios, at least in the midterm. Furthermore, in several practical applications, this is not considered as an actual requirement. Conversely, what is often needed in real-world factory automation systems is the ability to connect a few components to an already deployed wired communication system that cannot be reached (easily and/or reliably) with a cable. The most common example is a sensor mounted on a moving/rotating axis that has to exchange data with a controller attached to a wired segment.

This kind of problems may be tackled by providing wireless extensions to the existing wired systems. The resulting configurations are *hybrid* networks in which, typically, wireless segments have limited geographic extension (some tens of meters) and connect only few stations. In such a kind of networks, controller devices (e.g., programmable logic controllers, computer numerical controls, or industrial personal computers) are usually located on the wired segment. This means that wireless networks will have to coexist with more traditional wired communication systems for quite a long time. Consequently, the integration of wireless and wired communications in industrial scenarios is a crucial issue, which has to be dealt with carefully in order to achieve both timely performance and reliability.

This chapter focuses on some of the most relevant aspects concerning the aforementioned hybrid networks. After a general analysis of hybrid wired/wireless configurations and the related issues, the ways in which wireless extensions can be effectively implemented for both fieldbuses and RTE networks are described.

The wireless networks considered as candidate technologies for the extensions are both the IEEE 802.11 *Wireless Local Area Network* (WLAN) [9] and the IEEE 802.15.4 *Low-Rate Wireless Personal Area Network* (LR-WPAN) [10]. WLANs have already been considered in several studies and tested in practical applications that demonstrated their suitability for the use in industrial environment [11–13]. For such a reason, most examples provided in the following are based on that solution. On the other hand, LR-WPAN is a standard for short-range connectivity, mainly conceived for *wireless sensor networks*, that is characterized by long battery lifetime and low cost.

Bluetooth [14] is a further possible candidate for implementing wireless extensions. Such a kind of network, which was originally designed as a mere cable replacement system for mobile equipment, has progressively gained popularity thanks to its features and is now employed in several areas, including industrial automation. However, in spite of its interesting features, Bluetooth is not further considered in this chapter due to page room limits.

## 35.2 Implementation of Hybrid Networks

---

From a general point of view, different (and often dissimilar) communication networks can be interconnected through specific devices called *intermediate systems* (ISs) [15]. These devices have different structure, functionality, and complexity, according to the layer of the Open Systems Interconnection (OSI) reference model they refer to. In the following, some practical implementations of ISs are described, along with their features and related issues.

### 35.2.1 Interconnections at the Physical Layer

The simplest form of ISs are *repeaters*. They operate at the physical layer and are used to interconnect subnetworks that share the same medium access control (MAC) protocol. Repeaters are usually adopted for regenerating physical signals (electrical, optical, etc.) flowing across different network segments.

In Ethernet networks, for example, they operate according to the so-called *3-R principle*: reshaping, retiming, and retransmitting. In this way, it is possible to face the problem of signal attenuation over the cable when the network extension grows larger. Moreover, they enable the number of nodes that can be networked—which is practically limited by the current drained by devices attached to the bus—to be increased and achieve segmented network topologies in addition to the plain linear bus.

Besides simpler two-ported devices, a special kind of repeater exists (called *hub*) that is provided with several ports and can be adopted to set up networks based on star topologies. Because of the increased reliability (a defective cable no longer affects the whole network operation, hence avoiding partitioning faults), hubs are particularly suitable for deploying network infrastructures and for the cabling of buildings. More advanced versions of repeaters may sometimes be employed to interconnect subnetworks that rely on different media (e.g., copper wires and fiber optics) or signaling techniques (e.g., voltage/current levels).

When network segments are connected through repeaters, the MAC protocol that regulates the access to the shared transmission medium is exactly the same on the whole network. Thus, care has to be taken about the increased propagation delays. In many cases, such as, for example, in half-duplex Ethernet, CAN, or Profibus networks, this leads to limitations on the maximum number of repeaters that can be inserted between any two nodes or the maximum cable length for every segment.

Pure repeaters are quite unusual in hybrid wired/wireless networks, since the resulting physical communication support in most practical cases is not seen as a sufficiently uniform medium by the MAC protocol. This is because the signaling schemes and physical transmission techniques adopted by wireless networks are, typically, rather different from wired solutions, which means some form of nontrivial buffering has to be carried out by ISs.

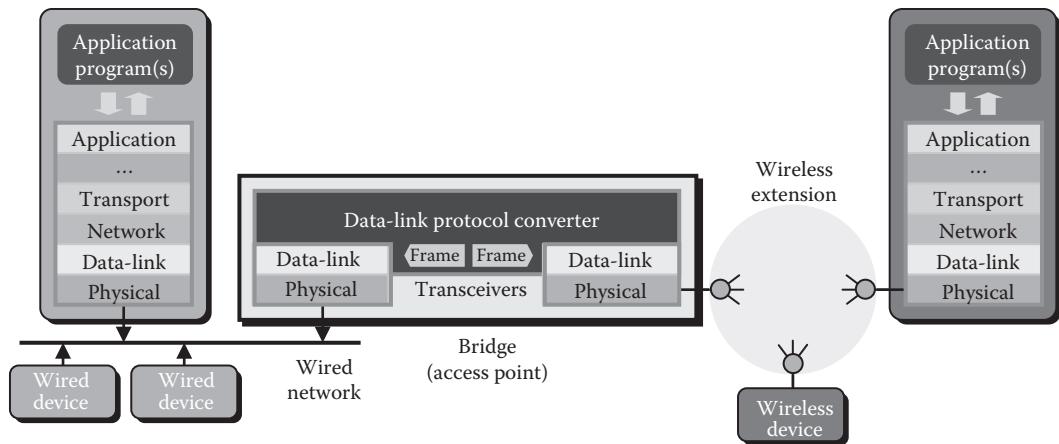

An interesting example of hybrid wired/wireless interconnection carried out at the lowest layer of the protocol stack (i.e., below the MAC) is provided in [16]. In that case, the authors refer to a hybrid architecture between Profibus [17] and Radio Fieldbus [11] (the latter was one of the firstly designed industrial wireless networks that, however, was never implemented, with the exception of some prototypes). The described hybrid network relies on cut-through forwarding devices located between wired segments and the wireless medium. Both networks use the same data-link layer protocol—specifically, the fieldbus data link as defined by Profibus, including its access scheme based on token-passing—but rely on completely different physical layers. Indeed, signal transmission in Profibus is based on the well-known RS 485 standard, whereas Radio Fieldbus is used to adopt a direct sequence spread spectrum technique similar to the one adopted in IEEE 802.11 WLANs.

### 35.2.2 Interconnections at the Data-Link Layer

An IS operating at the data-link layer is called *bridge*. Its main purpose is transferring frames between systems that are not (or cannot be) treated as a uniform communication support by protocols at the MAC level (e.g., switched LANs that are made up of several separate collision domains). Such devices usually operate according to the store-and-forward principle, that is, when a frame is completely received on one port of the bridge, it is forwarded (possibly, according to a selective strategy based on adaptive message filtering) to the other subnetwork(s) through the related port(s). As an alternative, forwarding may start as soon as a sufficient amount of information is received about the incoming frame (e.g., cut-through bridges). Even though featuring shorter transmission latencies, in this latter case, erroneous frames are not blocked by the bridge, hence reducing the net available bandwidth.

It is worth noting that, thanks to this decoupling mechanism, physical signaling, transmission speeds, medium access techniques, and even the frame formats might differ in the interconnected networks. A bridge, which is equipped with more than two ports, is commonly referred to as a *switch* (this kind of device is currently present in almost every real-life Ethernet network).

Even though the MAC mechanism is not required to be the same for the subnetworks interconnected through bridges/switches, the sets of communication services provided at the data-link layer should be

**FIGURE 35.1** Interconnection of networks via a bridge.

at least similar. Limitations on the kinds of networks that can be interconnected concern, for example, their addressing scheme (which has to be uniform on the whole network) and the *maximum transfer unit* (MTU) that affects the allowed payload size (this is because fragmentation is not permitted at the data-link level). When subnetworks with different MTUs are interconnected, care has to be taken so that the payload of the exchanged frames never exceeds a threshold equal to the smallest among the supported MTUs.

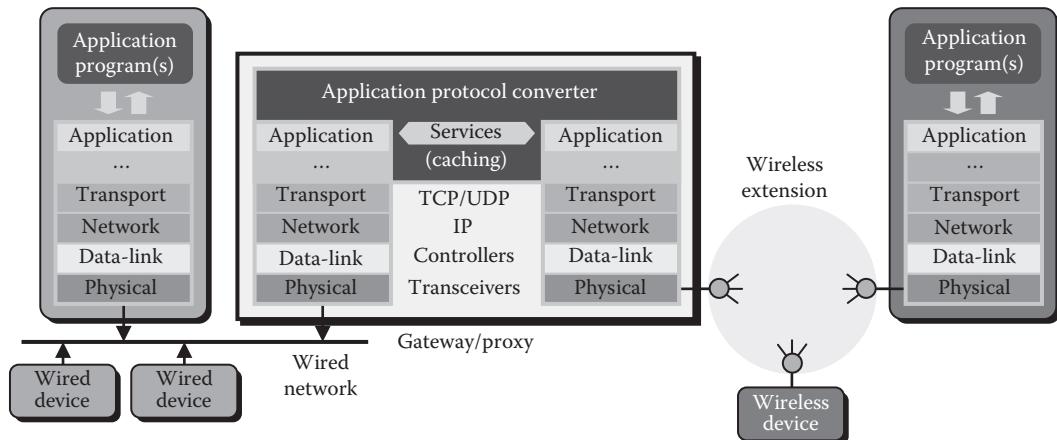

Figure 35.1 shows an example of interconnection taking place through a bridge for the hybrid networks considered in this chapter. From a practical point of view, the bridge used in hybrid wired/wireless networks is a device equipped with two (or more) transmitting/receiving interfaces (one for each subnetwork) and, optionally, a protocol converter. A frame originated from whatever segment (either the wired network or the wireless extension) is propagated to the other one by the bridge, which receives the frame, converts it into the suitable format, and then retransmits it.

When real-life devices and solutions are considered, *access points* (APs) are a very popular example of bridge. They are used to set up hybrid networks consisting of one (or more) wired IEEE 802.3 segments and an IEEE 802.11 wireless extension. Data-link layer services, in this case, are exactly the same for the two kinds of networks (i.e., those foreseen for the IEEE 802 family of protocols) as well as the 6-byte addressing scheme. On the contrary, frame formats and MTUs differ.

For the sake of truth, it is worth remembering that APs actually have a twofold role: they are used both to enable communication in an infrastructure WiFi network (also known as basic service set or BSS), by relaying frames among wireless stations, and to interconnect the BSS to an existing Ethernet backbone (portal function).

### 35.2.3 Interconnections at Higher Protocol Layers

For ISs working at the network layer or above, the generic term *gateway* is often adopted. A gateway is responsible for transferring *protocol data units* as well as for converting generic streams of information and application services between application processes executing in the nodes of the interconnected systems, by performing all required protocol translations. From a practical point of view, there is no particular restriction on the kinds of networks that can be interconnected through gateways. On the other hand, gateways are usually complex, expensive devices, often developed ad hoc for the considered systems by means of suitable software modules, and the performance they achieve is to several extents lower than bridges. Generally speaking, noticeably higher latencies have to be expected in this case, which could result in incompatibility with timings requirements of industrial applications.

**FIGURE 35.2** Interconnection of networks via a gateway.

ISs that operate specifically at the network layer are known as *routers*. At this level, a uniform addressing scheme and protocol are used (i.e., the *Internet protocol* [IP]), which ensure worldwide connectivity irrespective of the physical media, MAC mechanisms, and data-link services of the interconnected subnetworks. This chapter is not concerned with routers, since most industrial networks are deployed as local networks. However, when timing constraints are not very tight, interconnection techniques that rely on routers allow devices, which are natively enabled to communicate over local intranets and/or the Internet, to be directly embedded in the automation system (this is the case of remote monitoring and maintenance tasks).

When the interconnection takes place at the application layer, the IS should take care of the conversion of high-level services. Usually, this implies the gateway has to carry out nontrivial operations for gathering and converting information, which, in turn, often require a number of simpler communication services to be invoked on the interconnected networks. In these cases, the term *proxy* is sometimes adopted. Indeed, a proxy is much more than an application-layer gateway: it usually makes some parts of the network (e.g., a whole subnetwork) look as if they were a single node, possibly hiding the underlying structure for security or performance reasons. Sometimes, some form of data caching is provided as well in order to save bandwidth. For instance, proxies are used in fieldbus/IP configurations to connect legacy fieldbus segments. In this case, they integrate devices connected to the underlying fieldbus into the overlying Ethernet system, maintaining in such a way several advantages of fieldbus networks, like high responsiveness, powerful diagnostic functions, and automatic configuration. At the same time, planning is simplified (because workflows are well known) as well as commissioning and operation (thanks to the diagnostic capabilities offered by the fieldbus).

An example of wireless extension implemented at the application layer is shown in Figure 35.2. The gateway in the figure includes two interface boards that are fully compliant with the overall protocol stack of the relevant subnetworks and a protocol converter, usually implemented as a software module.

### 35.2.4 Wireless Extensions of Industrial Networks

Although technically feasible, wireless extensions of industrial networks to be used at the shop-floor (either fieldbuses or RTE networks) are not so straightforward. This is basically due to three main reasons: first, the transmission support (wireless medium) is shared among all nodes (possibly including those associated to nearby independent wireless subnetworks). Even operating at the maximum allowable speed, this may result in a low per-station net throughput—compared to that achieved in many wired networks—when the number of connected devices grows higher (this is particularly

true when either switched Ethernet or industrial Ethernet solutions based on a combined message are taken into account). Furthermore, the nonnegligible overhead introduced by the communication protocol (larger protocol control fields, acknowledgment and reservation mechanisms, no provision for full-duplex operations, and so on) has to be considered as well. For example, the minimum time needed to reliably exchange 8 bytes of user data over a WLAN—that is, bit rate equal to 54 Mb/s, no RTS/CTS mechanism, no TCP/IP encapsulation, ad hoc network mode, but including interframe spaces as they effectively waste network bandwidth—is about 100  $\mu$ s. Such a value is only slightly shorter than the worst-case time taken to send the same information over a CAN network operating at 1 Mb/s (i.e., 135  $\mu$ s).

The second reason is that random medium access techniques (e.g., CSMA/CA) are often employed by wireless networks. This means that, on the one hand, unpredictable—and unbounded—transmission delays might occur (because of the occurrence of repeated collisions) while, on the other hand, network congestions could be experienced, and this is surely the worst aspect. In other words, when the network load generated by devices exceeds a given threshold (even for a limited time), a condition may likely arise—because of the positive feedback due to the increased collision rate—so that the effective net throughput decreases as the load increases. This means that the network may become temporarily unavailable to carry out data exchanges timely, which might not be compatible with proper operation of distributed automation systems. The number of lost messages (discarded by the sender because the retry limit is exceeded) may even grow up to a point that it is no longer acceptable for the control application. Moreover, even in the case of lightly loaded networks, nonnegligible jitter may affect data exchanges and hence the accuracy of the system, unless some form of prioritization scheme is adopted for frame transmission.

Third and last, wireless channels are much more error-prone than wired cabling [18], and this is a serious drawback for industrial communications. Indeed, typical aspects of production environments like the movement of people and/or plant components, along with the interference that could arise from other systems, may increase the bit error rate (BER) and, consequently, compromise the achievement of reliable communications. Besides causing higher latencies and jitter, transmission errors directly affect the network reliability and, hence, the robustness of the overall system. They may also cause consistency problems—for instance, when a multicast message is received only by a part of the addressed devices.

As a consequence, there is a nonnegligible chance that messages sent over the wireless medium never reach the intended destination, even in nonnoisy environments.

Each one of the three drawbacks mentioned earlier can be tackled (at least partially) by means of already existing or soon available technologies. In particular, the throughput problem could be somehow lessened with the adoption of IEEE 802.11n, which exploits the multiple-input multiple-output technology and is theoretically able to provide a big leap (about one order of magnitude) in the network throughput. Indeed, as process data are usually small sized, the same level of improvement cannot be reasonably expected in industrial scenarios, where simple field devices are interconnected. A more viable choice is relying on several (smaller) separate wireless subnetworks (e.g., WLANs), possibly operating on different channels, interconnected by means of a wired backbone in order to limit the packet rate on each one of them.

The second problem (determinism) can be tackled through the adoption of enhanced medium access techniques, such as PCF in the case of IEEE 802.11. Unfortunately, PCF is only seldom implemented in commercially available devices. Variants of PCF, such as the iPCF mechanism introduced by Siemens [19], have the drawback of being proprietary solutions, and hence, compatibility and interoperability with standard equipment can hardly be ensured. Alternatively, the prioritization features offered by both the IEEE 802.11e and IEEE 802.11n standards (already supported by many WLAN adapters currently available off-the-shelf) might be exploited [20]. While not guaranteeing strict determinism, prioritization (mainly developed for multimedia applications) is able to provide tangible improvements, such as, for example, guaranteeing shorter transmission times *on the average* for critical frames, which might be often enough for several industrial automation systems. For example,

it is possible to ensure quasi-real-time behavior by assigning higher priorities (i.e., voice and video access classes) to those messages characterized by tight timing constraints.

TDMA techniques may be useful to solve the determinism problem. In such a case, for example, the guaranteed time slots provided by IEEE 802.15.4 represent an interesting opportunity. Also, it is worth observing that both Wireless HART and ISA 100.11a use a combination of TDMA and pseudorandom frequency hopping [21]. Other solutions, as described in literature [22], suggest the adoption of synchronization techniques on WLANs, so as to reduce the likelihood of a collision for data exchanges that take place according to predictable (e.g., periodic) patterns.

The third problem (robustness) can be faced in several ways. As a first measure, the introduction of both spatial and frequency diversity techniques is recommended. Whenever feasible, a proper selection and placement of antennas is envisaged. The use of both APs and adapters with removable antennas is often a good idea, as this permits boosting the strength of signals by replacing the built-in omnidirectional antenna with a high-gain or directional one. Moreover, wireless range extenders can be used to deal with the problem of dead spots (areas with no or weak reception)—even though setting up such devices in a proper way is not always straightforward.

In the case this is not enough, leaky wave antennas [23] can be used to ensure reliable communication over radio links. The drawback, in this case, is the need to deploy the leaky cable infrastructure, which makes it a nonuniversal solution. Usually, such an arrangement is adopted when the equipment includes some parts moving on fixed paths, so as to avoid cable wear and strain. As an alternative, if true mobility is required, devices operating in the 5 GHz band (IEEE 802.11a) can be adopted as a satisfactory choice [21]. In this way, in fact, interferences with other devices operating in the standard (and already jammed) 2.4 GHz ISM band are avoided, hence achieving a better signal-to-noise ratio and, consequently, a reduced error rate on the radio link.

### 35.3 IEEE 802.11-Based Extensions

---

#### 35.3.1 IEEE 802.11 Extensions of Fieldbuses

Typically, the transmission protocols adopted by fieldbuses are noticeably different from those employed in wireless networks, at all levels of the communication stack. For example, random access techniques typical of WLANs usually are not employed in any fieldbus network (they are sometimes used in building automation networks, which are characterized by relaxed timing constraints). Other differences are concerned with either the payload size of frames or the address space, both of which are typically quite small in real-world fieldbuses (few tens/hundreds of bytes/nodes, respectively), whereas they are considerable for IEEE 802.11 networks.

As a consequence, these differences discourage the interconnection of fieldbuses and IEEE 802.11 networks at the data-link layer. Thus, wireless extensions of fieldbuses have to be implemented mainly at the application layer, that is, through gateways. However, some remarkable exceptions exist: DeviceNet, for instance, ensures interoperability with all networks based on common industrial protocol (CIP), thanks to its native routing techniques that allow, in principle, the implementation of extensions operating below the application layer (i.e., through direct routing of CIP messages).

#### 35.3.2 IEEE 802.11 Extensions of Real-Time Ethernet Networks

Despite the wide availability of both hardware components and protocols, the implementation of wireless IEEE 802.11-based extensions to RTE networks is not as straightforward as one could think. Indeed, interoperability between Ethernet and WLANs is always possible by means of inexpensive off-the-shelf devices (i.e., APs), along with some commonly available protocols like the well-known IEEE 802.1D bridging protocol [24], which allows for interconnections at the data-link layer. Despite the good efficiency, implementing this kind of solutions in industrial environments might be sometimes not so easy,

due to access protocols adopted by RTE networks, which are often not entirely compliant with the original Ethernet specifications. Moreover, the unavoidable uncertainty affecting the IEEE 802.11 communication caused by the random backoff procedure, the possibly high BERs, interference sources, and electromagnetic noise, may seriously impair the determinism of the RTE networks.

An example of IEEE 802.11-based wireless extension is provided in [25] for Ethernet Powerlink [26], a very popular RTE network that adopts an access protocol based on a fast and precise periodic polling carried out on the (wired) nodes; this ensures fast operation (cycle times under 200 µs) and ultra-low jitter (below 1 µs). Results presented in the paper actually confirm the impossibility of maintaining the aforementioned tight timing performance when wireless nodes are introduced. Nonetheless, the adoption of prioritized frames made possible by IEEE 802.11e revealed to be promising, since it allows for a consistent reduction of jitter, especially when a limited number of wireless stations are employed.

A more straightforward interconnection technique, in general, can be obtained through the communication services offered by the TCP/IP protocol suite. Unfortunately, given the complexity of TCP, this solution is not suitable for achieving real-time behaviors. For such a reason, in several cases, the UDP protocol [27] is preferred. UDP, in fact, has lower overheads than TCP and provides simpler communication services, thanks to its unacknowledged transmission scheme (which lacks the sliding window mechanism of TCP). This implies that latencies and jitter become shorter than in TCP, even though the overall behavior cannot be considered as strictly deterministic, yet.

## 35.4 IEEE 802.15.4-Based Extensions

---

The IEEE 802.15.4 specification, as all networks defined by the IEEE 802 committee, is only concerned with the two lowest layers of the communication stack and does not specify any type of upper protocol stack. Thus, the access to IEEE 802.15.4 networks by higher layers may be achieved in two different alternative ways, as recommended by the standard, that is,

1. Via logical link control (LLC) Type 1 services [28]
2. Directly, by means of the MAC services

Both techniques are effective, even if it is worth mentioning that IEEE 802.15.4 board manufacturers rarely include LLC services in their products.

Unfortunately, IEEE 802.15.4 has a low transmission speed, and hence, wireless extensions are not able to provide fast communications in this case. Nonetheless, the high efficiency of the protocol makes it particularly appealing for applications where a limited amount of data have to be transmitted. Moreover, the guaranteed time slots available in the beacon-enabled mode allow for deterministic access to the shared medium by wireless nodes, with a consequent reduction of the uncertainty typical of CSMA/CA-based protocols.

### 35.4.1 IEEE 802.15.4 Extensions of Fieldbuses

The wireless extension of fieldbuses by means of IEEE 802.15.4 suffers from the same problems already discussed for IEEE 802.11. Specifically, differences between the MAC protocols of the two kinds of networks discourage interconnections at the lower layers. Hence, wireless fieldbus extensions based on IEEE 802.15.4 networks can be achieved only through a gateway that maps services foreseen by the fieldbus application layer onto calls to IEEE 802.15.4 services. The gateway may be typically implemented as a station that embeds the interface to the fieldbus and, at the same time, acts as a coordinator for the IEEE 802.15.4 network.

Also in this case, the implementation of the gateway does not impose any restriction on the protocol(s) actually employed in the wireless extension. In particular, the gateway may rely on functions provided by a proprietary protocol explicitly defined for managing data exchanges over the wireless extension.

Alternatively, IEEE 802.15.4 data-link layer services (LLC or MAC) can be directly employed by the gateway to access wireless stations. Once again, it is worth remarking that significant benefits can be obtained from the use of guaranteed time slots. As an example, in this context, the virtual polling algorithm described in [11] for IEEE 802.11 does not need to be implemented for IEEE 802.15.4 since, in practice, such a mechanism is natively provided by the beacon-enabled mode of the access technique.

### 35.4.2 IEEE 802.15.4 Extensions of Real-Time Ethernet Networks

The availability of the LLC protocol for IEEE 802.15.4 networks could enable, in principle, the implementation of extensions to RTE networks right at the data-link layer, since most networks provide access to such a layer as well. However, the noticeable difference of transmission rate (RTE networks usually work at 100 Mbps, whereas for IEEE 802.15.4, the maximum allowed rate is 250 kbps) practically prevents to include IEEE 802.15.4 devices in the RTE network cycles, since these latter may take values as low as some hundreds of microseconds. Also, the possibly frequent retransmissions that could reveal necessary to eventually deliver a frame would contribute to a further increase in the cycle times. Consequently, also in this case, interconnections are recommended to be implemented at the higher layers via gateways.

As a final remark, it is worth mentioning that ZigBee [29] offers a complete protocol stack based on IEEE 802.15.4, and consequently, it represents an appealing opportunity for implementing wireless extensions of both fieldbuses and RTE networks considered in this chapter. Particularly, ZigBee offers connectivity with whatever type of networks based on the IP protocol, by means of the purposely defined *ZigBee expansion devices*. Consequently, it can be directly interfaced to several RTE networks (practically all those that allow for TCP/IP communications) using a conventional IP router.

## 35.5 Conclusions

---

Because of the need to provide flexible, inexpensive, and reliable communications in production plants, it is currently envisaged that hybrid configurations resulting from wireless extensions of conventional (i.e., wired) industrial networks will be adopted more and more in the next future. This is mainly possible thanks to the availability of wireless technologies and devices able to cope with industrial communication requirements in a proper way.

In the same way, both the IEEE 802.11 family of WLAN standards and IEEE 802.15.4 Low Rate WPANs have been taken into account as wireless extensions, since they are some of the most promising technologies for use in industrial automation and control applications, and a lot of devices are already available off-the-shelf at (relatively) low cost.

In general, the extension of almost all fieldbuses can typically take place at the application layer, through the use of suitable proxies. While providing greater flexibility, this may worsen the overall performance, due to delays this kind of devices unavoidably introduce. As an interesting exception, DeviceNet can be interconnected at a lower level via CIP routers. This means that in hybrid networks based on DeviceNet, all devices (both wired and wireless) can be seen and accessed as conventional CIP nodes, whereas in the case a gateway/proxy is adopted, wireless nodes are no longer effectively part of the network itself.

When real-time (industrial) Ethernet networks have to be provided with a wireless extension, more alternatives are possible, in principle, including carrying out interconnection at the data-link layer. However, as these networks often rely on peculiar protocols to ensure predictable communications over conventional Ethernet, the integration with WLANs is not usually straightforward. As a consequence, a loss of performance and determinism in hybrid networks is expected to occur also in this case. Moreover, when IEEE 802.11 is selected for the wireless extension, the native randomness of the DCF medium access technique has to be taken into account carefully in designing/deploying the hybrid

network, since it likely leads to additional (possibly critical) delays. Significant improvements can be achieved by using deterministic techniques, such as, for example, PCF in WLANs (which, however, is not usually available in real devices) or guaranteed time slots in IEEE 802.15.4 networks (that, however, suffer from a noticeably lower bit rate).

Finally, an interesting option for achieving quasi-real-time communications over wireless extensions is provided by both the IEEE 802.11e and IEEE 802.11n standards, which support the concept of quality of service. It has been shown that, for example, traffic prioritization could be used to deal with different types of connections (and, hence, of timing requirements) defined and handled by the CIP protocol, so as to transparently enable control applications to meet real-time constraints, even when hybrid network configurations are adopted.

### 36.1 Introduction

---

The vision of ubiquitous or pervasive computing prescribes a paradigm shift where the computing power is embedded in our environment rather than concentrated in desktop or laptop machines. This broad vision of the future has fueled a number of narrowly defined research areas, among them wireless sensor networks (WSNs). WSNs originate from military applications such as battlefield surveillance, but are now being deployed in a large number of differing civilian application areas such as environment and habitat monitoring, healthcare applications, home automation, and traffic control. The intrinsic qualities of WSN, such self-powered, self-organizing, and self-healing, make them highly interesting also in the domain of industrial automation. However, industrial automation applications often have

very distinct and stringent requirements, which necessitates that we loosen and extend the classical definition of a WSN for it to be more applicable in an industrial setting.

This chapter will provide an overview of typical industrial automation applications, explain how they differ from other domains, and highlight the key challenges in developing WSNs for the industrial automation industry. A reference case will be used throughout the chapter to exemplify these challenges and illustrate practical implications of design choices and requirements trade-offs.

The chapter is organized in to four main parts outlined as follows:

1. *WSN in Industrial Automation*

We start off with a (re)definition of WSN from an industrial automation point of view and detail the key industry requirements and their impact on the core WSN technology.

2. *Development Challenges*

Following the description of applications and their requirements, we try to structure a generic development cycle or process that highlights key challenges of developing WSN devices. This section clearly shows how many different aspects are there that need to be considered, how intricate they are, and how intertwined they are with each other.

3. *Reference Case*

Here, we describe the application of the reference case including the environmental conditions, application requirements, and business motivation. The main elements of the design and implementation are described to provide a basis for comparison in the following sections on development aspects.

4. *Development Aspects*

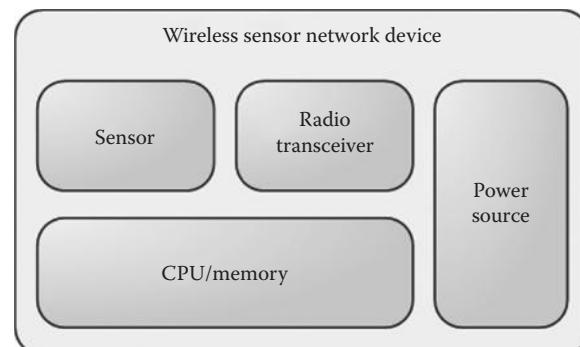

The final sections in this chapter elaborate on the key development aspects described earlier such as standards, low-power design considerations, packaging, hardware (HW) and software (SW) modularity, power supply, and component choice.

## 36.2 WSN in Industrial Automation

---

### 36.2.1 Classical WSN

Wikipedia defines a WSN as “a wireless network consisting of spatially distributed autonomous devices using sensors to cooperatively monitor physical or environmental conditions, such as temperature, sound, vibration, pressure, motion or pollutants, at different locations” [1]. The devices, which is the focus of this chapter, are self-contained units comprising a microcontroller, power source (usually, but not always, a battery), radio transceiver, and sensor element (Figure 36.1).

**FIGURE 36.1** Components of a WSN device.

WSNs have some intrinsic qualities, which can be derived from the distributed autonomous nature of the devices.

#### *Self-Powered*

WSNs are self-contained units with an internal power source (usually, but not always, a battery).

Because of the limitations of battery life, nodes are built with power conservation in mind and generally spend large amounts of time in a low-power *sleep* mode.

#### *Self-Organizing*

The nodes self-organize their networks in an ad hoc manner rather than having a preprogrammed network topology. For example, in wired network technologies, some designated nodes, usually with custom HW (routers, switches, hubs, and firewalls), perform the task of forwarding data to other nodes in the network. In a WSN, typically each node is willing to forward data for other nodes, resulting in a dynamic network configuration based on the network connectivity.

#### *Self-Healing*

WSNs have the ability to self-heal, that is, if one node goes down, the network will find new ways to route the data packets. This way, the network as a whole will survive even if individual nodes lose power or are destroyed. This type of dynamic reorganization can also be triggered by other conditions than node failure, such as maximum node power consumption and communication latency.

### 36.2.2 (Re)defining WSNs

Industrial applications differ from the definition earlier in a number of respects.

#### 36.2.2.1 Cooperative Sensing Is Not Commonplace in Industrial Automation

First, and maybe most importantly, all sensors are crucial to the operation of the plant. This implies that losing one node is not an option, even if the overall network stays operational. A faulty node will have to be replaced. Increasing the availability by adding redundant sensors would be technically possible but hardly feasible from a cost perspective. Although the cost of radio transceivers is continuously dropping, the majority of the cost of industrial-grade WSN devices is not driven by the cost of the transceiver alone. To this, you need to add the life cycle cost associated with installing and maintaining a device throughout its lifetime (which is a factor of at least two to five times longer than consumer products).

The notion of cooperative sensing prescribed by classical WSN is also not readily applicable to today's automation control systems, which are rather I/O centric. Measurement points are not *dispersed* across the plant but rather installed in very exact locations. The data are collected and fed back to the control system where they are processed and analyzed. Adding a measurement point is associated with manual engineering and application programming before it can be utilized in the system.

The cooperative nature of WSN still adds value though, as setup and installation of the sensors becomes easier and the overall operation more reliable. Since the position of the measurement point might not be optimal from a radio-frequency (RF) perspective, the self-organizing and self-healing nature of WSN help alleviate communication disturbances related to radio propagation in industrial environments. Instead of investing lots of time in frequency planning and network design, performance of the network can be improved by adding router nodes that provide alternate/redundant paths for the wireless sensors.

#### 36.2.2.2 Time Is of Essence

Time is money, also in the industrial automation world. Whereas a data packet in a standard WSN may spend an unknown time from its source to its destination, an industrial application will frequently

require hard bounds on the maximum delay allowed. This can put some strict bounds on network topology, for example, prescribing a star configuration rather than a multihop mesh network, and requires a careful trade-off between power conservation and response time. Although there is usually a strict bound on the maximum delay, the requirements can differ quite dramatically between applications. This makes a generic design of the WSN quite difficult, and the *one-size-fits-all* problem quite prevalent in industrial standards groups who seek to minimize the number of overlapping wireless communication standards.

### 36.2.2.3 Wireless in a Wired World

Although WSNs have made its entry on the industrial automation scene, the majority of sensors and devices have a wired infrastructure. This means that we need to cope with a mix of wireless and wired devices over a foreseeable future. Applications that are built upon a wired infrastructure can afford to *waste* bandwidth and make use of high-performance networks to solve their mission-critical goals. Simply adding a wireless sensor to the equation is often not straightforward.

A quite common mixed scenario on the other hand is to add wireless connectivity to already wired devices. This is done to provide access to diagnostic or asset data in the device in a nonintrusive manner, that is, without modifying or interrupting the wired network.

Since wireless solutions in industry will tend to also have a wired infrastructure, the data will emanate from the sensors and ripple through the network to some wired aggregation point. From here, it will, in general, be transported over a high-speed bus to a controller. Apart from the classical mesh networking topology of WSN, we have two more common topologies in industrial settings (Figure 36.2).

In the star topology, the most prevalent topology today, the wireless nodes communicate with a gateway device that bridges the communication to a wired network. This network configuration will have greater chances of minimizing delays in the network and can thus be used in applications that have strict bounds on the communication delay. Another common intermediate solution of WSN is to have router devices (often mains powered) that communicate with the gateway. The sensors only need to perform point-to-point communication with the routers and can therefore remain simple and low power, while the range and redundancy of the network are improved.

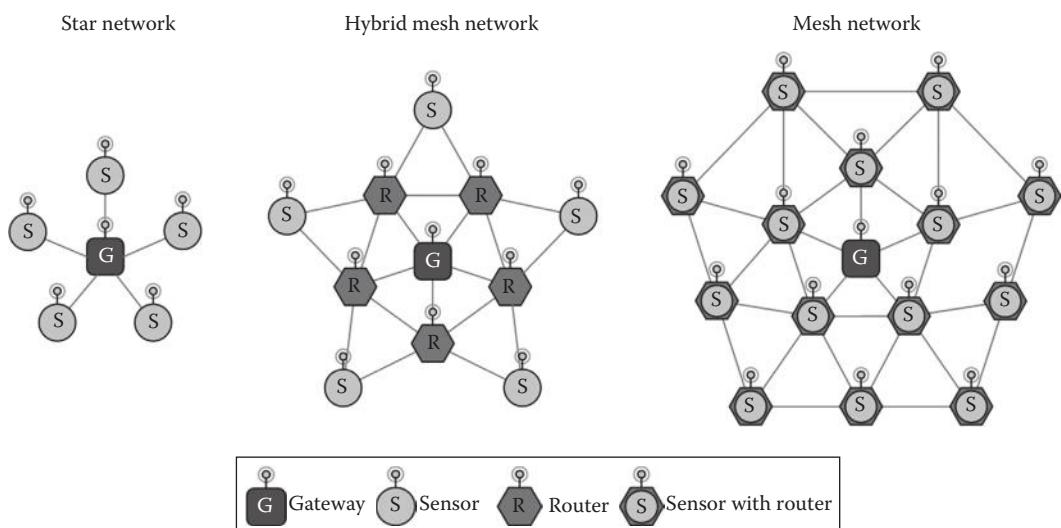

FIGURE 36.2 WSN topologies.

### 36.2.3 Industrial Automation Applications

#### 36.2.3.1 Industrial Plants, an Unfriendly Setting for WSN

The environmental conditions of industrial automation plants pose some heavy challenges in the development of embedded field devices, in general, and specifically for WSN devices.

Industrial automation environments are characterized by the following:

- *Harsh environments*: Extreme temperature, moisture, vibration, hazardous environments, steel constructions, and (moving) obstructions. Issues facing wireless communication in such environments are heavy multipath fading, fast/slow fading, coverage quality (due to reflection), and local variations in received power.
- Electromagnetic interference (EMI): EMI from electrical activity such as drives and welding, which cause noise in RF bands.
- *Other users*: Disturbance by occupation of frequencies over time (WLAN, Bluetooth, ZigBee, etc).

The following sections will elaborate more on the implications of these severe conditions on the embedded design of WSN devices.

#### 36.2.3.2 Typical WSN Applications

The requirements of any WSN solution will always depend heavily on the particular application in mind. There are many promising applications for wireless technologies in industrial automation, ranging from monitoring of process parameters to mission-critical control applications. ISA (The International Society for Automation [2]) defines six usage classes of wireless communication based on the criticality of the application, which directly govern the importance of the message response time (see Table 36.1).

WSNs in the traditional sense (i.e., low-power, multihop, mesh networks) are today usually deployed in class 4–5 applications. This is logical since most WSN solutions are usually optimized for low-power consumption to increase battery lifetime, and this stands in direct conflict with short and deterministic response times.

However, in real life, the boundaries between these classes are not always that clearly defined/identified. It's not uncommon that from a user's point of view, the application is a mixture of monitoring and control, making the requirements on message delay hard to specify. Defining a suitable wireless communication solution can thus be difficult unless we provide means to influence the network forming and optimization criteria.

**TABLE 36.1** ISA-100 Usage Classes

Category	Class	Application	Description	
Safety Control	0	Emergency action	(Always critical)	↑
	1	Closed-loop regulatory control	(Often critical)	
	2	Closed-loop supervisory control	(Usually noncritical)	
	3	Open-loop control	(Human in the loop)	
	4	Alerting	Short-term operational consequence (e.g., event-based maintenance)	
Monitoring	5	Logging and downloading/uploading	No immediate operational consequence (e.g., history collection, sequence of events, preventive maintenance)	Importance of message timeliness increases

**TABLE 36.2** Impact of Process Attributes on Wireless Technologies

Process Attribute	Description	Impact on Wireless Technology
Device types	Predominant or common mix of devices, for example, analog and/or discrete devices	The type of data (and consequently also amount) that is sent has a major impact on the design of the communication protocol. This in combination with the timing requirements sets boundaries on the frame/package size utilized.
Device count per unit	Typical number of devices in a manufacturing unit/production cell	The number of devices in a plant and their geographic distribution has a dramatic impact on the communication technology.
Unit physical size [m]	The physical size of a typical manufacturing unit/production cell	The ability to cover a whole factory with wireless communication depends on a number of factors such as <ul style="list-style-type: none"> <li>Range of the wireless device/network, which is governed in turn by the reliable operation range, the disturbing range, and <i>frequency reuse</i> range</li> <li>Number of wireless nodes per manufacturing unit</li> <li>Number of coexisting wireless networks within reliable operation range without performance degradation</li> </ul>
Units per plant	Number of manufacturing units/production cells in a typical plant	
Device density (units per 1000 m <sup>2</sup> )	Number of devices per 1000 m <sup>2</sup>	
Devices per plant	Number of devices in a typical plant	
Production cycle length	Length of a typical production cycle	
Unit start-up time	Start-up time of a manufacturing unit/production cell	The production cycle length and start-up times have a direct impact on the setup times for the wireless networks, such as network forming and adding/removing nodes.
Time		
Fast/subunit	Fast internal communication needs, for example, drives loop	This attribute in combination with the node density has the greatest impact on the technology selection.
Control loop	Time resolution of normal control loops	Depending on the required update rate and equally important the latency (variation in communication delay), very radical differences in design of the wireless communication solution might be required.
Slow/diag./HMI	Time resolution for noncritical data such as diagnostics or HMI	
Field device cost	Typical cost of the field devices	The cost of the device to a large extent puts some upper barriers on the target cost of the wireless communication solution.
Installation cost/device cost	Cost of the installation in comparison to the cost of the device	This metric provides guidance on the target cost of installing and setting up the wireless infrastructure.
Automation technology	Type of control system utilized to automate the process	The use of a DCS versus, for example, a PAC/PLC solution, to some extent, governs the logical network structure. This is also reflected in the device count and unit count measures listed.
Commonly used device networks	Typical wired infrastructure in today's plants	At some point, the wireless network has to interface with the existing network infrastructure. The employed wired network technology and topology have an impact on the way one could/should integrate the wireless system in the plant.
Power availability	Availability of line power/battery size/energy harvesting	The amount of energy that is available has a dramatic impact on the design of the wireless protocol (energy efficiency), as well as the possible duty cycle of the application.

### 36.2.3.3 Same, Same, but Different

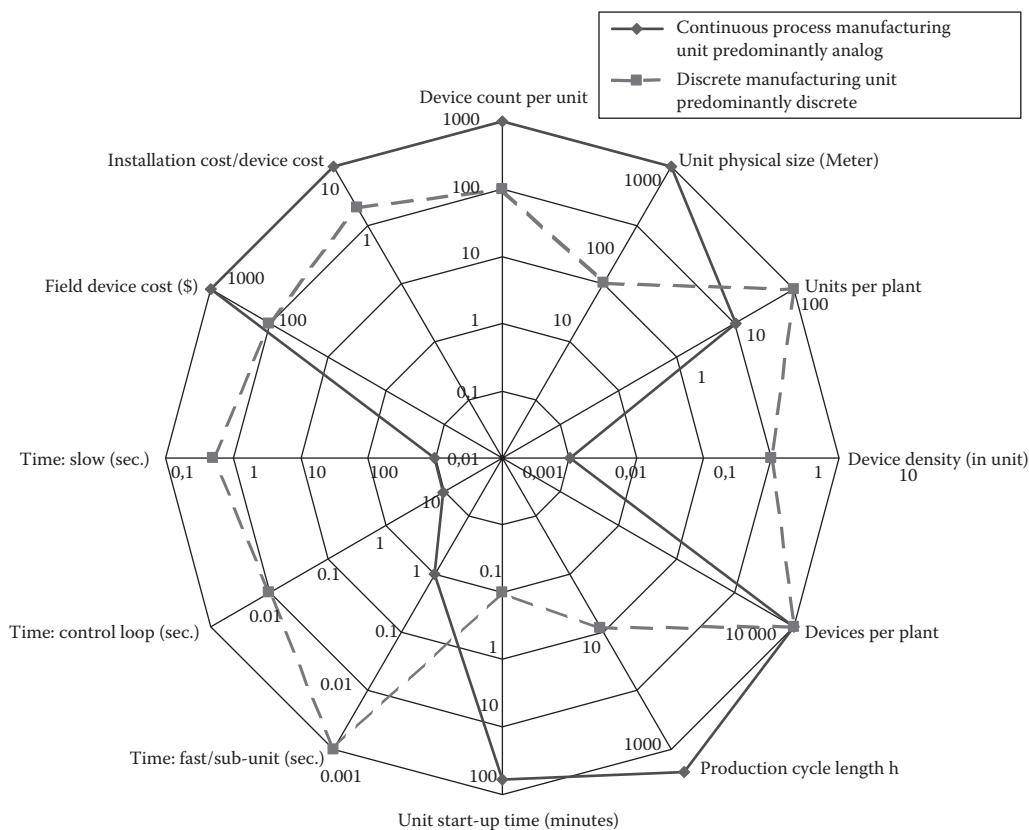

Industrial automation is a broad industry and comprises many segments and application domains. A common way to divide the market is according to the type and characteristics of the process being controlled:

- Process automation (continuous processes)
- Discrete manufacturing (manufacturing of discrete units)
- Hybrid automation (mix of continuous and discrete)

The industry segments can be characterized by a number of process attributes that govern the requirements on wireless communication technologies and consequently also the design and implementation. Table 36.2 provides a description of key process attributes and their impact on the requirements and design of wireless technologies.

Although similar (bad) environmental conditions can be found throughout the various industry segments, there are distinct segment-specific requirements that have a dramatic impact on the wireless technologies. Figure 36.3 provides a comparison of the key process attributes within process automation and discrete manufacturing (note that the scale is logarithmic).

As illustrated in the earlier figure, the two industry segments have quite different characteristics and consequently also pose quite different requirements on the wireless technologies employed.

**FIGURE 36.3** Process attributes.

Even though industrial automation standardization activities in the wireless domain have started out with a quite holistic view of the processes and target applications, these distinct differences have led to the forming of separate working groups (WGs) targeting process and discrete applications. For an overview of the industrial automation wireless standards landscape, see *Section 36.5*.

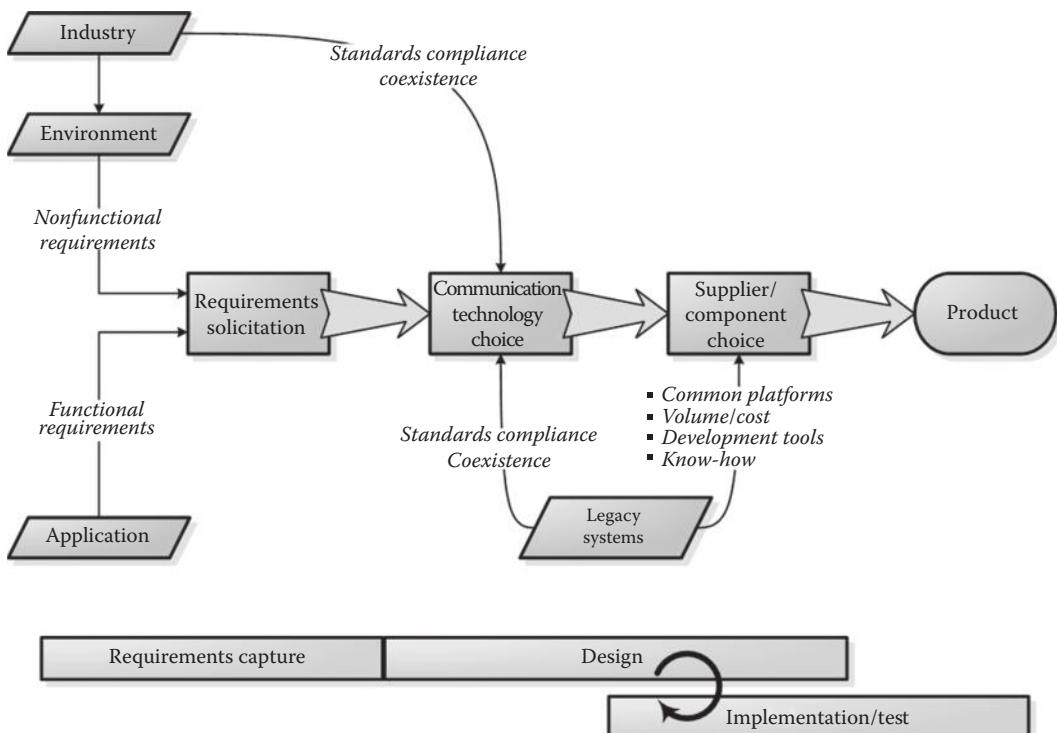

### 36.3 Development Challenges

The previous section presented a definition of the *classical WSN* and contrasted that to the complex set of requirements and applications of industrial automation. These requirements and use cases have a dramatic impact on the development of WSN devices.

Figure 36.4 depicts a generic development process.

Embedded development methodology and development processes in general are complex subject matters that merit a book of its own to do the topic justice. The process depicted previously thus only aims at highlighting some key characteristics of WSN development projects:

1. A thorough requirement analysis is required in order to be able to select the right communication technology.
2. The choice of technology is not driven by the requirements alone. Factors such as standards compliance and legacy systems also have a large impact on the final choice.
3. Component selection to a large extent follows the choice of technology but is many times already given by the platform choices of existing legacy systems.
4. Finally, when designing, implementing, and testing the device, we need to pull all the bits together. This usually requires quite an iterative process with many trade-offs and redesigns due to a combination of inaccurate or incomplete requirements and/or component specifications.

**FIGURE 36.4** Principal development process.

### 36.3.1 Diverse Requirements

As highlighted in the previous section, the target industry and application can pose quite differing requirements on the choice of communication technology as well as impose quite rigid restrictions on the embedded design. The requirements can be grouped into nonfunctional requirements that stem primarily from the target environment and functional requirements given by the target application.

The environmental conditions of the target industry have a major impact on the boundary conditions of the embedded design and choice of communication technology. For example, factors such as heat, moisture, and vibration influence the packaging of the device, which in turn imposes additional requirements on the power consumption as well as restrictions on the antenna design and power-supply solution. If the device shall be used in hazardous environments, special consideration must be taken throughout the design process.

The application requirements more or less dictate the duty cycle of the WSN, which has a huge impact on choice of technology and a direct influence on the low-power design and required response time. In addition to the autonomous operation of the device, the human-machine interaction can pose additional requirements on external interfaces that influence both the communication solution as well as the packaging of the device.

### 36.3.2 Choosing Communication Technology

A clear view of the requirements helps to eliminate obvious communication solutions. However, it's not uncommon that one needs to make a trade-off in the end to be able to address the main requirements that are driving the application.

Many industries, customers, and suppliers have adopted their own communication standards or, when possible, refer to international standards. If a different technology shall be acceptable, as a minimum requirement, it must be able to coexist with other technologies without unduly compromising the performance of installed devices/systems.

### 36.3.3 Choosing Suppliers and Components

The choice of technology has a direct impact on the availability of suitable SW/HW components and thus also on the total development cost/time. Since industrial devices have a quite long lifetime, legacy systems have a major impact on choice of technology as well as components. Many suppliers have streamlined their development processes and base their product portfolios on standardized platforms. This has great benefits in terms of volume/cost of components and development tools, as well as spreading of best practices and know-how. Introducing a new SW/HW component or platform is often a demanding and time-consuming task and always represents an additional risk. You can never be quite sure that the new component will behave in the same manner as those components that have undergone years of development/refinement and are proven in the field. It might therefore be better to utilize a well-known component and suffer/deal with the performance losses of utilizing a *nonoptimal* component from a WSN perspective.

### 36.3.4 Pulling It All Together

The development process depicted in Figure 36.4 gives the impression that the development follows a rather linear waterfall-type model. Even if you might start out that way, due to the complexity of the requirements and the boundary conditions imposed by industry and legacy systems, the design/implementation/test phase usually reverts to a highly iterative process. Developing WSN devices

for industrial automation applications often comprises a set of *chicken-and-egg* problems, where the order of design choices can result in very different outcomes in the final design. A key success factor is thus to have a very clear view of the driving requirements, that is, the absolute *must-haves*, stick to them and let the other lower priority requirements, the *should-haves*, undergo the inevitable trade-off exercise.

Figure 36.5 illustrates the interdependencies of key development aspects of WSN devices and shows how one design aspect (a row) affects other design aspects (the columns).

The following sections provide a walk-through of the table to demonstrate how design choices in one dimension can, directly or indirectly, affect other dimensions of the design (and vice versa).

### 36.3.4.1 Communication Standards

Most customers strive toward the use of standards when building their installations. This secures interoperability and availability of suppliers and leads to higher volumes (and ultimately lower cost). The use of a standard is thus often mandatory to be able to compete on the market. One of the key requirements of wireless devices in industry is coexistence. Hence, this needs to be considered when choosing a specific standard.

Once selected, the standard in itself will impose upper/lower bounds for the device in terms of power consumption. Regardless whether you employ low-power electronics and a clever sleep–wake-up scheme, the communication protocol has a vital impact on the final power consumption of the system. Some communication protocols are notoriously inefficient, and no smart embedded programming in the world will help get the consumption down to an acceptable level.

The standard can also impose certain physical interfaces, which will have a direct impact on the design of HW/SW as well as the packaging of the device. For example, the WirelessHART standard [3] requires that you provide a service port on your devices.

The scope and architecture given in the standard indirectly also prescribe the level of integration of HW and SW. This is of course highly linked to the available commercial offering that supports the standard, such as radio transceivers and communication stacks.

So, *simply* by choosing a specific standard, many design choices have been made that will drive the design of the device. In *Section 36.5*, we will dig deeper into the wireless standards jungle and provide some insight to the basic mechanisms of modern WSN solutions targeted toward industrial automation.

### 36.3.4.2 Low-Power Design

One important aspect of WSN is to keep the power consumption of a node at a minimum while at the same time providing the best possible performance to the system users. The low-power nature of WSN poses serious restrictions on the power consumption of the HW as well as on the SW architecture.

Integrating functionality can be one way to lower the overall power consumption but can put severe limitations on the modularity of the system. This not only affects the HW/SW maintenance of the device but may also limit your options concerning what to power up/down and when, which in turn can affect the overall power consumption as well as performance of the device negatively.

Although WSN devices are autonomous entities, a local human–machine interface (HMI) is often useful or necessary during commissioning and troubleshooting. The specific low-power design directly limits your options concerning the use of a local HMI, for example, liquid crystal display (LCD), light emitting diode (LED) and buttons.

Designing for low consumption involves choosing low-power components. This may seem trivial but is often a complex issue as it usually involves compromises on the performance. Typically, a low-power central processing unit (CPU) runs on reduced clock cycle with fewer on-chip features than its more power hungry counterparts. The trick is to choose elements with just enough performance to do the job. In addition, *overspecifying* components to create margins in your design can lead to cost and maintenance issues as the number of suppliers tends to shrink rapidly.

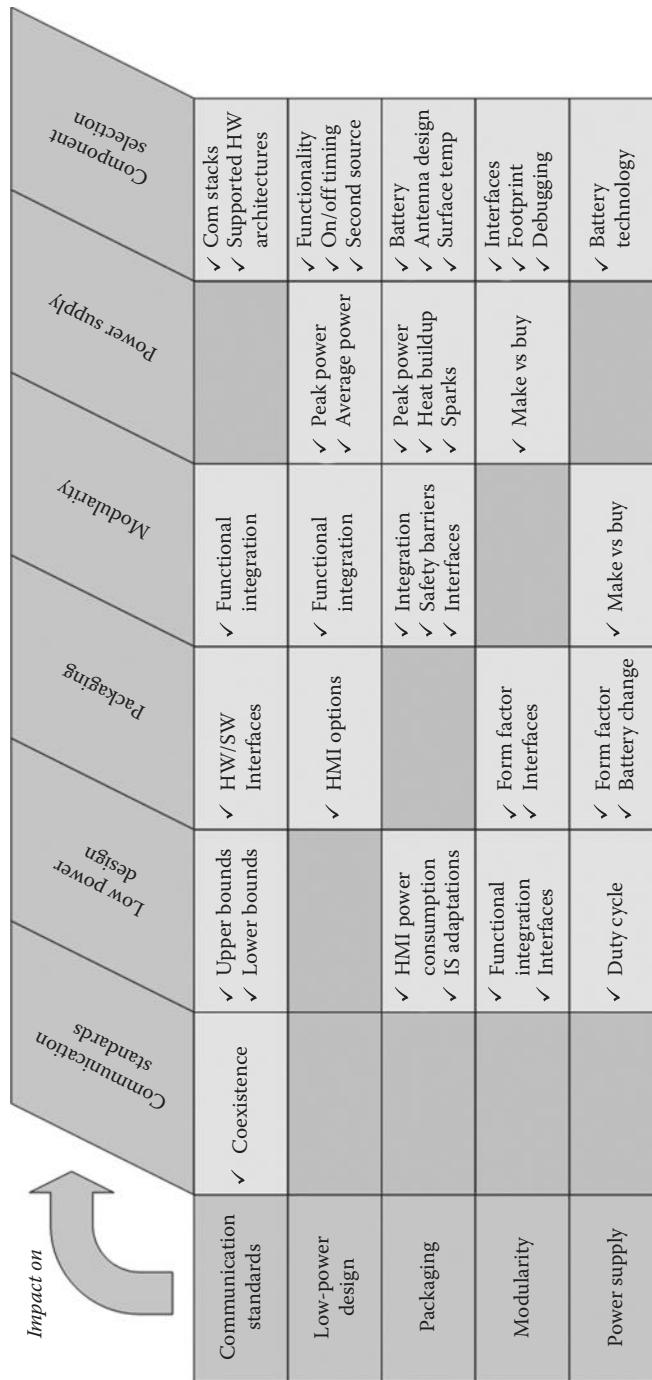

FIGURE 36.5 Development aspect matrix.

Finally, the low-power design more or less dictates the required average and peak power that needs to be available in the system, and this may have some serious consequences on the design of the power-supply solution, including the choice of power source.

Less really *is* more in the WSN world, and the more you take away, the more challenging the design task becomes. In *Section 36.6*, we invest some more *energy* in describing the intricacies of low-power design.

### 36.3.4.3 Packaging

The packaging of the WSN device represents one of the most costly parts of the total product. The environmental conditions and the device rating (IP class, explosive atmosphere [EX] temperature range, etc.) all influence the required ruggedness of the device and prescribe what material to use in the housing and how well it must be sealed off to protect the internal components from dust and moisture.

The use of a local HMI, whether it is an LCD or a single LED, can have a dramatic impact on the overall power consumption of the device and thus needs to be accounted for in the low-power design.

If the device is to be able to operate in a hazardous environment, great care needs to be taken throughout the design of the device. An intrinsically safe (IS) design is commonly required. The basic principles of an IS design are simple and easy to grasp but challenging to achieve in practice. It requires long experience in the field as well as certification by a notified body. Making IS adaptations can have a dramatic impact on the power consumption and the form factor of the device (due to additional protection and power-limiting components). Often, the maximum power that can be provided by the power supply needs to be limited. The major requirement for batteries operating in ATEX applications is for intrinsic safety. Specifically, this calls for a battery design that prevents both excessive heat buildup and the danger of an electric spark. The modularity of the device is governed by the need to define barriers with clear interfaces in the design to contain and transfer energy in a controlled and safe manner. The maximum surface temperature of any component on a circuit board under fault conditions must be considered.

The form factor of the device components is often given indirectly, either through product design guidelines to foster harmonization and common look and feel or by the requirement to utilize an already existing housing. This means that you often have a given space where you need to squeeze in your HW components, which can have a dramatic impact on the required level of component integration (single-chip solutions, double-sided printed circuit boards [PCBs], etc.). It's not uncommon that the size of one specific component can force a complete PCB redesign to fit within the given dimensions. Typical components that drive the PCB design are capacitors and batteries.

Apart from component selection and integration, the form factor also has a direct influence on the antenna design, which is very sensitive to the orientation and proximity of other electronic components.

Appearance is everything! This actually holds true to a large extent when it comes to embedded design of industrial WSN devices. In *Section 36.7*, we find out that what counts is the *inside*, but the appearance of the device (size, shape, material, and weight) does have a major impact on the final design.

### 36.3.4.4 Modularity

The lifetime of the devices is a key parameter to consider. The office/consumer industry is the main driver for wireless technologies today, with high volume applications. Industrial automation devices, however, tend to have a much longer lifetime than consumer products. This means that special care needs to be taken when integrating wireless components into industrial devices. A modular (HW and SW) design is crucial in enabling effective maintenance of devices—which are built on standard commercial off-the-shelf (COTS) components—throughout their lifetime.

Modular design is necessary in order to reuse elements, but it might seriously limit your control over individual HW/SW functions and thus influence the overall sleep-wake-up scheme of your device. Proper interfaces are thus vital to mediate between reuse and performance, something that can be hard to influence when COTS components are used.

The form factor of commercial components or subassemblies naturally has a direct impact on the packaging of the device, but again, the interfaces are just as important and need to be sufficiently general to allow portability.

One classical example of the separation of modules is the split between the communication protocol and the application SW. The latter is invariably written by the device vendor, but the former is frequently purchased from a third party. Embedding these two components onto the same microcontroller can be difficult. We also run the risk of suboptimizing, that is, the two SW modules are optimized (with respect to power, performance, code size, etc.) individually. This does not necessarily give a globally optimum solution. Even more complex is handling new releases, bug fixes, and documentation when the SW running on the same processor has several sources.

In addition to reuse, modularity is also a means to minimize design risks. For example, to avoid EMC problems in your power-supply design, it is often beneficial to buy predesigned and tested COTS components such as a DC-DC converter. If the device is going to be produced in large volumes, the cost of these COTS components can be prohibitive though, forcing you to make your own low-level design. Component specification can be another limiting factor when utilizing available designs, for example, if you require a large operating range.

The sum of the parts can equal more than the individual parts together, at least from a product maintenance point of view. However, great care must be taken to ensure that sum of the parts also provides adequate performance. In *Section 36.8*, we cut up the WSN device into logical pieces and look how we can put them back together again without unduly compromising the control over the final behavior of the device (power consumption, latency, etc.).

### 36.3.4.5 Power Supply

The power supply is a central part of the WSN device; it's the *motor* that provides power to the various parts of the system. The challenge is the same as the development team has regarding the final product, to provide the right level, with the right quality, at the right time.

The design of the power supply can put direct bounds on the duty cycle of the application. For example, in an energy-scavenging solution, the harvested energy is usually stored in an intermediate storage. This enables the power supply to provide an even power-supply level in spite of a varying *incoming* power and to handle intermittent peak consumptions. The size of this intermediate storage and the time it takes to charge it directly impact the *maximum* duty cycle.

Although battery technology is progressing, the battery still constitutes a major part of the footprint of the device if we are to reach the 5–10-year lifetime that is typically quoted. The same goes for the energy-scavenging solutions, which usually contain some form of intermediate storage as well.

Typical parameters to consider when choosing battery technology are operating temperature range, energy density, nominal voltage, and Watt hours (for a given cell size). However, there is more than meets the eye here as well. For example, in some types of lithium technologies, passivation may lead to voltage delay, which is the time lag that occurs between the application of a load on the cell and the voltage response. This behavior becomes more pronounced when you have very low duty cycles (since the passivation layer grows thicker).

If battery change in the field is to be supported, special care needs to be taken to allow separation of the battery from the device. This is especially tricky if the device is going to be deployed in a hazardous environment, where any spark must be prevented.

Low-power design is all about powering up/down various parts of the system. In *Section 36.9*, we find out that there is a lot more to consider than ON/OFF.

## 36.4 Reference Cases

As with other resource-constraint embedded systems, “the devil is in the details.” In this section, we present two specific use cases of WSN in industrial automation. These applications will be used as reference cases for the remainder of the chapter to exemplify some of the details that really matter when making design choices.

The first application is *wireless condition monitoring of AC motors using vibration analysis*. In the following sections, all references to this specific use case will be highlighted with a border:

# WIRELESS VIBRATION MONITORING CASE EXAMPLE

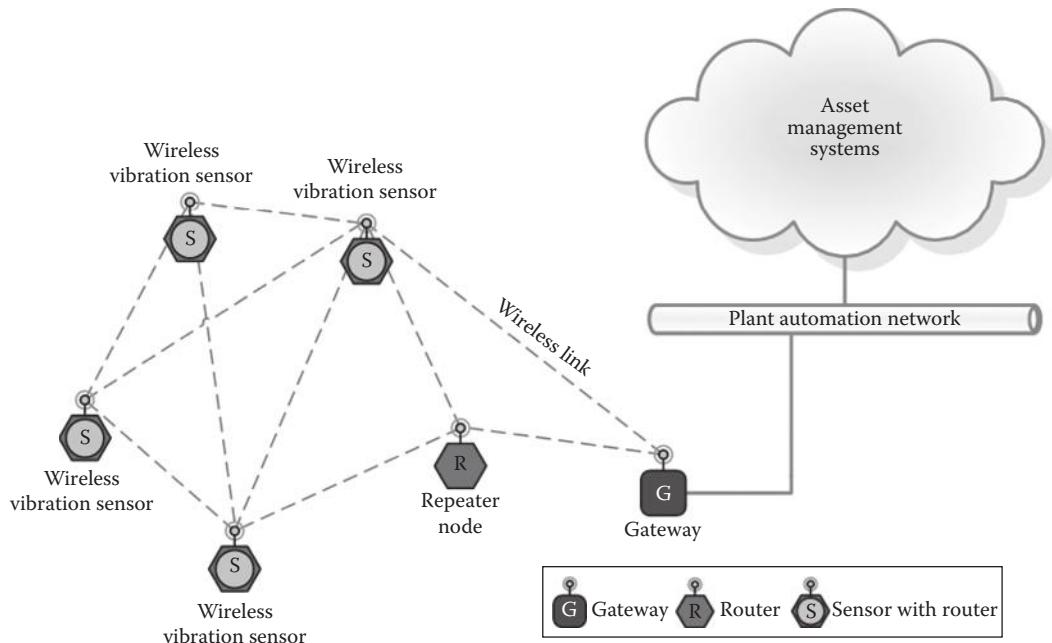

The Wireless Vibration Monitoring application will be used as the main example use-case for reference throughout the rest of the chapter.

### 36.4.1 Wireless Vibration Monitoring Application

The goal of the vibration monitoring application is to detect early signs of bearing degradation on small AC motors (less than 400 kW), located on offshore oil/gas rigs, in order to be able to schedule maintenance. The motors drive equipment such as pumps, air compressors, and fans, and the load conditions as well as the operating environmental conditions will vary (Figure 36.6).

FIGURE 36.6 Wireless vibration sensor.

**FIGURE 36.7** Wireless vibration monitoring system.

The application consists of several parts as illustrated in Figure 36.7: vibration monitoring sensor nodes, repeater nodes, a gateway, and an asset management system (vibration analysis SW).

For the remainder of the chapter, we will only refer to the WSN part of the application, which consists of the sensor and router nodes. The gateway is actually also part of this but is considered to be part of the infrastructure and often regarded as a COTS component. It is (usually) mains powered and does not face the same design challenges as the resource-constraint sensor nodes. The need for repeater nodes depends on the communication technology and the operating environment of the WSN.

The WSN part of the application has the following design goals and requirements:

- *Low cost*: The sensor/repeater nodes are very restricted in what they are allowed to cost, which has a large impact on component selection and packaging. This also has the effect that the number of nodes that will be deployed in the field should be minimized; that is, the range of the wireless communication should be as long as possible.
- *EX certification*: The environment in oil and gas rigs is hazardous. The sensor and repeater nodes must be certified to operate in an EX Zone 1 area, that is, nodes will intermittently be subjected to flammable material (oil or gas), and must therefore limit the energy of any sparks and surface temperature.
- *Nonintrusive (easy to mount and retrofit)*: The sensor/repeater nodes must be easily mounted on the motors. Some motors have mounting locations prepared, while others don't, and the mounting constructions also differ from case to case. The orientation of the sensor element and location on the motor (preferably close to the bearing) matters from a vibration analysis point of view, which can be in direct conflict with an optimal antenna positioning. All of these must be taken into consideration for the physical design of the sensor nodes.
- *Battery powered and a long battery life*: The requirement is that a sensor node should have a 10-year lifetime without any battery change.
- *Duty cycle*: Each sensor node should perform one vibration measurement per 2 weeks and send it to the asset management system for analysis. This is a bit opposed to the *typical* view of a WSN, which sends small amounts of data *fairly often* (minutes, hours, or days).

- *Operating environment:* The temperature can vary from well below zero up to, or even over, 100°C. In addition, the wireless communication solution must be able to cope with the possible interference caused by the many metal constructions found on an oil rig.
- *Security:* Authenticity (making sure data come from the correct sensor node) and integrity (making sure no one has tampered with the data) are very important. Therefore, it is also important that we only allow authorized nodes to join the network.

Latency is not a critical requirement for the application because the data are not part of a process control loop. Reliability on the other hand is a much more important requirement, because missing data will result in a flawed view of the actual motor condition.

### 36.4.2 Communication Standard

WirelessHART was the selected communication technology for the vibration monitoring application. It was the first industrial wireless communication standard to become available (released on September 2007). It is explicitly designed with industrial applications and requirements in mind and is the most widespread standard for process automation.

ZigBee is also a currently available wireless communication standard but was not considered sufficient for operation in industrial environments, especially an environment such as the one on an offshore rig. Basically, it lacks effective means with which to alleviate the effects of interference and fading. We provide more details on ZigBee's shortcomings in industrial environments in *Section 36.5.3*.

### 36.4.3 Communication Technology

As mentioned, WirelessHART is the chosen communication standard for the vibration monitoring application, because it's currently the only available wireless communication standard designed for industrial applications.

However, because it was just recently released, technology suppliers have not yet provided any components supporting the standard. This has led to a decision to use a proprietary technology, as an intermediary solution, until WirelessHART components become available. This leads to another important decision we must make; we must select a proprietary solution that will provide/enable an easy migration to WirelessHART.

In the end, the decision fell on a solution offered by DUST Networks [4] called SmartMesh-XD. It's a system-on-chip (SoC) wireless sensor networking solution called Mote-on-Chip (MoC) (see Figure 36.8). The SmartMesh-XD MoC (DN2140/2040) is a *black-box* solution, which hides all details related to the wireless communication from the rest of the application.

DUST Networks will also provide a WirelessHART-based solution (SmartMesh IA-500), which uses identical HW to the SmartMesh-XD MoC (including the interface), thus only requiring a firmware upgrade in order to become WirelessHART compliant. This will allow for a smooth transition to WirelessHART.

SmartMesh-XD is IEEE 802.15.4 standards compliant and operates in the 900 MHz and 2.4 GHz industrial, scientific and medical (ISM) frequency bands. It is a robust wireless sensor networking technology that combines low-power radio technology with the Time-Synchronized Mesh Protocol (TSMP).<sup>\*</sup> TSMP, which was also the basis for the WirelessHART standard, provides features such as time-division multiple access (TDMA), frequency hopping, and redundant paths (mesh), which makes it suitable for the harsh operating environment of the application. The SmartMesh-XD communication uses a concept called a network frame. The network frame is a fixed-length, cyclically repeating, sequence of time slots (TDMA), in which all nodes have been assigned dedicated slots for message transmission and reception.

---

\* TSMP is a proprietary wireless sensor network protocol developed by DUST Networks.

FIGURE 36.8 DUST Networks SmartMesh MoC solution.

In the following sections, we will describe the impact the decision to use SmartMesh-XD, as well as allowing for future migration to WirelessHART, has on the design of the application.

## WIRELESS PROCESS CONTROL CASE EXAMPLE

Utilizing wireless as an infrastructure for closed loop control presents many advantages such as cost reduction, flexibility and improved performance. However, wireless control also presents many challenges such as deterministic communication, security and battery lifetime decreases.

### 36.4.4 Wireless Process Control Application

Wireless measurement devices are becoming common features of modern process control systems. They allow plants to quickly and relatively inexpensively add new measurement and control capabilities, especially where it has been too difficult or expensive to use wired instruments. Wireless measurement devices also allow plants to quickly and economically test new control schemes. Today, the most common wireless control applications typically involve noncritical, open-loop control tasks, or closed-loop control applications with longer time constants such as tank level control, temperature control of heated jackets, or control of oil field steam injection for secondary recovery operations.

Utilizing wireless as an infrastructure for closed loop control presents many advantages such as cost reduction, flexibility, and improved performance. However, wireless control also presents many challenges such as deterministic communication, security, and battery lifetime decreases. For the latter, it can be solved by reducing the overall number of signal transmissions, which can significantly

extend battery lifetime. Wired devices often *oversample* a process variable, sending measurements to the control 4–10 times more often than the controller performs algorithm executions. Furthermore, many measurement updates that traditional wired devices transmit are essentially identical (or very similar) to previous measurement updates, meaning that it does not serve a practical purpose and only conserve bandwidth.

#### 36.4.4.1 Application: Storage Tank Heating Control

Level monitoring devices are frequently located on top of very large storage and process tanks (Figure 36.9). Using WirelessHART makes it easier and more cost efficient to monitor and control the levels in process and storage tanks by eliminating the need to manually take and record the measurements. As an example application, we consider storage tank heating control where existing manual measurement and control methods were unsatisfactory for maintaining the temperature of fatty nitrites and amines in several tanks where they were stored before shipment to customers. Too much steam was sometimes used to heat materials, and one problem was that the delivered product was too hot. Existing procedures for detecting potential problems required an operator to make regular trips into the field to take snapshot readings from pressure gauges on the tank farm's venting conduits. This is time consuming and fails to provide continuous and immediate information. A typical wired process control system shown in Figure 36.10 was installed before. From the controllers down to the wired instruments, the communication can be achieved by different standards such as HART, Modbus, Profibus, and Profinet.

One possible solution is to install a number of WirelessHART temperature transmitters to control the temperature on a number of tanks (see Figure 36.11 for a conceptual framework) and the controllers are then connected further to the enterprise management system, etc. Measurement data are transmitted every minute to the distributed control system (DCS), which controls a simple ON/OFF

FIGURE 36.9 Storage tank.

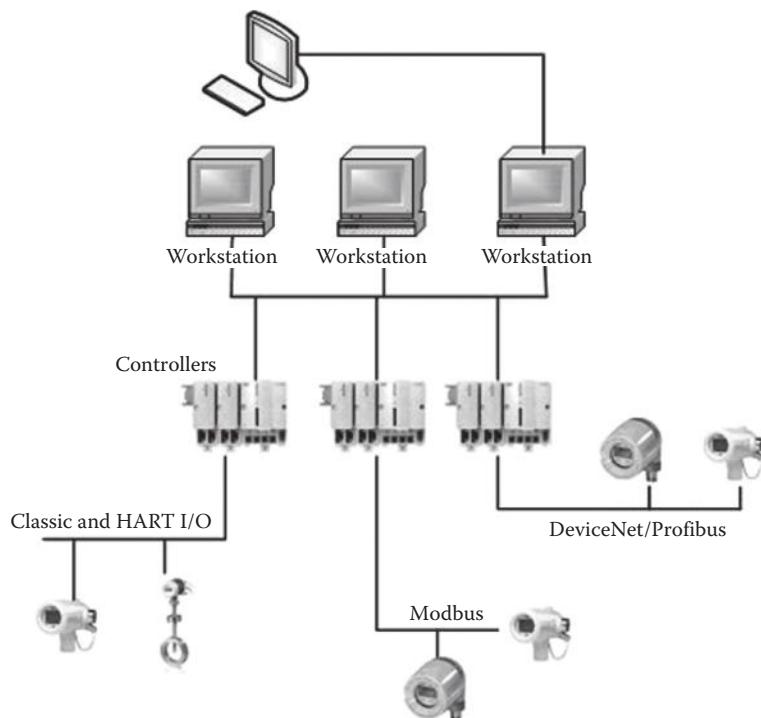

FIGURE 36.10 A wired process control system.

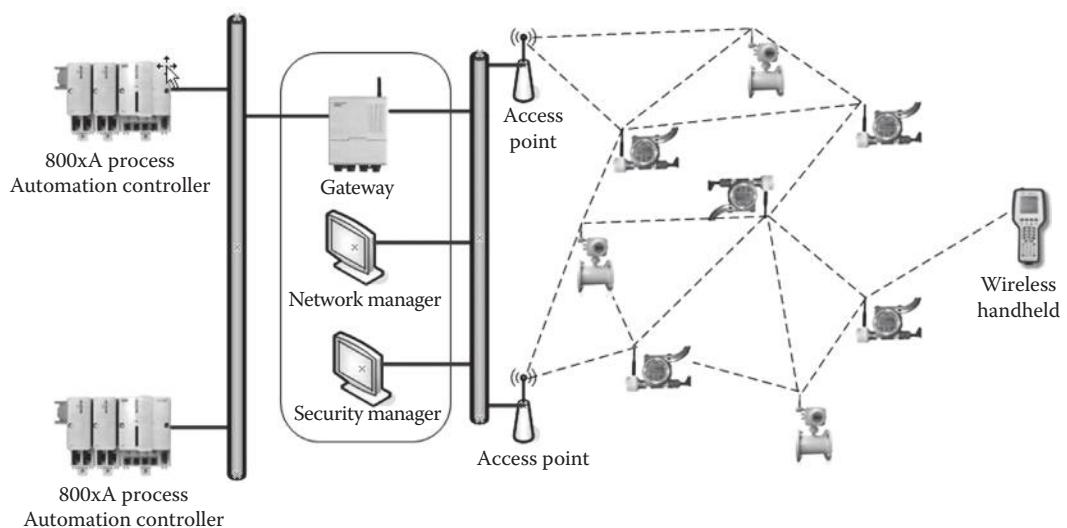

FIGURE 36.11 A wireless process control system.

steam valve. The temperature can now be maintained by using this wireless closed-loop control. This solution leads to reduced steam consumption, lowering operational costs, and ensuring that customers receive the right temperature.

### 36.4.5 Communication Standard

WirelessHART is the selected communication technology for the wireless control application. The choice of WirelessHART is mainly since it is the most widespread communication standard that currently exists for process automation. The solution would probably also have been working with the ISA 100.11a or *Wireless Networks for Industrial Automation—Process Automation* (WIA-PA) standards, which are very similar to WirelessHART.

### 36.4.6 Communication Technology

As mentioned, WirelessHART is the chosen communication standard for the storage tank heating control, because it's the most widespread used wireless communication standard for process automation domain. The RF chip is from the same vendor as used in the vibration monitoring application (see Section 36.4.3 for more information).

### 36.4.7 Challenges for the Future

WirelessHART and the other available standards such as ISA 100.11a, WIA-PA, ZigBee, and *IPv6 over Low-Power Wireless Personal Area Networks* (6LoWPAN) are mainly made for monitoring applications, and the standards lack a proper downlink communication channel. One of the more demanding challenges for control applications in the future is to offer deterministic communication and ensure that packets are delivered correctly within the given deadline. Up to now, neither of the aforementioned standards can guarantee deterministic communication and needs to be revised in order to enable fast wireless control applications, which have refresh rates about milliseconds. It should also be mentioned that 6LoWPAN adds additional overhead to the IEEE 802.15.4 since data/packet aggregation is needed. Furthermore, it will be even worse to guarantee delay constrained applications with the introduction of 6LoWPAN.

## 36.5 Communication Standards

---

The advent of WSNs brings many new and exciting technologies into the world of industrial automation. There are currently a number of initiatives underway for standardizing WSN for industrial use. General trend on the market is consolidation of suppliers and migration toward standards, most noticeably the release of WirelessHART and the development of ISA100. Additionally, a major automation network organization, PI (PROFIBUS) and PROFINET International, has decided to use WirelessHART as a base for its wireless process automation solution [7].

### 36.5.1 Standards Landscape

Table 36.3 provides an overview of the three main WSN standards targeting the industrial (process) automation market. Most fieldbus organizations refer to either one of these standards when they think about how to integrate WSN into their wired bus infrastructure. In addition, there are proprietary solutions out on the market, which could be considered de facto standards in certain niche applications.

**TABLE 36.3** Comparison of Key WSN Standards in Industrial Automation

	ZigBee PRO	WirelessHART	ISA100.11a	WIA-PA
Availability	2007	September 7, 2007	September 9, 2009	
PHY layer	IEEE 802.15.4-2006	IEEE 802.15.4-2006	IEEE 802.15.4-2006	IEEE 802.15.4c-2009
Standard specifics	Layers 3 and 7	Layers 2–4 and 7	Layers 2–4 and 7	Layers 2–4 and 7
Frequency	868 MHz 915 MHz 2.4 GHz	2.4 GHz	2.4 GHz	
RF transmission	DSSS (frequency agility) 2.4 GHz 16 channels 868/915:1 + 10 channels	FHSS 2.4 GHz 15 channels	FHSS 2.4 GHz 16 channels	
Media access	CSMA/CA optional GTS	TDMA, optional CSMA/CA in shared slots	TDMA optional CSMA/CA in shared slots	TDMA for CFP and CSMA/CA for CAP
Network topology	Mesh, star, hybrid	Mesh, star, (hybrid possible, but not specified)	Mesh, star, hybrid	Two layers: mesh and star
Bit rate	20 kbps at 868 MHz 40 kbps at 915 MHz 250 kbps at 2.4 GHz	250 kbps	250 kbps	250 kbps
Security	Symmetric keys, AES-128 encryption (enhanced security compared to ZigBee 2007)	Symmetric keys, AES-128 encryption	Symmetric keys, AES-128 encryption; optional use of asymmetric keys	Symmetric keys
Coexistence	CSMA/CA	Optional channel blacklisting, optional CCA, settable transmission power levels	Optional CCA, settable transmission power levels	CCA used in CAP

The following discussion gives some more details on the background of these standards. For a more technical description of the underlying technologies that are employed, see *Section 36.5.2*.

### 36.5.1.1 ZigBee

One of the best-known standards is the ZigBee standard, a low-power, low-cost, low-data-rate wireless specification, which targets home appliances, toys, industrial applications, building automation, and the like. The ZigBee standard is developed, managed, and promoted by the ZigBee Alliance [5]. The scope or focus of the ZigBee Alliance is on defining the network, security, and application SW layers, providing interoperability and conformance testing specifications and promoting the ZigBee brand.

### 36.5.1.2 WirelessHART

WirelessHART is the only industrial WSN standard currently available. It was released in September 2007 [3] and is a secure and reliable wireless technology for industrial applications ranging from class 2 to 5 (see Table 36.1), that is, from control to process measurement/monitoring. WirelessHART extends the well-known HART standard into the wireless domain, enabling new market areas for the large number of HART users. HART Communication [3] is a bidirectional industrial field communication

protocol used to communicate between intelligent field instruments and host systems. HART is the global standard for smart process instrumentation and the majority, more than 25 million of smart field devices installed in plants worldwide, are HART enabled.

### **36.5.1.3 ISA100**

Another ongoing initiative is ISA100\* (formerly called ISA-SP100) [2]. Originally, the intent of ISA100 was to standardize all elements in the system, instead only to specify the upper levels in the stack (i.e., the open standards interface [OSI] stack), with a number of potential lower-level implementations. This scope has been changed to include all levels of the stack as part of the specification.

The ISA100 workgroup also contained two subgroups that investigated wireless solutions for different use cases: SP100.11a aimed for control use cases, while SP100.14 targeted monitoring use cases.

Compared to WirelessHART, ISA100 takes a more generic path as an industrial WSN technology. It will support the transportation of many different fieldbus formats (where HART is one of them). ISA100 aims to support industrial applications in the range from class 1 to 5, that is, from critical control to monitoring.

The standard was released in 2009.

### **36.5.1.4 6LoWPAN**

6LoWPAN is an acronym for *IPv6 over Low-Power Wireless Personal Area Networks*, which is a protocol for transmission of IPv6 packets over IEEE 802.15.4 networks. This technology will enable the extension of the typical WSN structure into an IP-based system, basically allowing any computer in the automation plant to access any WSN device. It also allows reuse of existing IP network tools developed for home and office use, such as commissioning and network debugging support. In 2007, RFC 4919 with the problem statement and RFC 4944 with the protocol specification were published. RFC 4944 has since been extended by RFC 6282 with an improved header compression mechanism in 2011. Neighbor Discovery Protocol for 6LoWPAN technology is described in RFC 6775. There is a specification for applying 6LoWPAN technology to Bluetooth low energy, which is a part of the Bluetooth 4.0 specification, marketed as Bluetooth Smart. There are other Internet Engineering Task Force (IETF) WGs who are involved in 6LoWPAN-related work. The routing over low-power and lossy networks (ROLL) WG has a routing protocol for constrained node networks (RFC 6550). The CoRE WG is in the process of completing an application protocol (CoAP) that does many of the things that HTTP does well, with much less complexity.

### **36.5.1.5 WIA-PA**

WIA-PA is an acronym for *Wireless Networks for Industrial Automation—Process Automation*, which is an IEC standard developed by the Shenyang Institute of Automation, Chinese Academy of Sciences. Contrary to WirelessHART and ISA100.11a, WIA-PA retains full compatibility with IEEE 802.15.4, supporting Beacons, Guaranteed Time Slots (GTSs), etc. It also builds a two-tier network where a mesh network forms the backbone and star networks connect the sensor and actuator devices. WIA-PA is targeting the same applications as WirelessHART and ISA100.11a.

### **36.5.1.6 Proprietary Solutions**

There are many suppliers of proprietary WSN solutions, who offer a wide range of solutions, from bare technology/components (stack and HW) to complete WSN systems. There are also industrial automation suppliers who offer WSN solutions as part of their automation system.

However, the industry advocates the use of standardized solutions, and there is a strong trend to standardize solutions (like it has been for wired industrial communication technologies).

## 36.5.2 Technology Primer

### 36.5.2.1 ZigBee

#### 36.5.2.1.1 Architecture

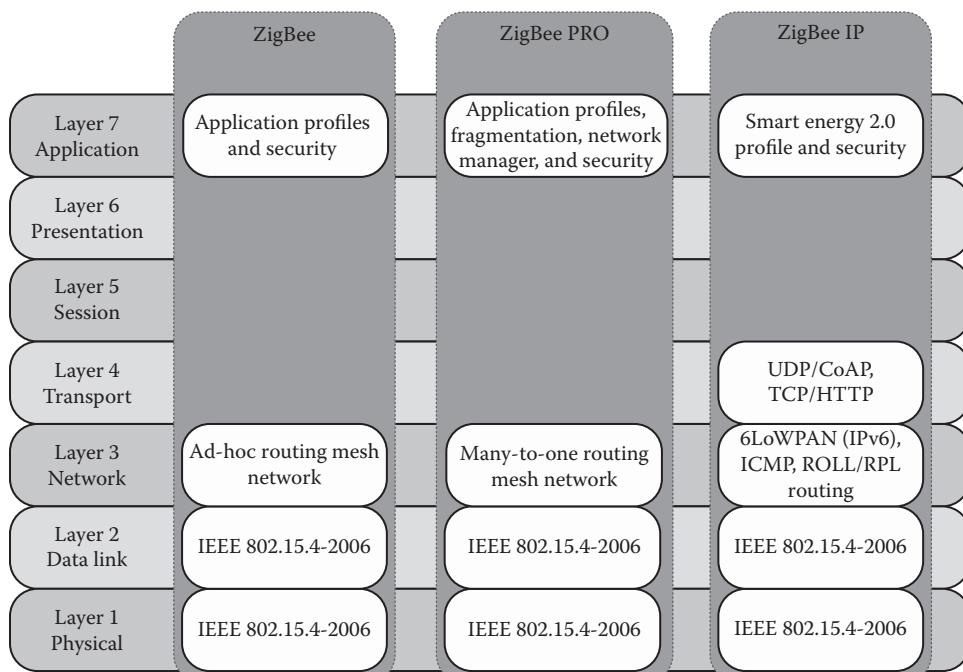

ZigBee is a specification for a cost-effective, low-rate, and low-power wireless communication protocol for home automation, monitoring, and control. It aims to provide short-range wireless networking, which is scalable, self-organizing, and secure, while providing battery life up to 2 years. Although having existed since late 2004, ZigBee has yet to prove its success, at least in the industrial domain where reliability and security are of utmost importance. ZigBee has been more successful in neighboring areas such as building and home automation, as well as for automated meter reading applications.

ZigBee is a specification for the higher protocol layers and builds upon the physical (PHY) and medium-access control (MAC) layers in the IEEE 802.15.4 specification [6], as seen in Figure 36.12.

#### 36.5.2.1.2 Basic Functionality

Mesh networking topology is supported, and routing is achieved through the ad hoc on-demand distance vector (AODV) algorithm. This means that the devices themselves are responsible for route discovery and that peer-to-peer communication is possible. In a ZigBee network, all nodes share the same channel, and frequency agility is minimal. There is no frequency hopping, and the only option is to scan for a channel with the least amount of interference at start-up.

There are two classes of network devices in ZigBee: full-function devices (FFD) and reduced-function devices (RFDs). The former can route messages in mesh networks and act as the network coordinator, whereas the latter can only communicate with one FFD in a star network setup.

**FIGURE 36.12** The different ZigBee protocol stacks.

ZigBee can operate in both beaconed and nonbeaconed modes. In the beaconed mode, the nodes are to some extent synchronized, and the superframe is divided into 16 slots. The slots in the frame are generally contention based, using CSMA/CA.\* There is an option to dedicate up to seven of these slots to specific nodes in order to increase determinism, so-called GTS. However, support for this is not mandatory, and use of this feature might break interoperability.

### 36.5.2.1.3 Security

In the 2006 version of the specification, security is not mandatory. However, support for authentication, integrity, and encryption for both network and application layer is present. MAC layer security available through 802.15.4 is not explicitly addressed in the ZigBee standard, and its use might break interoperability between different vendors' products. Replay attacks are protected against using sequential numbering. ZigBee makes use of the security mechanisms in 802.15.4, Counter with CBC-MAC<sup>†</sup> (CCM) with AES-128 encryption, but with the option to employ encryption only or integrity only.

Three key types are used: *master key*, *link key*, and *network key*. The master key is necessary to be able to join the network. The link key is used for end-to-end encryption and would by that provide the highest level of security at the price of higher storage requirements. The network key is shared between all devices and thus presents a lower level of security, though with the benefit of reduced storage requirements in the devices. All keys can be set at the factory or be handed out from the trust center (residing in the network coordinator), either over the air or through a physical interface. For commercial grade application, the trust center can control the joining of new devices and periodically refresh the network key.

### 36.5.2.1.4 ZigBee PRO

ZigBee 2007 is an update of the ZigBee specification, which specifies two profiles for the stack: the first profile, called ZigBee, is compatible with the earlier ZigBee 2006 stack version. The second profile, called ZigBee PRO, provides new features such as multicasting, many-to-one routing, higher security (using Symmetric-Key Key Exchange), frequency agility (possibility to change channel when the interference is too high), and fragmentation and reassembly.

### 36.5.2.1.5 Application Profiles and ZigBee IP

The ZigBee Alliance publishes application profiles for various areas, for example, Home Automation, Smart Energy, and Health Care. An application profile allows multiple OEM vendors to create interoperable products. In addition to specifying the application profile, the Smart Energy 2.0 profile also defines an IP-based protocol, called ZigBee IP, which replaces the ZigBee PRO stack.

ZigBee IP uses RFC (Request for Comment) specifications developed by the IETF, that is, 6LoWPAN (IPv6 for WPAN), ROLL, RPL (IPv6 Routing Protocol for Low-Power and Lossy Networks), etc., to form the ZigBee IP stack.

## 36.5.2.2 WirelessHART

### 36.5.2.2.1 Architecture

WirelessHART was designed based on a set of fundamental requirements: it must be simple (e.g., easy to use and deploy), self-organizing and self-healing, flexible (e.g., support different applications), scalable (i.e., fit both small and large plants), reliable, secure, and support existing HART technology (e.g., HART commands, configuration tools).

Figure 36.13 shows that the architecture of WirelessHART mimics the OSI layer design. WirelessHART is based on the PHY layer specified in the IEEE 802.15.4-2006 standard [6]‡ but

\* Carrier-sense multiple access with collision avoidance.

† Cipher Block Chaining Message Authentication Code.

‡ WirelessHART only supports the globally available 2.4 GHz ISM frequency band.

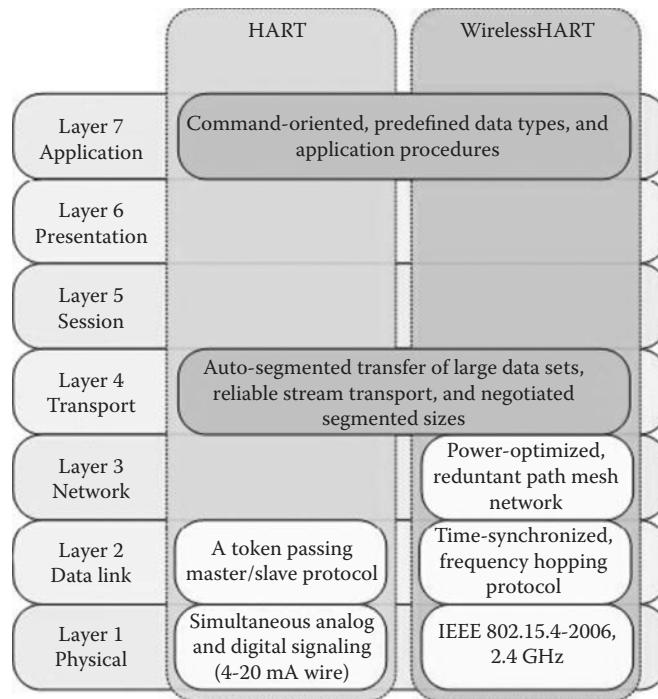

FIGURE 36.13 HART and WirelessHART protocol stacks.

specifies a new data link (including MAC), network, transport, and application layers. The figure also shows the backward compatibility of WirelessHART because it shares the transport and application layer with HART.

#### 36.5.2.2 Basic Functionality

WirelessHART is a TDMA-based network. All devices are time synchronized and communicate in prescheduled fixed-length time slots. TDMA minimizes collisions and reduces the power consumption of the devices.

WirelessHART uses several mechanisms in order to successfully coexist in the shared 2.4 GHz ISM band:

- *Frequency-hopping spread spectrum* (FHSS) allows WirelessHART to hop across the 16 channels defined in the IEEE 802.15.4 standard in order to avoid interference.
- *Clear channel assessment* (CCA) is an optional feature that can be performed before transmitting a message. CCA works like CSMA/CA but without using an exponential back-off. This improves coexistence with other neighboring wireless systems.
- The *transmit power level* is configurable at a node level.
- A mechanism to disallow the use of certain channels, called *blacklisting*, is available.

All of these features also ensure WirelessHART does not interfere with other coexisting wireless systems that have real-time constraints.

All WirelessHART devices must have routing capability, that is, there are no RFDs like in ZigBee. Since all devices can be treated equally, in terms of networking capability, installation, formation, and expansion of a WirelessHART network become simple (self-organizing).

WirelessHART forms mesh topology networks (star networks are also possible), providing redundant paths, which allow messages to be routed around physical obstacles, broken links, and interference (self-healing). Two different mechanisms are provided for message routing: *graph routing* uses predetermined paths to route a message from a source to a destination device. To utilize path redundancy, graph routes consist of several different paths between the source and destination devices. Graph routing is the preferred way of routing messages both upstream and downstream in a WirelessHART network. *Source routing* uses ad hoc-created routes for the messages without providing any path redundancy. Source routing is therefore only intended to be used for network diagnostics, not any process-related messages.

### 36.5.2.2.3 Security

Security is mandatory in WirelessHART; there is no option to turn it off or to scale it up/down. WirelessHART provides end-to-end and hop-to-hop security measures through payload encryption and message authentication on the network and data-link layers (DLLs). However, the security measures are transparent to the application layer.

WirelessHART uses CCM\* mode in conjunction with AES-128 block cipher, using symmetric keys, for message authentication and encryption.

A set of different security keys are used to ensure secure communication: A new device is provisioned with a *join key* before it attempts to join the wireless network. The join key is used to authenticate the device for a specific WirelessHART network. Once the device has successfully joined the network, the network manager will provide it with proper session and network keys for further communication.

The actual key generation and management are handled by a *plant-wide security manager*, which is not specified by WirelessHART, but the keys are distributed to the network devices by the network manager. A *session key* is used on the network layer to authenticate the end-to-end communication between two devices (e.g., a field device and the gateway). Different session keys are used for each pairwise communication (e.g., field device to gateway, field device to network manager). The DLL uses a *network key* to authenticate messages on a one-hop basis (e.g., to and from neighbors). A well-known network key is used when a device attempts to join the network, that is, before it has received the proper network key.

Keys are rotated based on the security procedures of the process automation plant.

### 36.5.2.3 ISA100

The following description of ISA100.11a is a snapshot of what the standard looks like at the time of writing (March 2008). The standard will very likely undergo some (minor) changes before the final version is released.

#### 36.5.2.3.1 Architecture

ISA100.11a is designed to fit the needs of many industrial protocols, such as HART, Profibus, and FOUNDATION Fieldbus. Its scope also includes parts of the plant backbone network.

Figure 36.14 shows an ISA100.11a network that includes a part of the backbone. The leftmost part, from the backbone routers and to the left, is called the DLL subnet, that is, it consists of nonrouting devices, routing devices, and backbone routers. However, in the simplest network scenario, the backbone routers are replaced by one gateway and manager device, which is directly connected to the plant automation network.

Figure 36.15 shows the architecture of ISA100.11a described in terms of the OSI reference. The *physical* layer is based on IEEE 802.15.4-2006 and so is the MAC part of the DLL. The upper part of the DLL handles all communications aspect in the DLL subnet part of an ISA100.11a network. A DLL subnet corresponds to a WirelessHART network, that is, a time-synchronized, frequency-hopping mesh network composed of field devices. The *network* layer is based on a subset of the 6loWPAN (IETF RFC 4944) specification, that is, sending IPv6 packets over 802.15.4 networks. The transport layer is also based on 6loWPAN, which specifies the use of user datagram protocol (UDP) for end-to-end delivery of packets.

---

\* Counter with CBC-MAC (corrected).

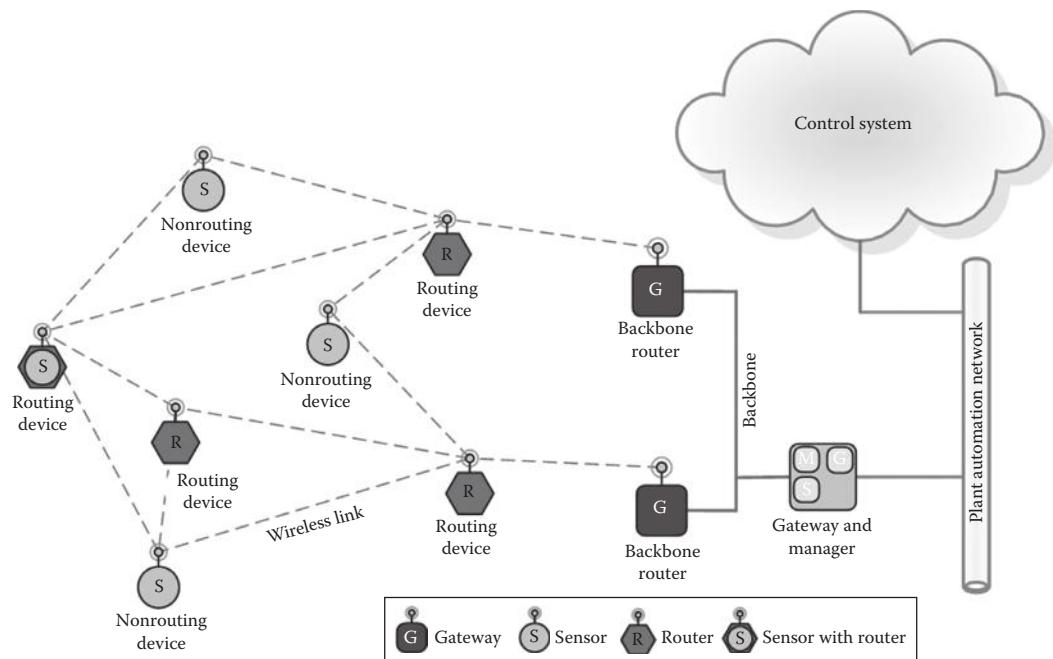

FIGURE 36.14 ISA100.11a network.

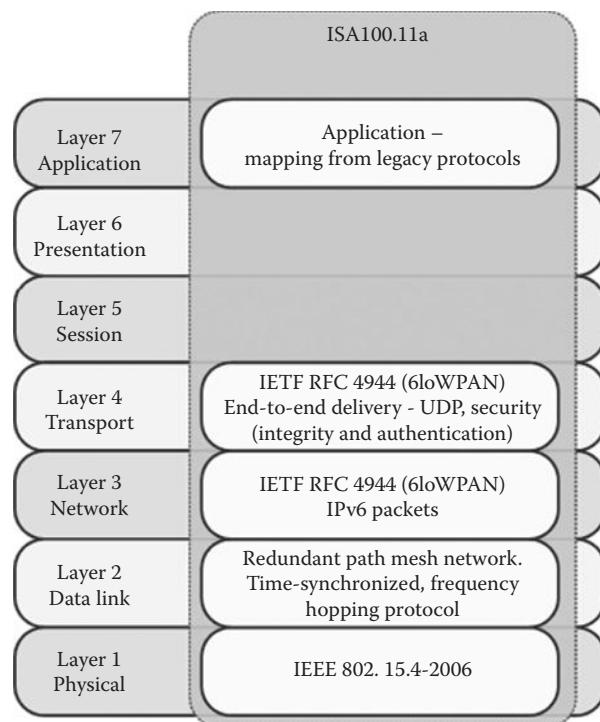

FIGURE 36.15 ISA100.11a protocol stack.

Note that UDP is an unreliable delivery service. Delivery reliability for a DLL subnet is handled in the DLL, whereas reliable delivery on the backbone network is handled by the backbone protocol, which is not within the scope of the standard. The transport layer also contains options for securing the delivery of packets, for example, encryption, authentication, and integrity.

### 36.5.2.3.2 Basic Functionality

As WirelessHART, ISA100.11a is a TDMA, frequency-hopping, mesh network. In addition, it supports the IPv6 protocol and the UDP transport protocol (through the use of 6loWPAN). Thus, all devices in an ISA100.11a network have an IPv6 address, which makes them globally visible within the plant.

In an ISA100.11a network, there are several different kinds of devices, as can be seen in Figure 36.14. ISA100.11a supports both *routing* and *nonrouting* devices, as well as a special kind of routing devices, *backbone routers*, which utilize the backbone in order to transport messages within, or between, DLL subnets.

The DLL provides time synchronization, frequency hopping, mesh networking, and routing, within a DLL subnet. A *time slot* in ISA100.11a can vary between 10 and 12 ms. This flexibility allows the use of *duocast*, which is a procedure in which each message is sent to two receivers, who both answer with an ACK on successful reception. Even if one transmission fails, the other might succeed, which increases the communication reliability of the network.

Frequency hopping can be either *slotted*, that is, the frequency is changed for every slot, or *slow*, that is, the frequency is only changed when several sequential slots have passed. Slow hopping relaxes the time synchronization requirements for devices, allowing low-cost clocks and crystals to be used.

ISA100.11a DLL subnets can have many topological shapes: mesh, star, or hybrid (a mix of both), and the network as a whole also incorporates the use of a backbone network. The gateway/manager device can be connected either directly to the DLL subnet via a radio or through backbone routers, in which case, it is located somewhere on the backbone network. Routing in DLL subnets is handled through the use of either graph routing (preallocated redundant paths) or source routing (ad hoc-created nonredundant paths), but routing on the backbone network is not within the scope of the standard.

### 36.5.2.3.3 Security

ISA100.11a provides a two-layer security measure: single-hop and end-to-end security. The single-hop security is handled in the MAC sublayer (DLL), and the end-to-end security is handled in the transport layer.

Both security layers use shared-secret symmetric keys (it is optional to use asymmetric keys) and AES-128 in order to provide encryption, authentication, and integrity checking. Payload encryption is optional in ISA100.11a. The ISA100.11a specification is designed with future *upgrades* of the security specification in mind.

### 36.5.2.4 WIA-PA

WIA-PA is an industrial WSN standard developed by the Chinese Industrial Wireless Alliance (CIWA) for the Chinese market. WIA-PA became an IEC Publicly Available Specification (PAS) in 2008 (IEC/PAS 62601), and in 2011, it was approved as an IEC standard.

#### 36.5.2.4.1 Architecture

WIA-PA is based on the IEEE 802.15.4-2006 standard and supports two types of network topologies: a hierarchical topology, which combines star and mesh, and a pure star topology. The hierarchical network topology that combines star and mesh (both based on IEEE 802.15.4-2006) is illustrated in Figure 36.16.

The first level of the network forms a mesh topology consisting of the gateway device and routing devices. The second level of the network forms several star topologies, where each star consists of field devices and handheld devices, which are centered around one of the mesh routing devices.

Figure 36.17 shows the OSI layers of the WIA-PA stack. WIA-PA is fully compliant with IEEE 802.15.4c and supports Beacons and GTSSs on the PHY and MAC layers. The two lowest layers of the

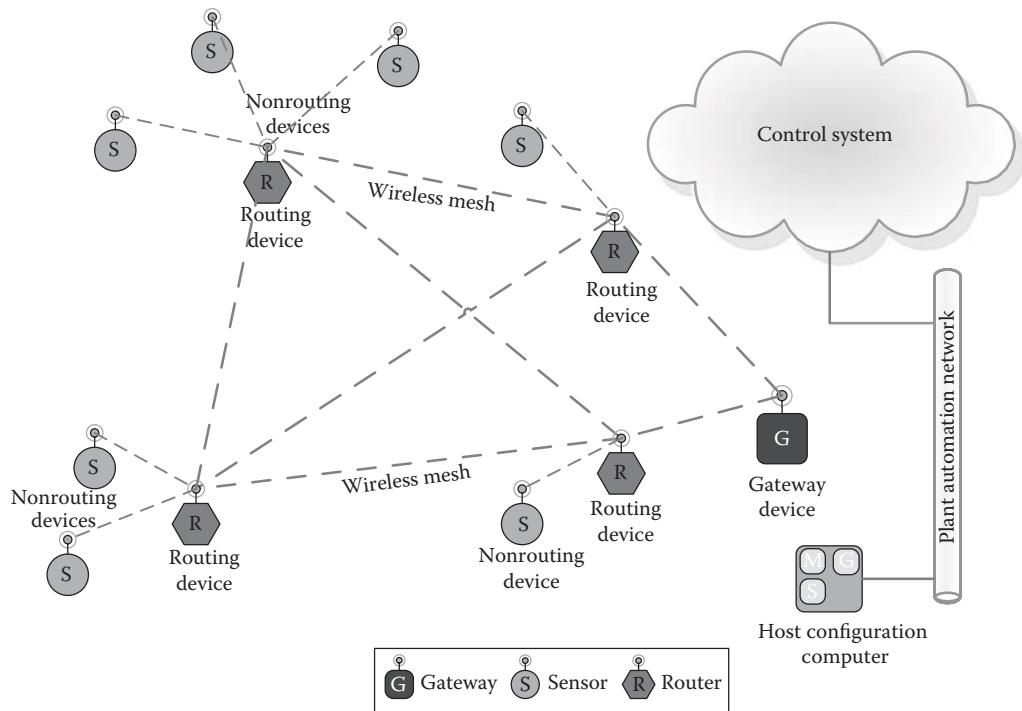

FIGURE 36.16 WIA-PA network.

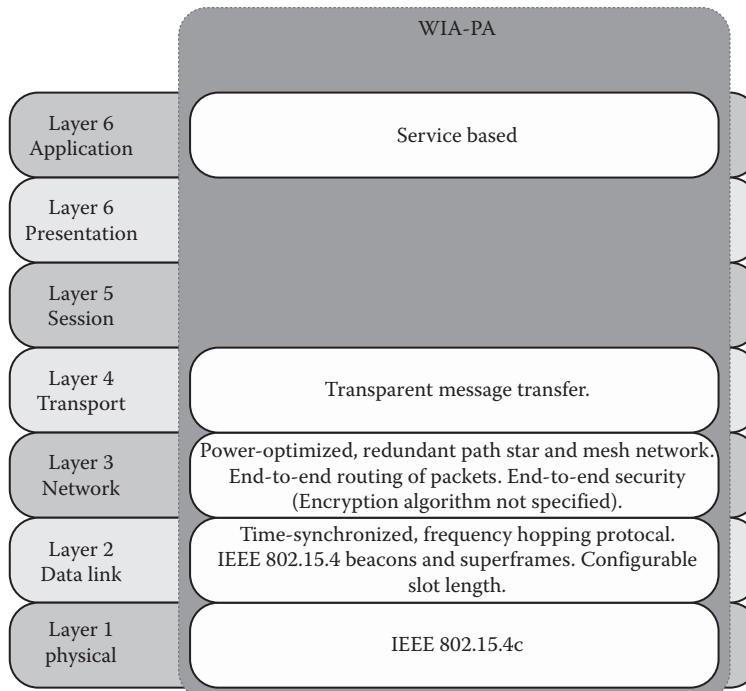

FIGURE 36.17 WIA-PA protocol stack.

stack (PHY and data link) form the star networks in WIA-PAs hybrid topology, while the upper parts of the stack (network and transport layers) form the mesh backbone network. Security is implemented on two levels: per-hop security on the DLL and end-to-end security on the application layer.

#### 36.5.2.4.2 Basic Functionality

As WirelessHART and ISA100.11a, WIA-PA uses time-slotted communication; however, it uses the beacons specified in IEEE 802.15.4. The network manager generates superframes (see for each routing device, where the superframe length is set as the lowest data update rate of all the members in the star network of that router). WIA-PA uses shared time slots for transmission of aperiodic data, and dedicated time slots are used for intra- and intercluster transmission of periodic data.

WIA-PA also supports frequency hopping and uses three different mechanisms for this. Each of the mechanisms is tailored for different types of communication. *Adaptive frequency switching* is used to change the channel for the Beacon, contention access period (CAP), and contention-free period (CFP) for each superframe period. The channel is only changed if the conditions are bad. *Adaptive frequency hopping* is used for intracluster communication and changes the channel per time slot and only if the channel condition is bad. *Time slot hopping* is used for intercluster communication and always changes the channel for each time slot.

WIA-PA uses static routing, which is configured by the network manager based on information on devices' neighbors.

WIA-PA supports both data and packet aggregation. *Data aggregation* is used by the source of the data to combine several data packets into one packet before sending it to the router device. *Packet aggregation* is used by routing devices to combine several data packets from different field devices.

#### 36.5.2.4.3 Security

WIA-PA provides a flexible way to use the security measures defined in the IEEE 802.15.4 standard. Both data integrity (message integrity codes [MICs]) and confidentiality (encryption) are provided on the application and DLLs (i.e., end-to-end and per-hop security). Security is optional in WIA-PA, and it is possible to configure the use of either application or DLL security separately as well as if MIC or encryption-only protection should be used. There is also an option to encrypt the application layer payload. The MIC and AES-128 encryption guarantee integrity and confidentiality for communication on the DLL.

### 36.5.3 Why Is ZigBee Not Enough?

Since any problems with the equipment translate to economical loss for an industrial user, reliability is a primary concern for these users. Hence, parameters like network robustness, reliable message delivery, authentication, and integrity are all important for industrial use. Moreover, the threat of industrial espionage advances the requirement for encryption to hide information that can reveal anything about the production in the plant to competitors.

One of the loudest arguments against ZigBee has been the lack of industrial-grade robustness. First of all, in older versions of ZigBee, there was no frequency diversity since the entire network shared the same static channel, making it highly susceptible to both unintended and intended interference. This has been remedied in later versions (i.e., ZigBee PRO), which add frequency agility in order to increase the robustness. However, at that time, many industrial efforts to develop robust wireless communication were underway or even completed; unfortunately, ZigBee was probably too late with the additions to have an impact on the industrial area. It has, and is, expected to have a bigger impact on the neighboring areas of home and building automation.

Secondly, there is no path diversity meaning that in case a link is broken, a new path from source to destination must be set up. This increases both delay and overhead and eventually will consume all bandwidth available.

Battery operation for routers with many peers is not realistic, since the CSMA/CA forces it to keep its receiver on for a large part of the frame. Keep in mind that industrial users require several years of battery life, since frequent battery change on thousands of sensors is not an option.

Security in ZigBee can to a great extent be set up to meet the requirements from industrial users, although care must be taken to use equipment from vendors, which support the necessary security mechanisms. A good guideline for ZigBee security is found in [8].

In summary, the harsh operating environment and battery operation and lifetime requirement render ZigBee a nonviable option for the industrial automation application. WirelessHART, ISA100.11a, and WIA-PA on the other hand are very suitable as they are designed to be very robust communications technology in the presence of interference and fading. In addition, these standards have features that allow them to efficiently coexist in a *crowded* frequency band, that is, they are *nice neighbors*.

## 36.6 Low-Power Design

In this chapter, we dive more deeply into the issues related to low-power design of HW, SW, and the communication protocol.

### 36.6.1 Basic Principle

The aim is to use the available resources within the acceptable limits of the specification and never have anything powered up, if it doesn't have to be. The task reduces to switching units, such as the sensor, CPU, and transceiver on and off with the right timing. Assume a node needs to wake up at regular intervals and transmit its sensor value if it differs from the last value by more than a predetermined amount. After the value has been sent over the radio channel, the unit waits for an acknowledge message indicating that the packet has been correctly received.

The required behavior of the node is best explained using what is known as a state diagram—a schematic representation of the state the node is in, the events that may cause it to move from one state to another and the actions associated with each state transition.

Figure 36.18 illustrates a typical high-level state diagram for a sensor node, in which the *measure* and *send* states together form an operational mode. The transition from active to sleep is managed by a sleep–wake-up scheme, which has been derived from the measurement of duty cycle requirement.

A natural prerequisite to implement an efficient sleep–wake-up scheme is that the active/sleep state of various system components can be controlled externally. If and how this is accomplished can vary greatly between components and can have quite an impact on the duty cycle of the device.

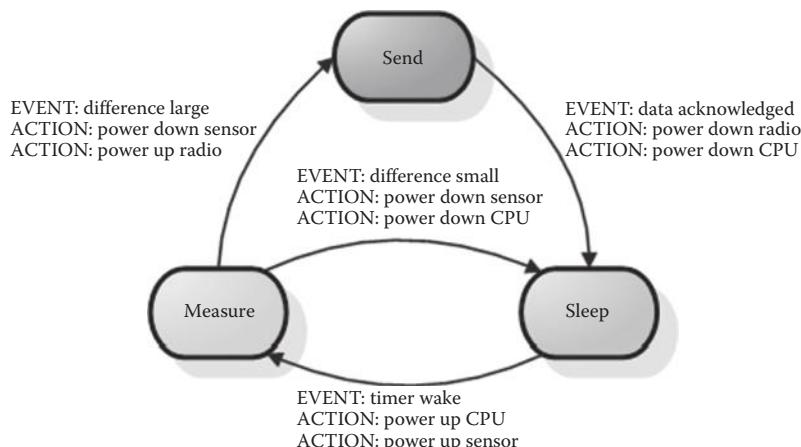

FIGURE 36.18 Sensor node state diagram.

# WIRELESS VIBRATION MONITORING CASE EXAMPLE

The vibration sensor is build around the following controllable components:

- *CPU*: The microcontroller has several controllable low-power modes.
- External *real-time clock (RTC)*: The clock can be powered on and off as well as controlled using its *normal* SW interface.
- *Radio chip*: The radio is a *black box* that only provides on/off control as well as a reset possibility.
- *Analog filter electronics*: These filters can be powered on and off.

The state diagram shown earlier is rather simplistic as it only shows the *normal* measurement use case. In real life, many additional and alternative use cases need to be considered. As the following sections will show, this simple state chart can become quite complex to design.

## 36.6.2 Sleep Modes

The first parameter to consider is the power consumption in normal operating mode (i.e., active mode) for the CPU, sensor, radio transceiver, and possibly other elements such as external memory and peripherals. However, since the sensors spend most of their time *sleeping*, it is important that the consumption during sleep mode is low. Often, we can switch power to the sensor and transceiver off completely. However, the CPU will need some form of sleep mode from which it can be woken. The consumption in this sleep mode is absolutely crucial for the overall power budget.

Additionally, one must ensure that all the necessary elements can be controlled by the CPU. It is the master in the system and needs to have complete control over the other functional blocks. However, the possibility to exert this control often varies in the different power modes supported by the CPU. The lowest power-saving mode typically shuts down (stops) the CPU, which will not allow it to control anything.

# WIRELESS VIBRATION MONITORING CASE EXAMPLE

The CPU, a Texas Instruments MSP430 variant, used in the vibration monitor device supports five low-power modes. The CPU can be operated at voltage levels ranging from 1.8 to 3.6 V. When operating at a 3.0 V supply level, the *lowest* power-saving mode (the CPU is practically turned off) typically requires 0.1  $\mu$ A; in *standby* mode (next lowest), it requires 1.6  $\mu$ A; and in *active* mode, it requires 400  $\mu$ A. Looking at these numbers, it's obviously most desirable to use the *off* mode during sleep time, as it has a  $16 \times$  lower power consumption compared to the standby mode. The drawback with the *off* mode is that the CPU can only wake up from external stimuli (i.e., an externally generated interrupt), which is not the case in the standby mode (or any of the other low-power modes).

One aspect that is often overlooked is the time the elements need to turn on and off. For example, the transceiver will need some minimum time for its oscillators to stabilize. While they wait, both the transceiver and the CPU burn power. This therefore needs to be minimized. The same obviously holds true for both the CPU and the sensor.

## WIRELESS VIBRATION MONITORING CASE EXAMPLE

The sensor node uses analog electronic components to filter the *raw* vibration signal into a desired format. The CPU has control over the activation/deactivation of this analog part and only activates it for the duration of the measurement. The analog part has a fairly long settling time, ~15 s, which forces the node to wait until a usable signal is available for processing (fortunately, the CPU can spend this time in the standby low-power mode).

Another very important settling time is the time it takes for the CPU to become fully operational when waking up from a power-saving mode. For the MSP430 variant used, this time is only 6  $\mu$ s from both the *off* mode and the standby mode. But the *off* mode has the added benefit of allowing us to further decrease power consumption by shutting off the oscillator signal from the RTC to the CPU (which is used to generate the CPU clock). However, without the oscillator signal, the CPU will default to an inaccurate, internal, RC-generated, lower-frequency clock. Thus, when waking up from the *off* mode, the RTC oscillator signal has to be activated before the CPU will stabilize, which adds to the 6  $\mu$ s wake-up time.

Timers are an integral part of any sleep–wake-up scheme. Generally, ultralow-power CPUs only have 8- or 16-bit resolution timers, which, when used to generate interrupts at scheduled timeouts, have fairly *short* maximum intervals (in the order of a few seconds). If a longer sleep interval is desired, the timer is forced to wake up (i.e., the CPU becomes active), reset its counter, and go to sleep several times during that interval. Furthermore, in some power-saving modes (as described in the previous example), the CPU shuts down its internal clock, which disallows the use of the internal timers. Thus, if internal timers are the choice for the wake-up scheme, some power-saving modes will not be usable.

## WIRELESS VIBRATION MONITORING CASE EXAMPLE

The duty cycle of the vibration monitoring device is 2 weeks. The MSP430 CPU used is driven by a 32 kHz crystal, and only provides 16-bit timers, which equates to a maximum interval of only 2 s. This would require the timer interrupt to (1) activate, (2) reset the timer counter, and (3) decrement the total sleeping time, a total of 604,800 times (14 days = 1,209,600 s and a 2 s time-out) during the 2-week interval! In combination with the desire to use the lowest power-saving mode (*off* mode) of the CPU, the solution was to choose an external timer, that is, an RTC, which supports very long time-out intervals (actually years), and allows the CPU to stay in the *off* power-saving mode during the sleep time.

### 36.6.3 HMI

As noted in previous sections, a local HMI is commonly required to check the status, calibrate, and maybe even instruct the device to perform a measurement. From a low-power-design point of view, this represents additional components that consume power. Depending on the requirements on packaging or the available power budget, several alternatives are used in the industry ranging from simple LEDs and buttons to LCDs. When designing the HMI functionality, great care must be taken how the HMI is used. As battery-powered systems cannot afford to constantly have the HMI active, it must therefore be switched on and off at appropriate times, while maintaining a user-friendly interface (e.g., that responds in a timely manner according to your expectations).

When the HMI is used to asynchronously wake up a device and maybe issue a request to perform a measurement, the normal duty cycle is changed, which will result in a different power consumption of the device. The update rate of an HMI is typically a lot faster than the normal duty cycle of the WSN devices (since it's often used to get a *quick snapshot* of the process). If the HMI is used extensively, not only will the HMI consume power, but the device will also run according to an entirely different, from the planned, duty cycle. This could result in early depletion of batteries or even peak power consumption that exceeds the bounds of the available power.

## WIRELESS VIBRATION MONITORING CASE EXAMPLE

The vibration monitoring device has an HMI consisting of two LEDs and one button. The LEDs are used to indicate activity, such as powering on/off, status (sleeping or active), and transmitting data. The button is used to activate or deactivate the device, force it to start a measurement, and consequently transmit the data to its destination.

The device uses low-power LEDs, which each have a current consumption of 2–4 mA when lit (LEDs are normally specified for a 4–20 mA consumption); the exact consumption depends on the supply voltage level (2.7–3.6 V). Compared to the current consumption of the CPU in active mode, 400 µA, this is a very high consumption.

To further lower the power consumption of the HMI, it is only activated when a human is interacting with the device. Although it makes no sense to blink a LED if no one is watching, there are situations when this could be necessary, for example, if the sensor is in a hard-to-reach place but can be inspected visually. The button is used to interact with the device, and the response is always indicated by blinking the LEDs in different patterns. This pattern, for example, short blinks and long blinks, indicates the internal state of the device (sleeping, measuring, sending, etc.). In order to even further decrease the power consumption of the LEDs, the digital I/O pins used to control them are set to an inactive state when they are inactive.

It's important to note that an HMI does not necessarily have to be a physical component within the device itself. For example, a handheld unit could communicate (wired or wirelessly) with the device and request data outside of the normal duty cycle. The same goes for a remote terminal connected to the

network, which would cause additional traffic routed through the network. This means that in order to make any guarantees in terms of battery lifetime, the topology and usage scenarios need to be clear for the entire network.

### 36.6.4 Energy-Efficient Protocols

In addition to utilizing low-power electronics and a clever SW architecture (i.e., sleep–wake-up scheme), the communication protocol has a major impact on the final power consumption of the system. The communication protocol prescribes when the system needs to wake up, how it synchronizes, how long it needs to stay on, etc. Relevant protocol design choices from a power consumption point of view include the following:

- Media access scheme: In a contention-free media access scheme, for example, TDMA, collisions are minimized, thus requiring less active time to send the data. The reverse is true for contention-based media access such as CSMA, where the node first has to listen before it can send its data (which degrades rapidly when there is lots of communication).
- Topology: The topology not only affects the timeliness of message delivery but also the power consumption. In a multihop system, a node may have to wake up to forward data from other nodes, which is not the case for a single-hop system. In addition, intermediate nodes don't know when they may be called upon to route packets for others. This is what motivates the hybrid mesh topology with mains-powered router nodes shown in Figure 36.8.
- Data package size: The size of the payload, header, CRC, etc., all have a direct impact on how long the radio needs to be turned on to send its data. This is regardless of what media access scheme is employed. When designing the protocol, a trade-off has to be made between throughput, latency, and power consumption, and at least one of them has to suffer.
- Security: It is important that the data are secured from intentional corruption (i.e., integrity) and that it is sent from a valid device (i.e., authentication). Security adds overhead to the packets and to the computation performed at the devices (i.e., to check the integrity and authenticity). This, in turn, possibly leads to the need of specific HW (i.e., encryption support) in order to achieve the required communication timing requirements.

Details in the communication protocol thus dictate the lower bounds of the consumption. Some communication protocols are notoriously inefficient, and no smart embedded programming in the world will help get the consumption down to an acceptable level. Others are designed to give low consumption without unduly compromising communication performance. The WISA [9] platform is one such low-power protocol. The high performance can be attributed to two reasons: it is single hop and it uses time-division multiplexing (TDM). The former avoids delays in intermediate nodes. The latter guarantees that a node will be alone on the channel, that is, there will be no collisions. WISA is designed for manufacturing control applications, which require high node density and deterministic response times but have rather relaxed requirements on throughput and range.

The recently developed WirelessHART specification with the underlying 802.15.4 protocol is more general but will have lower communication performance. It specifies multihop, where a message can use several radio hops to get to its destination. This introduces uncertainty in the delivery time of a message but extends the range while keeping power consumption acceptable.

In short, the WISA protocol is well adapted to the requirements of discrete manufacturing, while WirelessHART is ideally suited for asset monitoring applications.

# WIRELESS VIBRATION MONITORING CASE EXAMPLE

In the WSN of the reference case, all nodes have the capability of routing traffic. The network manager continuously changes communication links in the mesh network, in order to cope with fading and interference, as well as trying to evenly spread traffic over all nodes (thus evenly spreading the power consumption between the nodes).

Furthermore, the TSMP solution provided by DUST networks allows the designation of leaf nodes, that is, nodes that will never route any traffic. This provides the possibility to form a mesh *backbone* network consisting of pure routing nodes (i.e., without vibration measurement capability) and to have all sensor nodes configured as leaf nodes, which will further decrease their energy consumption.

## 36.7 Packaging

### 36.7.1 IP Rating

The international standard IEC 60529 [10] classifies the degrees of protection of an electric system against solid and/or liquid. The rating consists of the letters IP (International Protection marking) followed by two digits and an optional letter. Certain IP codes require that the device is completely sealed, which might cause problems for the antenna (detuning) and battery design. A completely sealed device does not permit an easy access for battery change. The sealing could also force the use of an internal antenna, that is, inside the housing.

### 36.7.2 Hazardous Environments (EX)

When designing devices intended for use in potentially explosive atmospheres, special measures need to be taken to prevent or minimize the risk of explosion. This means that you must consider

1. Every possible electrical or nonelectrical source of ignition
2. All potentially hazardous environments where the device could be deployed
3. The different ways the device could be deployed and the technical ability of the person using the device

To design and develop devices for hazardous environment requires long experience in the field as well certification by a notified body. The overview provided in this chapter should thus not be considered a cook book for safe designs.

Conformance to a number of standards is required to achieve EX certification. The IECEx\* Scheme [11] was created to facilitate international trade in equipment and services for use in explosive atmospheres, while maintaining the required level of safety. The IECEx Scheme is based on the use of specific international IEC Standards for type of protection of EX equipment. Since July 2003, EX products that are placed on the European market must be certified to the ATEX† directive (ATEX 94/9/EC) [12]. This involves the testing and assessment of such products to the latest ATEX standards.

---

\* International Electrotechnical Commission for Certification to Standards Relating to Equipment for Use in Explosive Atmospheres.

† From the French—Atmospheres Explosibles.

To achieve an EX safe design, a number of principle protection concepts are applied, depending on the applications and target hazardous area (zones):

- Nonsparking devices: Typically applied to transformers, motors, cells, batteries, etc., but not appropriate for equipment or components containing semiconductors. Protection relies upon a dust/watertight enclosure to avoid tracking across live circuits.
- Keep flammable gas out: Encapsulation (enclosing circuit in potting compound), oil immersion, or pressurized enclosures to keep the potentially explosive atmosphere away from the source of ignition. The downside of this approach is that it adds significant cost and weight to your design and sacrifices accessibility and serviceability of the device.
- Limit energy of sparks and surface temperatures: Protection relies upon an electronic design that limits the emitted/transferred power of the device and prevents hot surfaces above the given temperature class. This approach is commonly referred to as *intrinsic safety*.

An IS design has built-in measures to prevent excessive heat buildup and the danger of an electric spark. To achieve this, you need to put limitations on voltage, current, capacitance, and inductance to ensure that the available energy within the device is below the minimum ignition energy of the potentially explosive atmosphere.

A practical implication of this is that you need to limit the maximum amount of energy supplied by the power supply, as well as dividing your design into clearly isolated blocks and limiting the energy transfer between these blocks. The interfaces between the system blocks thus constitute the majority of the design work and also have the most dramatic impact on other design aspects.

Additional components are typically required to limit discharge energy or isolate blocks, for example, resistors, fuses, and zener diodes. These additional components tend to increase the overall power consumption of the device as you will experience losses when traversing through the different blocks of your design.

In addition to providing means for limiting the energy, you also need to provide some guarantees that these protection and power-limiting components will not fail. When designing an IS circuit, all possible scenarios for connections of components need to be considered when calculating the safety circuit parameters. Defining clear interfaces helps to determine worst-case failure mode and devise possible solutions to handle these failures. Typically duplication or triplication of components is required, as well as using the components below their specified ratings and observing sufficient creepage and clearance distances. This further lowers the efficiency of the device and can impact the form factor of the device and require additional redesigns.

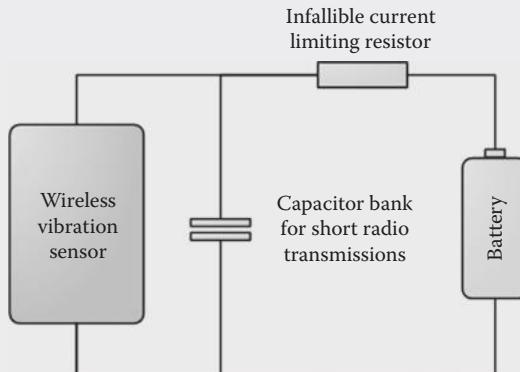

Since a component with a high surface temperature could cause an ignition of the gas, the maximum temperature of any component on a circuit board under fault conditions must be considered. Limiting the energy alone does not automatically result in a low component surface temperature, especially when considering small components. This means that you need to take great care when selecting components and ensure that the heat dissipation is satisfactory to avoid an excessive heat buildup. Usually this is solved by choosing sufficiently large components, which again can impact the overall form factor of the electronics and lead to space problems.

# WIRELESS VIBRATION MONITORING CASE EXAMPLE

A battery with IS approval was selected. The battery is connected to the PCB of the device via an infallible current-limiting resistor. This will ensure that the maximum power loss in any component on the PCB is limited. The temperature rise can then be calculated for each component on the PCB.

In addition, the resistor was carefully chosen with a specified temperature rise that will ensure that the maximum power dissipation in the resistor upon a short will not result in an unacceptable temperature rise in the resistor.

Since the battery voltage level will vary with the surrounding temperature, we might not have enough energy to operate the radio circuit under all conditions (especially during start-up). To solve this, a capacitor bank was connected across the power supply. The capacitor bank stores just enough energy required for the radio transmission. The capacitor bank was carefully designed to comply with relevant safety standards (Figure 36.19).

**FIGURE 36.19** Principle battery design.

### 36.7.3 Other Environmental Considerations

In addition to the IP and EX environments described earlier, most industrial environments are also subject to vibration and extreme temperatures.

In an environment where the device is subject to severe continuous or occasional vibrations (shock), there is a risk that internal components will shake loose due to these vibrations. Therefore, as a protection, a device can be filled with a shock-absorbing material. Drawbacks with this solution are that the filling materials usually have a high cost and can force a design solution where the battery is also encased in the material, which make battery changes impossible.

Depending on the specified tolerance of the device components, a high or low temperature can force the device to have a thermally insulating housing or some kind of cooling mechanism to protect its internal components. Thermal insulation housing consists of materials that do not transfer heat quickly, in order to separate and insulate the sensitive internal components from the external temperature. It is also possible to have a thermally insulating barrier, a non-heat-conducting material positioned between the hot/cold part and the critical part of the device.

There are different kinds of cooling mechanisms available: active, such as fans, and passive, such as heat sinks and heat pipes. A problem with active cooling components is that they also wear out and

could pose problems if they fail, for example, overheating. This would require maintenance of the cooling mechanism on the device, possibly outside the normal maintenance schedule, which is too costly. Thus, active cooling is not a desirable solution.

### 36.7.4 Form Factor

The form and shape of an embedded device is very important. It depends on various requirements, such as

- The environment where the device will be located, which usually is very close to the process it will monitor
- Possible reuse of legacy housing
- Mounting requirements
- Design guidelines of the device manufacturer

The housing material of the device is also a very important part of the form factor. As mentioned in the previous subsection, there might be a requirement for the material to be thermally insulating or cooling or just that it should be rugged, which also affects the physical dimensions of the device, for example, weight difference between a metal and a plastic housing. Casting or filling also affects the weight of the device and can also make component replacement or upgrading impossible, for example, battery replacement.

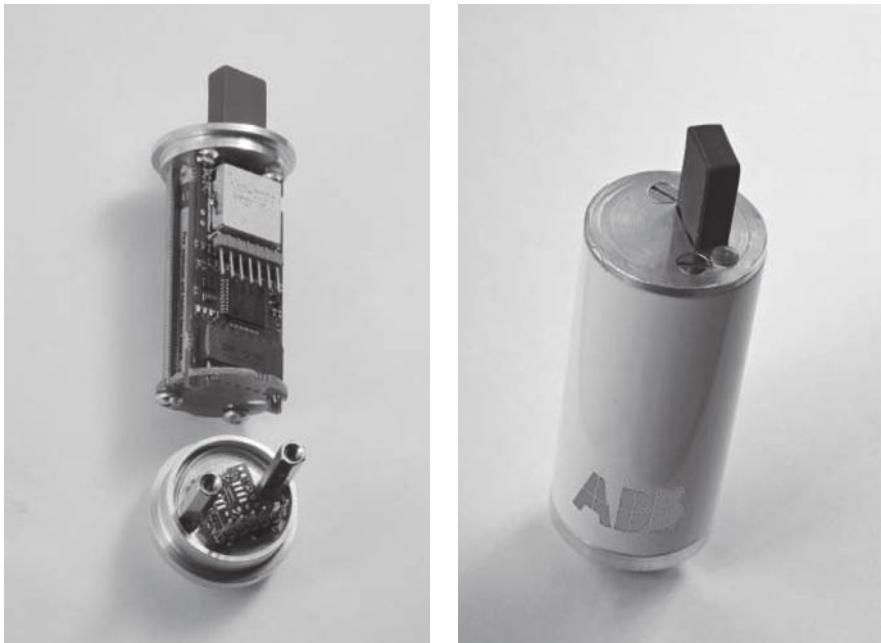

The power source, for example, a battery or capacitor, will affect both the weight and physical shape of the device and thus has a major influence on the design. Batteries (and capacitors) have a correlation between stored power and physical dimensions, that is, larger batteries can store more energy. If the form factor forces a certain maximum physical size for the power source, the device's life length will be effectively limited by that size. Low-power design will push the limits of the device's life length based on the resulting power source.

The resulting physical form can impose limitations and requirements on the design of the PCB and positioning of electronic components, which could have performance and maintenance effects. For example, the form factor could force the antenna to be mounted at a nonoptimal position (i.e., from a radio communication point of view), which could cause degraded communications performance. It is also possible that when selecting certain components, or a combination of components, the whole PCB must be redesigned in order to fit the components onto it in conjunction with having it fit within the device housing.

## WIRELESS VIBRATION MONITORING CASE EXAMPLE

The physical form and shape of the vibration monitoring device is very much dictated by the dimensions of the battery, which is selected based on the life-length requirements on the device. This in turn restricts the shape of the PCB and thus the area available for mounting electrical components. The result is a cramped area, which has forced a solution that uses both sides of the PCB for component mounting (which has a slightly higher cost).

The weight of the device is also an important requirement. It should be as low as possible because the device weight directly influences the quality of the vibration measurement (a heavy device is harder to move, i.e., vibrate). A related requirement is the size of the mounting area for the device; this should be as small as possible while still be large enough to provide solid mounting, which also affects the quality of the vibration readings. Finally, a more esthetic requirement is that the device should have a similar look and feel as a rugged industrial accelerometer.

## 36.8 Modularity

The main driving force behind a modular design is improved maintainability, that is, how easily we can modify the device in order to fix bugs, implement new functionality, and upgrade to another SW/HW version. This is achieved by a clear separation of system features into modules or components that overlap in functionality as little as possible. These HW/SW modules are integrated into the device via clearly defined interfaces, which provide an abstraction of the module, that is, a separation of the external communication with the module from its internal operations. This means that (in theory) you are able to modify the module internally or even replace it with another similar module, without affecting how the rest of the device is operating or interacting with the module.

However, modularity comes at a cost as it places restrictions on the design, and care must be taken to ensure that the interfaces between modules are sufficiently general, while adhering to the nonfunctional requirements (response time, footprint, power consumption, etc). Table 36.4 illustrates some typical aspects or goals of a modular design and their trade-offs.

**TABLE 36.4** Modularity Trade-Off Examples

Aspect	Pros	Cons
Reuse elements	Minimized development effort due to reuse of HW/SW design (and code)	Lower performance (footprint, response time, power consumption, etc.) due to increased overhead
Risk reduction	Design based on well-proven and tested components	Integration of several components can result in unclear/untested behavior
Migration	Minimized effort to migrate to other (newer) SW/HW versions	Lower performance due to <i>wrappers</i> needed to maintain system interfaces
Cost reduction	Lower cost due to second source and larger volumes ( <i>standardized</i> components)	Added cost due to additional resources required to support the <i>standardized</i> components

As modularity does come at some cost, we have to balance the need for a highly modular design with, on one hand, the nonfunctional requirements and, on the other hand, the products' envisioned life cycle. There is no need to pay the price for a highly modular system if you are going to change it once every 10 years. However, it can be quite tricky to foresee the maintenance need of industrial products very accurately as it depends on large variety of aspects such as new user requirements, deployment in unforeseen applications, and availability of the COTS components that make up the design. Some form of modular design is therefore generally speaking a well-invested development effort.

### 36.8.1 Levels of Modularity

What does a modular design really mean? Aren't all modern embedded systems modular in some sense since they are built on standardized electronic components that you purchase and integrate on a PCB? The answer is yes and no. Yes, the components are standardized and can be replaced by another brand or type, but this does not automatically equate to a design that enables easy modification, extensions, migration, or reuse of parts of the design.

There is always a value of standardizing on a given set of low-level components, but to achieve a higher level of maintainability, you often need to raise the level of abstraction and divide the device into a set of core system features that overlap in functionality as little as possible.

#### 36.8.1.1 HW versus SW Components

Standardizing on a given (set of) processors (CPU, MCU, DSP) of the same architecture has benefits in terms of reduced training cost of engineers and facilitates porting of SW. Reuse of PCBs, either actual HW or of layout with design modifications, has a direct saving in production cost, testing, and competence buildup. Reuse of mechanical solutions such as the packaging of the device often has large direct cost savings due to the elimination of design costs and cost of tooling. However, you need to balance the cost savings associated with utilizing a common housing; with the design restrictions, this will put on other parts of the design (form factor, antenna placement/design, etc.).

Reuse of SW components is advantageous under the condition that the sum of costs related to purchasing the code (internal or external), competence buildup, modification of components, integration of components, and testing is less than the cost of designing a component from scratch. Experience has shown that this is not easy unless other elements of the development organization are in place such as clear organizational roles, requirement management, and product platform architecture and design.

#### 36.8.1.2 Single versus Multiple Chips

One of the major design choices that must be made is whether to integrate functionality in one HW chip or to have it distributed into different chips. In certain cases, there is no choice; the desired functionality is only supplied as a separate chip, that is, as a COTS component, while in other cases, the component can be designed in house and suitably located. Typical functionality and subsystems available in a WSN device are CPU, radio communication, sensor, signal processing (filters, DSPs, etc.), RTC, external memory (RAM, ROM, flash, etc.), HMI (LEDs, buttons, etc.), and an AD converter. Many of these subsystems could be integrated into one chip, for example, the CPU could contain almost everything.

A typical design choice for a WSN sensor device is whether to separate the radio communication stack and the application into different chips (see Figure 36.20). To conclude on a suitable solution, a trade-off between low-level control, form factor, cost, overhead, and performance has to be made.

Figure 36.20 shows a very clean separation between the application and the communication stack. In reality, this separation is often far from clear. A typical example is what a stack supplier considers being part of the communication stack and what is considered to be the *application* (and thus excludes from the supplied stack offering).

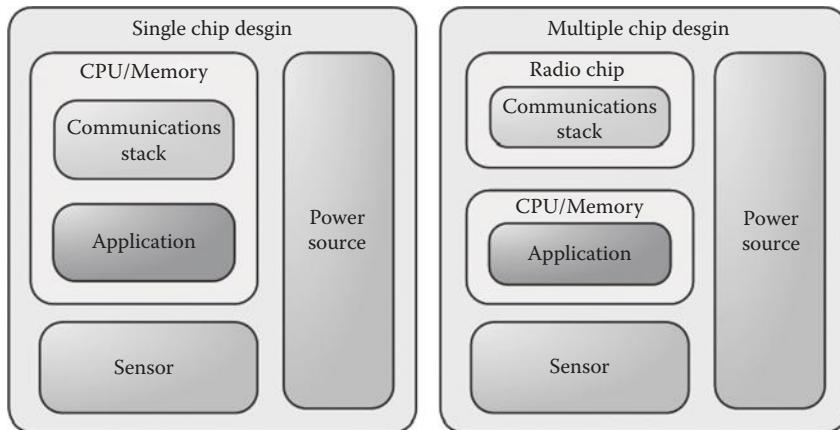

# WIRELESS VIBRATION MONITORING CASE EXAMPLE

In the reference case, the chosen communication solution, that is, DUST Networks SmartMesh-XD chip, provides a complete SoC solution, where both the HW and SW are hidden within the box.

However, a small portion of the communications interface resides outside the SoC component, possibly in the application. This is functionality that handles packet preparation, such as byte stuffing and FCS\* calculation for packets, which will be transmitted, and the corresponding operations for received packets.

This means that we need to implement communication-related functionality in the application, which normally would be considered to be part of the protocol stack.

\* Frame check sequence (FCS) calculation.

**FIGURE 36.20** Example of single- versus multichip solution.

Modularity can also be achieved at a lower level. For instance, the communication protocol can be seen as consisting of several blocks, known as the OSI layers. Given a healthy design procedure, one may be able to exchange a single layer with one from a different source. Obviously, the more the code is split up, the more modular it becomes. At the same time, the risk of suboptimizing increases, that is, the modules are optimized (with respect to power, performance, code size, etc.) individually, but this does not necessarily give a globally optimum solution.

### 36.8.1.3 Lifetime

Industrial automation devices have a life expectancy that could be measured in 10ths of years. This puts a lot of demand on a modular and flexible design, which is easily maintained. Even if the device functionality would not change over its lifetime (which is highly unlikely), we still need to cope with availability of components. For certain parts of a WSN device, where the technology changes more rapidly, this is especially critical. For example, the sensor part (see Figure 36.7) evolves quite slowly, whereas the radio and power source technologies evolve very quickly. This fact warrants a high degree of modularity around the radio solution, something that is not always advantageous from a performance point of view.

## 36.8.2 Interfaces

The key to achieving a good modular design, and thus being able to reuse components, are the component interfaces. The interface provides an abstraction of the component, that is, a separation of the external communication with the component from its internal operations. This abstraction enables the internal modification of a component without affecting how the rest of the device is operating or interacting with the component.

A well-defined interface allows for easy maintenance and reuse of the component, but since interfaces are a form of indirection, some additional overhead and decreased performance is incurred versus direct communication. A modular design can thus introduce extra overhead in the sense of protocols needed to communicate between the different components (using the interfaces), which leads to increased power consumption and can result in bottlenecks in the system. The reason is that the system can only operate at the *speed* of its slowest component, at least if that component is part of the central functionality of the system.

Reusing and exchanging integrated circuits (ICs) require that their interfaces are compatible with each other. This is commonly referred to as pin compatibility and comprises the following:

- Functional compatibility implies that two ICs have the same functions (inputs, outputs, power supply, ground, etc.) assigned to the same pins.
- Mechanical compatibility ensures that ICs can be inserted into the same socket or soldered to the same footprint.
- Electrical compatibility implies that the components work with the same supply and signaling voltage levels.

Pin compatibility can play a major role when choosing components as it offers a degree of freedom in terms of migrating from one HW component to another without requiring a complete redesign of the PCB.

## 36.8.3 Subsystem Behavior

### 36.8.3.1 Local versus Global Optimum

As discussed previously, the sum of the parts can equal more than the individual parts together, at least from a product maintenance point of view. However, great care must be taken to ensure that sum of the parts also provides adequate performance (speed, power consumption, footprint, etc.). Even if each component has been optimized individually (for speed, power consumption, footprint, etc.), this does not guarantee that the final system behavior is optimal.

The principle operation of a WSN device can be described by the generic state machine depicted in Figure 36.18. This describes the overall behavior of the WSN device. The components that make up your device will in turn have their own state machines. The timing and interaction between the components are thus critical to arrive at an optimal overall system behavior. Care needs to be taken to ensure that a given functionality from one component is available when it is needed (according to the overall device state chart) or that enough memory or power is available to execute the requested operation. This can be difficult to achieve, especially if COTS components are utilized where you have little influence over the internal behavior of the component.

### 36.8.3.2 Control Freak

When reusing components, either developed in house or COTS, they will provide an interface and level of control that could be nonoptimal from a low-power design perspective. For example, if the communications stack is a *black-box* COTS component, which only provides limited possibility of controlling its internal behavior, it could seriously affect the sleep–wake-up scheme and thus the power consumption of the device. How much control a component allows will thus dictate the low-power design, which we describe in more detail in *Section 36.6*.

The interfaces are thus the Achilles' heel of a modular WSN design. As stated earlier, they need to be sufficiently general to enable efficient integration and porting, while not adding an excessive overhead. In addition, the interfaces also need to provide some control of the internal behavior of the component to be able to mediate between generality and performance. This goes against the basic principle of information hiding employed by component-based development, where internal state information is not shared and interaction is accomplished by exchanging messages carrying data. However, in low-power WSN devices, where the system is asleep most of the time, this *low-level* control is sometimes crucial to adhere to the sleep-wake-up schedule of the device.

### 36.8.3.3 Debugging a Black Box

Using *black-box* components has the advantage that the functionality provided by the component is completely hidden. The developer thus does not need to bother about how the component works in detail, nor invest time and effort in testing and validating its functionality. In theory, this is true, but in addition to loss of control as described earlier, there is an additional risk that problems will appear when debugging the total system and the component functionality is part of the debug trace. As the name states, it's a *black box*, and there is no way to peer into the box to see what happens. This increases the difficulty of locating bugs, that is, determine if they are present inside the component or in other parts of the system. This problem is especially pronounced if the COTS component is itself in a *beta stage* (which is very common in early development phases of new technology) and bugs are certain to exist within it.

## WIRELESS VIBRATION MONITORING CASE EXAMPLE

In the reference case, a *black-box* communication solution was chosen, that is, DUST Networks SmartMesh-XD chip. It's actually a complete SoC solution, where both the HW and SW are hidden within the box. There is very limited control over how the communication is managed, for example, the protocol and wake-up scheme for radio.

A small portion of the communications interface resides outside the SoC component, possibly in the application, which handles packet preparation. This makes the integration between the SoC and the rest of the system very tight.

The advantage is that minimal design effort has to be spent on the communications protocol. But the drawback is that debugging is very difficult because of the limited control and debugging support available through the provided interface.

## 36.9 Power Supply

The power supply is a central part of the WSN device; it's the *motor* that provides power to the various parts of the system. This motor can take many different shapes and forms and consequently provide varying degree of performance and lifetime. The general requirement is an energy autonomous system that requires little or no manual intervention (charging, maintenance, battery change, etc.) to

operate throughout its target lifetime. This requires a thorough requirement analysis of the power demands and a clever design that is able to bridge power outages and handle variations in power consumption.

### 36.9.1 Requirements

#### 36.9.1.1 Power Demands

Before deciding on a suitable power-supply technology, the power demands of the system need to be clearly defined. The power demand is directly related to the sleep–wake-up scheme of the device as discussed in *Section 36.6*. It can thus be divided into a constant *housekeeping* part corresponding to the losses associated with the operation of sensor and electronics and a time-varying power level that is related to the communication.

#### 36.9.1.2 Energy Buffer

Regardless of the energy source employed, an internal energy storage is commonly used in low-power WSNs. This internal buffer enables the power supply to provide an even supply level in spite of a varying power inflow (e.g., when employing an energy-scavenging solution) and to handle intermittent peak consumptions (e.g., during start-up sequences). If an alternative power supply with a discontinuous power inflow is used, the buffer size will mainly be determined by the time characteristics of the power source. As such, the charging and discharging of the internal buffer need to be accounted for in the sleep–wake-up scheme of the device.

## WIRELESS VIBRATION MONITORING CASE EXAMPLE

As the wireless vibration sensor is rated for temperatures well below zero, the battery voltage level might decrease too much with the load. In combination with the current-limiting resistor (IS adaptation) might result in a situation where we do not have enough voltage to operate the radio (especially during start-up). To solve this, a capacitor bank was connected across the power supply, which stores just enough energy required for short radio transmissions (see Figure 36.19 for an overview of the battery design).

#### 36.9.1.3 Lifetime

Typical quoted lifetime values of industrial WSN devices are often closely related to the lifetime of the power supply. This means not only that the components of the power supply should not fail within the specified time frame but also that the available energy is enough to operate the device for at least the specified period.

If the power supply is based on a permanent storage such as a battery, the lifetime is highly dependent on how the device is used in the field, that is, it's dependent on the size of the network, the duty cycle, the amount of data to transmit, and any asynchronous (nonscheduled) data access. Poor radio conditions

will result in increased retransmits, which further decrease the actual possible operating time. So unless you specify these conditions, quoting, for example, 5-year lifetime of a battery-operated device really does not say anything about how long you can run your device in the field.

To determine the size (Wh) of the permanent energy storage required to reach the desired lifetime, you also need to account for material aging, leakage, and self-discharge effects.

### 36.9.1.4 Form Factor

The form factor of the device is a critical parameter when designing WSN devices, and the power supply often has the most dramatic impact on the final form and shape of the device. There must be some volume or area available in the WSN device, which is appropriate to mount the energy storage or energy converter. This volume/area has a direct relation to the required energy density of the storage or power density if an energy converter is used. The often desired small size and weight of WSN devices are thus a clear limiting factor when determining the suitability of available power-supply technologies.

### 36.9.2 Power Management

Depending on the availability, time behavior, and output characteristics of the source, some kind of power management will be necessary as illustrated in Figure 36.21.

Apart from the primary source of energy converter, a power-supply solution could involve an intermediate storage (energy buffer), a backup supply (e.g., a battery, which would also allow to keep the buffer size within reasonable limits), and a control unit in order to cope with input and output power fluctuations and downtime periods, which are typical for many alternative sources, but also for the power demand of an event-triggered sensor.

Also, a DC/DC converter in the control unit might be necessary to adapt the voltage and/or current level of the source to that of the system and to increase the total efficiency. This is especially important at low available power levels. If, on the other hand, a battery is the main energy source, backup with alternative power can be used to extend its lifetime and reduce the need of service.

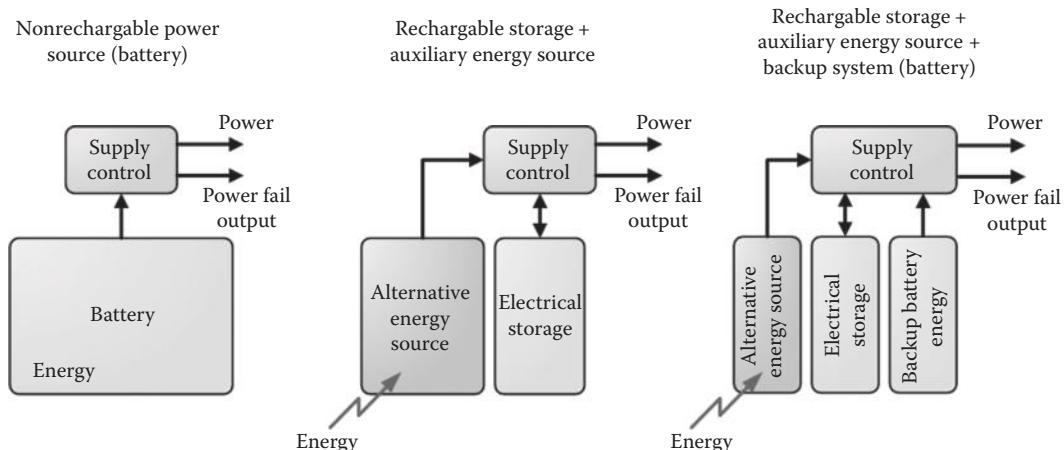

FIGURE 36.21 Power management.

### 36.9.3 Sources and Technology

The energy required to operate the WSN device can be supplied in three principal manners. It can be stored in the device (energy storage), transmitted from a dedicated external source (energy transmission), or it could be based on converting waste energy from the environment, the monitored/controlled process, or from some user action (energy conversions). The first category is by far the most prevalent method employed in WSN devices, while most research is being conducted in the energy conversion area. The approach of converting available energy, often labeled as energy scavenging or energy harvesting, holds the promise of energy autonomous devices with lifetime limited only by the component lifetime.

#### 36.9.3.1 Energy Storage

If energy is stored in the device, great care needs to be taken when calculating the required energy needed to operate the device for the targeted lifetime (as discussed in *Section 36.9.1*). Energy storages can be divided into permanent storage and electrical buffer storage.

Permanent storages include the following:

- Primary batteries: Primary batteries remain the most common means to power WSN devices today. Although continuous improvement is being made to battery technology in terms of battery capacity and cost, the energy density has not really improved that much over the years. The practical energy density of primary batteries is around  $1.2 \text{ Wh/cm}^3$ . However, based on which technology you employ, the energy density, open-circuit voltage, self-discharge rates, and properties at high and low temperatures can vary greatly.
- Chemical storage/fuel cells: Combustible materials (chemical fuels) enable the storage of energy with very high densities, which can be converted into electric power by converters like a combination of a machine (motor, turbine) with a generator or a fuel cell. Availability of fuel cells is currently limited to hydrogen, methane, or methanol, with achievable energy densities in the range of a little more than  $2 \text{ Wh/cm}^3$ .
- Heat storage: Heat storage systems make use of the latent heat involved in melting or evaporation of so-called phase-change materials (PCMs). Latent heat storages are, for example, used for the heating and cooling of buildings. Commercially applicable PCMs are available in a wide temperature range and with melting energies of up to  $0.14 \text{ Wh/cm}^3$ .

Depending on the required energy and power densities, electrical buffer storages can be used in many cases in order to buffer energy as described in *Section 36.9.2*. Two types of electrical buffer storages are commonly used:

1. Accumulators: Accumulators are based on similar chemical principles as primary batteries, but they are designed for being recharged many times. Although performance is slowly approaching that of primary batteries, lower energy densities, significantly higher self-discharge rates, and the limited lifetime (around 3 years) must be taken into account.
2. Capacitors: Double-layer capacitors (DLCs), also named supercaps, ultracaps, or gold caps, are special capacitors with very large capacitance and low resistance. As no chemical reactions are involved with the charging and discharging processes, rapid changes of the stored charge, that is, high currents, are possible. A major advantage over accumulators is longer lifetime ( $>10$  years) and significantly higher number of load cycles. The technology is rapidly progressing, and commercially available products provide energy densities up to  $0.005 \text{ Wh/cm}^3$ . Currently, they are often used in photovoltaic systems to bridge the day and night cycle of solar power.

# WIRELESS VIBRATION MONITORING CASE EXAMPLE

The main requirement when choosing battery technology for the wireless vibration sensor was a high energy density (to comply with size/weight requirements). A primary battery based on a single lithium-thionyl chloride cell was chosen due to its high energy density, high nominal voltage, low self-discharge rate, and overall good properties at both high and low temperatures.

However, this type of primary battery has two main drawbacks. Large batteries may pose safety problems (subject to transportation restrictions) and voltage delay due to passivation.

Due to the size requirements, the chosen cell was small enough not to be subject to any transportation restrictions.

Passivation on the other hand could still be a problem as it might lead to voltage delay. Voltage delay is the time lag that occurs between the application of a load on the cell and the voltage response. As we have an extremely low duty cycle in the wireless vibration application (each sensor node should perform one vibration measurement per 2 weeks), this behavior becomes particularly pronounced (since the passivation layer grows thicker). As described earlier, a capacitor bank was added in order to secure sufficient energy to operate the radio circuit despite a varying operating temperature (see Figure 36.17). This buffer also provides a remedy for potential passivation issues, as the initial energy will be drawn from the capacitor bank, thus eliminating any voltage delays.

### 36.9.3.2 Energy Conversion

Harvesting and converting waste energy from the environment certainly appears as an appealing solution, as the lifetime of the device would (in theory) be limited only by the component lifetime. However, this requires that the *waste* energy is readily available with a constant (or predictable) level. If this is not the case, large internal buffers might be required to guarantee reliable operation (which increases the size/weight/cost of the device). This also means that the applications in which the device can be deployed might be restricted or that special considerations and/or measures need to be taken to guarantee some minimal level of power inflow (which makes device installation more complex and costly).

Energy conversions can be achieved in many ways, but the most common methods include the following:

- Photovoltaic cells: A wide range of photovoltaic systems are available on the market today based on diverse materials and technologies that have reached different maturity levels. Cell types also differ with respect to cost, electrical characteristics, efficiency, topology, thickness, shape, mechanical properties, and adaptation to various lightning conditions. Regardless of the varying energy conversion efficiency (5%–30%), the lightning conditions have by far the greatest impact on the feasibility of photovoltaic cells. In typical environments, the illumination density will vary within at least three orders of magnitude. For example, compare the illumination density of full sunlight ( $\sim 100 \text{ mW/cm}^2$ ) with normal office lighting ( $<1 \text{ mW/cm}^2$ ). This difference is even more pronounced by the nonlinearity of the cell output power, which results in reduced efficiencies at low illumination intensity.
- Thermoelectric converters (TECs): Utilize temperature gradients to generate electrical energy. If there is waste heat available, which is normally conducted or radiated to the environment, it would be possible to connect a TEC to a hot surface, let part of the heat flow pass through it, and generate electrical energy, which could then be used to power the WSN device. In order to achieve sufficiently high efficiencies, TECs need to be appropriately designed and thermally and electrically matched to the respective application. Especially, in order to increase the heat flow (and with it the temperature

difference across the module), it is important to make very good thermal contacts to the hot surface and to the environment at the same time. The latter requirement usually causes the use of air coolers or other heat spreading elements, which may be even much larger than the module itself.

- Mechanical converters: The most common type of mechanical converters is based on vibrations. In industrial applications, energy-harvesting oscillators need to be adapted to low vibration amplitudes, high forces, and resonance frequencies of typically 50 to several hundred Hz, as this is the range of vibrations in machines. These conditions can be well adapted with piezoelectric converters, which can collect power levels of 10 mW up to several hundred mW dependent on the existing acceleration amplitudes. However, sufficient vibration amplitudes cannot be generally assumed in all applications. Also, the mechanical system must be well tuned to the vibration frequencies (which may change both with the application and with time) in order to achieve high efficiency and power density. Design for broadband response will reduce the available output power amplitudes. One of the first commercial vibration energy harvesters for the supply of small wireless devices like sensors and transmitters was offered by a company called Perpetuum [13]. They offer inductive generators that deliver a few mW and up to 3.3 V depending on the amplitude and frequencies the vibration.

## WIRELESS TEMPERATURE INSTRUMENT WITH ENERGY HARVESTING EXAMPLE

The wireless temperature instrument uses WirelessHART as communication standard since it is widespread and has many proven operational hours. The temperature transmitter has been equipped with a thermal energy-harvesting unit containing two Micropelt Thermogenerators MPG-D651 with a footprint of 6 mm<sup>2</sup> each. With a minimum difference about 30 K between the process and ambient temperatures, the system is able to generate sufficient energy to supply both the measurement and wireless communication electronics. At temperature gradients greater than 30 K, more energy is generated than is needed, which could be used to allow for faster update rates, for example.

### 36.9.3.3 Energy Transmission

Another principle method of supplying energy to the WSN device is to transmit the power to the WSN device. This method thus requires some form of external power source that needs to be installed in the plant in *close* proximity of the WSN devices that are going to be supplied. The maximum distance between the power source and the WSN differs depending on the technology employed. Three main technologies can be conceived:

- Inductive transmission: Currently used inductive power transmission systems are different with respect to range (wireless vs. contactless) and operation mode (continuous vs. pulse operation as often used with radio-frequency identification [RFID]). A rather large variety of commercial solutions are available such as contactless rotary power and signal connectors, linear contactless solutions for rail and transport systems, and solutions for the supply of small consumer devices. In addition, RFID and transponder solutions are available from a large number of suppliers. ABB seems to be the only company offering a wireless *long-range* (a couple of meters) inductive power-supply system for sensors and actuators [9]. The system, called WISA-POWER, can deliver 6 mW of continuous power to the wireless sensors even under worst-case conditions and close to 100 mW to concentrator modules with larger receiver coils.
- Capacitive transmission: Power transmission can also be achieved by means of high-frequency electric fields. Contactless solutions for rotary signal transmission are available on the market, but no *wireless* power solutions, as the available power levels are rather limited within the range of allowable field amplitudes.
- Optical transmission: Optical power transmission is possible with fibers, a focused (laser) beam, or with diffuse lighting. In most applications, little would be gained by the replacement of wires by optical fibers. Focused beams are not applicable for the supply of many sensors dispersed throughout the automation facility/cell where there often is no direct line of sight. An alternative could be the simultaneous supply of the sensors in an automation cell with a diffuse artificial lighting. However, reliability, cost-effectiveness, and customer acceptance of such a solution make it a highly questionable approach. Even with such an approach, shadow effects cannot be excluded for general automation applications.

Although this list of power-supply technologies is by far complete, it should provide an idea of the various conceivable power-supply solutions for WSN devices. Noticeable are the varying levels of energy/power density and characteristics of the power-supply solutions, often highly dependent on the conditions under which they are employed. To choose a suitable technology, you thus need to fully understand the static and dynamic power demands of your device, as well as the applications and environmental conditions under which the device will operate. A more comprehensive overview of various solutions is given by [14] and [15].

## Acknowledgments

I would like to thank all contributing authors. In particular, authors from industry and industry consortia whose job priorities usually are different from writing chapters in books. I wish to acknowledge the work of Dr. Ronald Schoop of Schneider Electric, who passed away before finishing his contribution. I am grateful to the members of the Handbook's Advisory Board for so generously taking part in the making of this book.

I also wish to thank at CRC Press Nora Konopka, publisher of this book; Michele Smith, Jessica Vakili, and Richard Tressider, the production manager.

### 37.1 Introduction

---

Wireless communication is increasingly used in many industrial automation applications, which have many differing requirements [1]. The main automation domains are as follows:

- Process Automation, typically dealing with continuous processes (e.g., the continuous or batch processing of liquids)
- Factory Automation, where discrete, stepwise manufacturing dominates (e.g., mounting a product from many different parts)

In discrete manufacturing, again different application levels exist (see Figure 37.1). Consequently, there is a need for different wireless implementations to cover differing applications like mobile operators,

**FIGURE 37.1** Automation hierarchy in factory automation, communication levels, and number of possible nodes to be connected wirelessly.

controller-to-controller communication, and the machine and device level. It is obvious that especially in the machine and device level, a large number of wires and connectors are operated in a harsh environment.

Sensors and actuators in the machine and device level operating over wireless links:

- Allow a very flexible installation, a significant advantage in many parts of the machine-building industry, where often a custom or special purpose machine is built just once. The installation and commissioning often starts already in parallel to the ongoing design process.
- Enable fully mobile operation of sensors and actuators.
- Enable new sensor or actuator applications that would not be possible with wired devices.
- Avoid cable *wear and tear* problems.
- Avoid costly and time-consuming integration of mechanical cable tracks/chains, slip-rings, or similar mechanical elements.

In an automotive assembly plant, up to 100,000 input or output points (IO) may be wired, and many of the cables and connectors are subject to repeated movement or reconnection.

Wireless communication systems for the machine and device level in factory automation must guarantee high reliability and low and predictable delay of data transfer. The requirements in the machine level are mission-critical and considerably more stringent than typical requirements for other areas and especially compared to home, building, or office applications.

Requirements on power supply and real-time communication for such applications are highly demanding and cannot be satisfied with today's off-the-shelf wireless systems.

Wireless systems offer advantages in terms of availability, cost, and flexibility also in the device and machine level of factory automation.

To gain most of these advantages, a truly wireless solution, where communication and power supply are wireless, is needed. A novel factory communication system, called Wireless Interface for Sensors and Actuators, has thus been developed, which provides both wireless communication and wireless power supply. The power supply is based on magnetic coupling, while the real-time wireless communication uses a collision-free TDMA protocol, combined with frequency hopping (FH) based on the physical layer of IEEE 802.15.1. The Wireless Interface provides reliable and low-delay transmission for a high number of nodes.

This chapter explains the practical requirements and the system specifications, the design concepts for communication and power supply, and describes practical experience gained especially with respect to reliability and coexistence with other wireless systems. It further derives simple performance profiles for the Wireless Interface and other wireless technologies being discussed for industrial use, based on the requirements in factory automation.

## 37.2 Wireless Interface Requirements and System Specifications

---

The basis for system specification of the Wireless Interface has been a thorough analysis of the requirements of typical applications of the targeted machine and device level:

- *Roundtable production machines*: These are used in various forms in many automated discrete production facilities. They can have up to 10 devices per  $\text{m}^3$  machine volume (300 per machine). Many of these devices have a relative movement with considerable stress on wires and connectors. Most of them are also triggered at different times in one production cycle. Cycle times may vary from 1 s (one product produced and tested per second) in many steps to 1 min.
- *Production lines*: An automated line-type machine assembling, testing, and packing a standard consumer or household product may have 2000 (1000–3000) IO points.
- *Automotive robot production cells*: These have an IO point density of around two devices per meter cube machine volume (200 per  $7 \times 6 \times 2 \text{ m}^3$ ). Sometimes, several cells are collocated and work together.

All of the aforementioned applications are typically found several times in a factory hall (5–20), often closely together.

In an *average automotive assembly plant* ( $150 \times 150 \times 2 \text{ m}^3$  machine/application space), around 100,000 IO points can be encountered, leading to an average wireless device density requirement of around  $2/\text{m}^3$ . Assuming that only some of the devices are wireless and some are wireless IO concentrators with, for example, eight IO points, an average figure of a suited technology should be at least 0.25 wireless devices/ $\text{m}^3$ .

There are two related basic wireless requirements in such applications:

- Low additional latency due to the wireless link (e.g., <10 ms) in order to
    - Not unduly increase the cycle time of the application, which otherwise would mean lost product output
- Fifty devices (or IO points) triggered independently and always having to wait 10 ms for each signal to arrive would mean 1 s of additional cycle time already (a 100% increase in a fast roundtable application!)
- Stay within time limits given by the application (e.g., a critical mechanically controlled movement), which otherwise could mean destruction of the machine, tools in the machine, or at least the produced product
  - Very high reliability to get a signal within a defined upper time limit (e.g., in order to avoid the earlier-described destruction)

In contrast to other wireless use cases like mobile operators and service, the very high reliability to get a signal within a defined time limit is an absolute requirement.

**TABLE 37.1** Events in a Roundtable Production

100 wireless nodes or 10 pts. <sup>a</sup>	1 production step per 2 s min. 1 events per second
Per hour	100 telegrams per second 360,000 telegrams
Per day (3 shifts)	8 Mio. telegrams
Per year (w/o weekends)	2400 Mio. telegrams

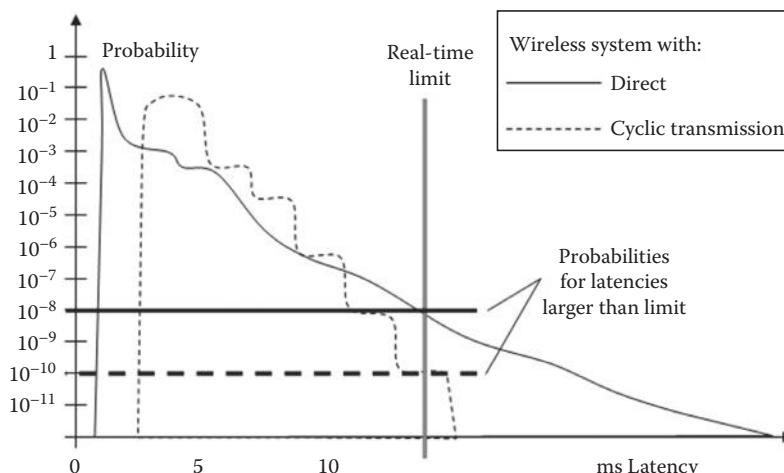

Less than one failure can be tolerated per year, resulting in a needed error rate of  $<10^{-9}$ .

<sup>a</sup> Digital 10 assumed, concentrating 10 nodes would have the same amount of telegrams, as only rarely 10 points are simultaneously triggered!

Practical values for the error rate of not getting the signal in time depend on the industrial use case assumed. A typical roundtable application can have easily 300 IO points, mainly sensors, of which 100 are here assumed to be wirelessly transmitted in the following Table 37.1. A roundtable is a typical arrangement in a factory, where a stepwise rotating table is used to do many different assembly, testing, or loading/unloading steps in parallel. The substations on the table have additional relative movements, so wireless is an issue due to two-dimensional movements. Typically, most of the IO signals are digital and the events are typically separated in time (unsynchronized), resulting in many telegrams, worst case equaling two times the amount of IO per production cycle (see Table 37.1).

In principle, the distribution of wireless latencies will qualitatively look like in Figure 37.2 in practical implementations. Sketched is a coexistence situation with other frequency users. If the wireless system has a cyclical transmission, for example, as in the Wireless Interface: A, a distribution pattern with steps can be noted (— — curve).

In practical applications, a large difference between the two curves can be noted by comparing the error rate for keeping a certain time limit, like sketched with the vertical bar. A factor of 100 results, which means that in the roundtable application with one wireless system (— — Wireless Interface), there is an error, for example, a production stop or even more severe problem, to be expected less than once a year, and in the other case, nearly once a week: a dramatic difference seen from the user side.

**FIGURE 37.2** Typical distribution of latency measurements in wireless automation devices.

The wireless communication subsystem transmits messages between the S/As and a base station. The communication requirements derived from the aforesaid include the following:

- Fast response times (generally less than 15 ms)
- (Practically) guaranteed upper time limit for the response time (e.g., 15 ms on the Wireless Interface with a miss probability of less than  $10^{-9}$  under normal operating conditions)
- Guarantee a high reliability of data transmission even in the unfriendly environment of factories, where radio propagation may be affected by many obstacles and where various sources of interfering signals must be expected, for example, with other users of the same frequency band
- Have low power consumption, which is crucial due to the limited capacity of any wireless power supply
- Serve a large number (up to 120) of sensors/actuators to one base station
- Permit coexistence of multiple cells: Up to 300 devices in a single machine have to be supported
- Have a practically unlimited number of S/As in a large area ( $>1$  device per  $m^3$  volume to cover 100,000 nodes in a factory)
- Permit coexistence with other wireless systems
  - Be robust
  - Efficient use of the valuable frequency band resource

Currently, the most suitable radio frequency band available for high-bandwidth, short-range wireless communication is the industrial, scientific, and medical (ISM) frequency band at 2.4 GHz. Radio transceivers operating in this band are readily available, for example, radios adhering to the IEEE 802.15.1 standard (Bluetooth physical layer).

The ISM Band also has a good balance between possible disturbances (more likely at lower frequencies; see Figure 37.9) and a good range. Range is lower at higher frequencies with a given transmit power. Electromagnetic interference is a concern; however, measurements in different environments (see Chapter 4, Industrial Electromagnetic Interference; Section 37.4.3) have shown that typical industrial electromagnetic noise is significantly reduced above 1 GHz, with only arc welding providing broadband noise up to 1.5 GHz.

The protocols of existing standardized wireless systems designed for other purposes do not satisfy the requirements of the sensor and actuator level in machines used in automated factories:

- Wireless local area networks (WLAN) (IEEE 802.11) [2] and Bluetooth (IEEE 802.15.1) [3,4] and also forthcoming systems [5], including ultra wideband (UWB) systems, are all designed for high throughput between a small number of terminals, with less stringent latency, reliability, and power requirements.
- ZigBee (IEEE 802.15.4 based) [6] cannot reliably serve a high number of nodes within the specified cycle time.
- Specialized low energy protocols from building automation like EnOcean [5] are not reliable and real-time suited as defined earlier.
- Passive electronic tagging systems (RFID, Radio Frequency Identification tags), as used for electronic article surveillance, do not have sufficient range, speed, and flexibility.

Hence, it was necessary to design a new communication protocol, which however uses much of the available standard hardware.

### 37.3 Communication Subsystem Design

The radio characteristics of the new Wireless Interface system are those of the IEEE 802.15.1 physical layer specification [7]. The raw data rate is 1 Mb/s and transmit power is 1 mW. This comparatively low transmit power is appropriate and sufficient for a range of 5–10 m, as required for the typical node and base station density.

Not so obvious is that the low transmit power and therefore limited range is also dictated by the requirement of a sufficiently large average node density. A good comparison is human communication, where also a large number of people, for example, at a cocktail party, can communicate reliably and fast, due to fairly low voice/range, which allows others to reuse the transmission medium in a certain short distance. Just a few participants increasing their transmit power/range will disturb many others.

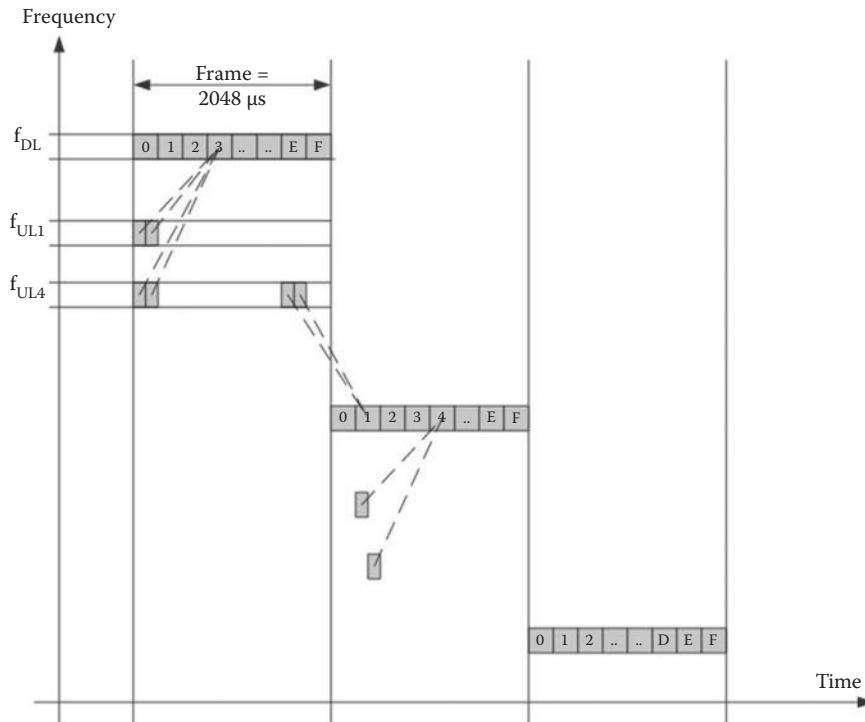

### 37.3.1 Medium Access and Retransmission

Time division multiple access (TDMA—one fixed time slot per device) with frequency division duplex (FDD—device and base station can send at the same time) and FH is used, as illustrated in Figure 37.3. The downlink transmission (from the base station) is always active, for the purpose of establishing frame and slot synchronization of the S/As. Uplink transmissions from an S/A occur only when it has new data or an acknowledgment to send (event triggered). The Wireless Interface allows up to 120 S/As per cell in different time/frequency slots.

The TDMA frame length,  $T_{frame}$ , is 2048  $\mu$ s. Each S/A may transmit in one out of 30 slots per frame. In order to support up to 120 S/As per cell, each S/A is part of one of four uplink groups  $\{UL_1, UL_2, UL_3, UL_4\}$  with separate frequencies. The five frequencies hop synchronously at each frame boundary.

The slot structure is shown in Figure 37.4. The downlink slot format is a compromise between the efficiency of channel usage and synchronization latency of the downlink.

A device transmits its data packet in its assigned uplink time slot. An acknowledgment is expected in the corresponding downlink slot, which is staggered by 256  $\mu$ s to allow for TX/RX-turnaround time (see Figure 37.3). If no acknowledgment is received, the S/A will retransmit the data packet in the next frame.

**FIGURE 37.3** Wireless Interface TDMA/FDD/FH pattern. *Dotted lines* connect downlink/uplink slots allocated to one sensor/actuator. (TX/RX-turnaround time = 2 double slots = 256  $\mu$ s; see Figure 37.4).

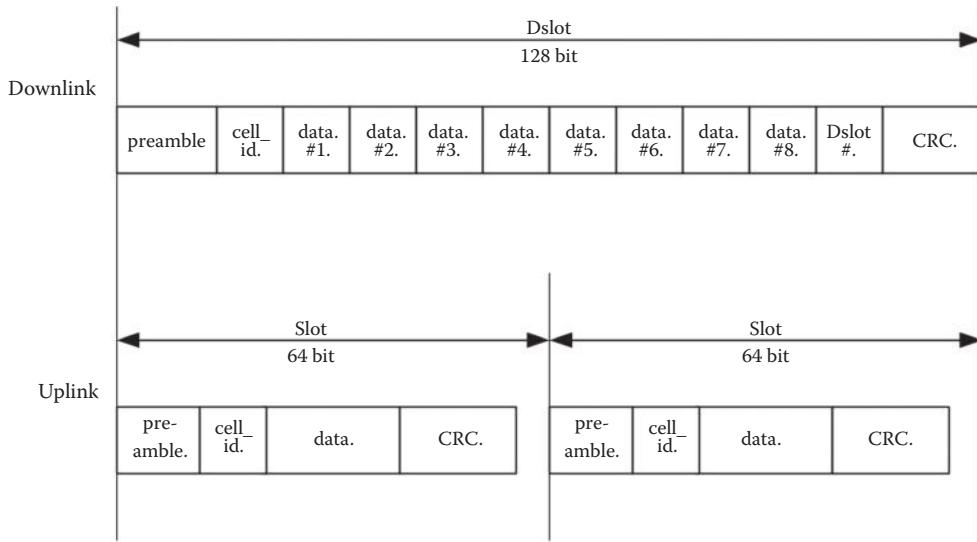

FIGURE 37.4 Wireless Interface slot format: downlink double slot duration = 128  $\mu$ s.

With frame-by-frame FH, the radio channel used for retransmission will largely be independent of the previous transmission, thus increasing the probability of successful transmission.

### 37.3.2 Frequency Hopping

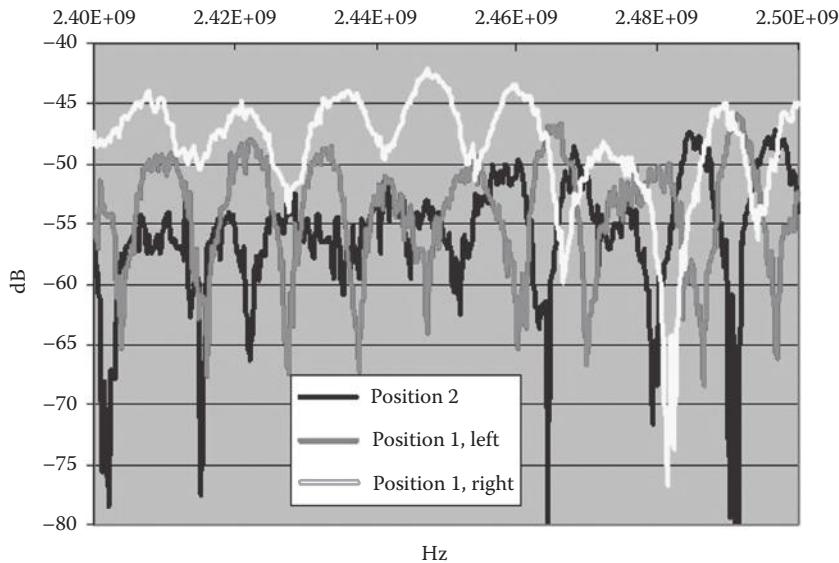

Figure 37.5 shows the measured frequency-depending attenuation in the 2.4 GHz ISM band. It can be seen that the coherence bandwidth of the signal may be some tens of megahertz (corresponding to propagation path length differences of 30 m). Wideband FH will thus improve transmission performance. It also reduces the effect of other devices that operate in this band. The GSM [8] and Bluetooth [7] systems are well-known wireless communication standards using TDMA and FH. Their FH sequences are determined in a pseudorandom manner and therefore do not control frequency separation between consecutive hops. Hence, consecutive transmissions may have similar high packet error probability. It is for the Wireless Interface of interest to employ FH sequences with the property that consecutive hops are widely separated in frequency. Its use of the ISM band of 80 MHz is partitioned in seven disjoint subbands, each containing 11 hop frequencies at a given channel spacing of 1 MHz. The subband bandwidth of 11 MHz is normally larger than the typical bandwidth of the fading, and the seven subbands together cover the available band. The method produces 60 different FH sequences with low cross-correlation. The hopping sequences have a period of  $7 \times 11 = 77$  frames. Each hopping frequency is visited exactly once per period. An example of the five FH sequences for a given cell\_id is shown in Figure 37.6.

In summary, the constructed FH sequences have a number of desirable properties:

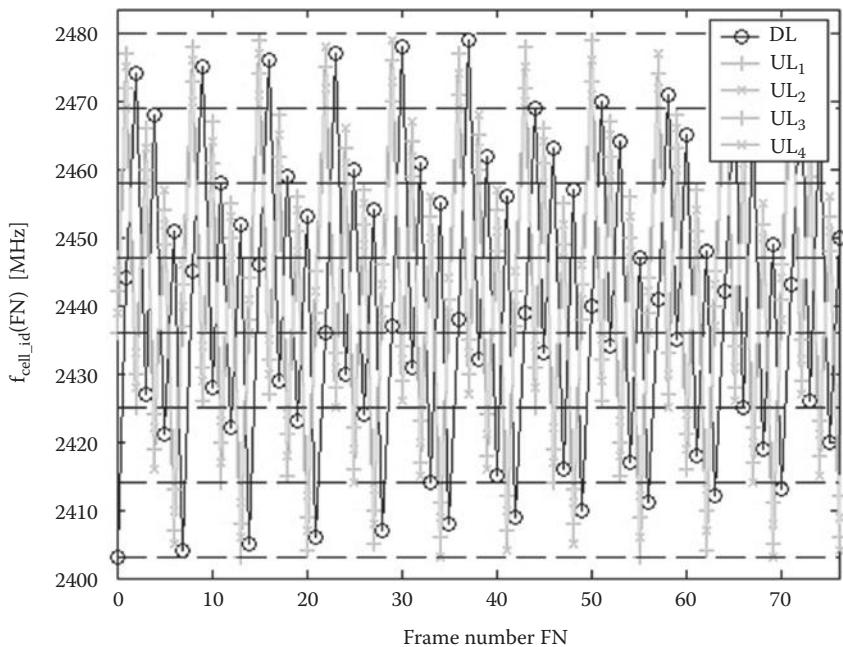

- Consecutive frames are in different subbands.
- The (duplex) spacing between downlink and uplink frequencies is three subbands apart.
- The four concurrent uplinks are in the same subband and hop with a fixed spacing of 3 MHz apart.

### 37.3.3 Antenna Diversity and Switching

To additionally improve robustness, multiple antennas with separation of at least half a wavelength  $\lambda$  may be used to reduce the effects of multipath fading and shadowing. This effect is exploited by antenna diversity reception. With  $\lambda = 12.5$  cm, only the base station (BS), for practical reasons, may be fitted with multiple antennas. The simplest way is to switch transmit and receive antennas once per frame in a round robin sequence.

**FIGURE 37.5** Frequency selective fading in the 2.4 GHz ISM band: frequency-dependent attenuation from a sensor/actuator to 3 BS antennas in a test installation. Gray and light gray: pair of base station antennas, separated by 37 cm; black: third BS antenna, line of sight path obstructed by a robot arm.

**FIGURE 37.6** Example FH sequences (cell\_id = 27).

### 37.3.4 Multicell Operation

The Wireless Interface system is designed such that each cell uses the entire 2.4 GHz ISM band of 80 MHz, without any need for intercell coordination, except that a different cell\_id has to be set in each cell. Where cells operate in close proximity, or are even colocated, the interference depends on the correlation properties of the FH sequences and the cell traffic load. Cross-correlation between periodic integer sequences has been studied in [9]. In general, there are a number of interference effects to be considered:

- Co-channel interference from same frequency transmissions becomes relevant if the C/I ratio is below 14 dB [7] (distance effects).
- Adjacent channel interference is relevant if the adjacent channel interference C/I ratio is below -20 dB. This condition may well be true for colocated base stations.
- Multiple interference from any of the five links.
- (DL, UL<sub>1</sub>, UL<sub>2</sub>, UL<sub>3</sub>, UL<sub>4</sub>) of an interfering cell within range. While downlink transmissions are continuously active, the uplink load is typically far lower: With a frame rate of 488 frames/sec, and assuming a maximum uplink rate of five transmissions per second per S/A, a slot is only used with a probability of 1.02%.
- Multiple interference from the links of more than one adjacent cell. Links from different cells are mutually asynchronous, causing interference to occur at different times.

To assess these effects, a generalized cross-correlation was defined and its properties were analyzed. The results confirm that even in the worst case, the retransmission protocol ensures that messages can be reliably transmitted.

## 37.4 Communication Subsystem Implementation

---

Figure 37.7 shows a Wireless Interface base station which is controlled by a microcontroller. Time-critical control of the RF transceiver and baseband signal processing are delegated to an FPGA. The base station maps the wireless links to the addresses of the fieldbus connecting it to the automation controller. Diagnostics and configuration features are supported.

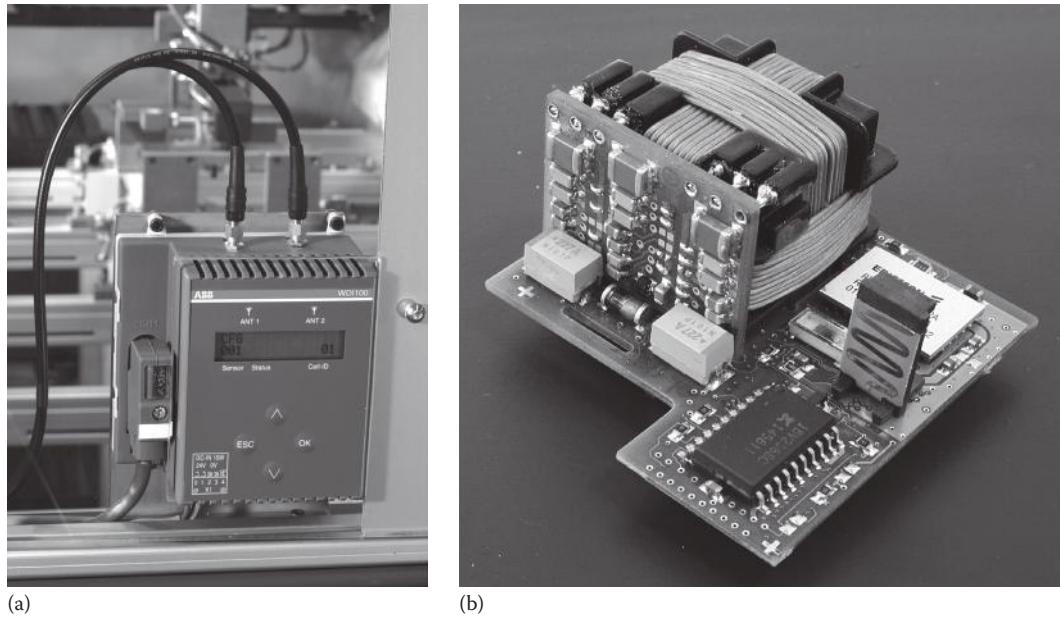

Due to the communication protocol requirements, a standard RF front-end cannot be used for the base station implementation. The requirements differ significantly from those found in WLANs and Bluetooth in that the BS must operate in full duplex mode. The BS must simultaneously receive signals from up to four S/As with a dynamic range of more than 60 dB.

In contrast to the BS, the node may use existing RF transceiver hardware (IEEE 802.15.1 based). A sensor module is shown in Figure 37.7 (in this implementation a proximity switch [10]), with the power receiving coil, an IEEE 802.15.1-based transceiver, and a microcontroller and an FPGA for the Wireless Interface protocol. For low power consumption, the transceivers *sleep* until an event occurs. The communication antenna on the module has an omnidirectional radiation characteristic in order not to have to line up the device at installation.

### 37.4.1 Coexistence

Wireless coexistence is a practical and increasing concern in industrial automation applications. Many different applications may use wireless systems, which may compete for the same frequency band with different technologies. The limited resource are the radio frequencies, and for the Wireless Interface that is in the ISM Band from 2.4 to 2.483 GHz.

The situation may be compared with highways, which have a limited width and many different types of vehicles fulfilling different transport tasks. For each of the transport tasks different requirements apply, the capabilities of the vehicles are quite different also. In addition, certain rules apply to avoid dangerous situations (e.g., speed limits).

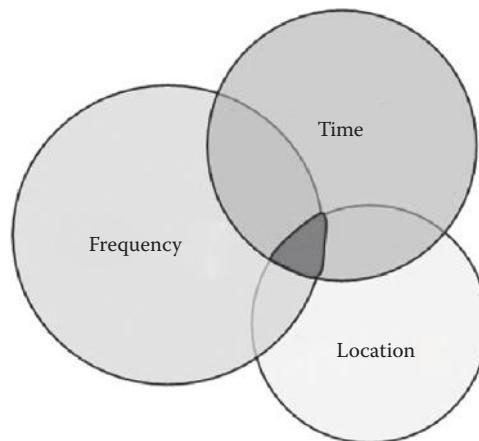

**FIGURE 37.7** Wireless Interface implementation. (a) Base station with antenna connectors and FieldBusPlug (FBP) connection to controller. (b) Sensor module with receiver coil for wireless power supply and communication transceiver, controller, and antenna.

In today's factories, coexistence or frequency management has to be established to coordinate the use, as the frequency bands are a valuable resource. In a larger factory, generally every system has to be announced in advance and released by a person/committee responsible for frequency use allowance [11,12].

Wireless coexistence is an issue only if the same frequency is used at the same time and close by (Figure 37.8).

Separation in location is seldom a free parameter; therefore, time and frequency can be optimized.

If there would be an unlimited bandwidth available, simple frequency separation would be the simplest approach. Nevertheless, the highway example shows that reserving a full lane of the highway just

**FIGURE 37.8** Coexistence issue: Occurs if there is a *hit* in time *and* frequency *and* location.

for one vehicle type is generally not efficient. Many different vehicles may use the same lanes if they have the ability to change lane and if on average a low duty cycle or low density of vehicles can be guaranteed.

Separation in time, by low duty cycle is exactly the approach being used in many wireless installations by frequency management, thus allowing many users with low duty cycle.

In practical applications, coexistence always has two aspects:

1. Robustness against interference from other wireless users (low susceptibility)
2. Efficient usage of radio frequencies (spectral efficiency and low duty cycle) in order to leave enough free resources for other users

The Wireless Interface was designed to be robust by using adaptive retransmissions. Nevertheless, the continuous use of a significant part of the frequency band by an unfriendly system with a high duty cycle and long telegram lengths (longer than the maximum number of retransmits) will make it impossible for a system to transmit its data within the time limit requirement (e.g., 15 ms).

To discuss coexistence more quantitatively, characteristic numbers are helpful, which are defined here as follows:

Robustness can be measured by the factor between the maximum to the minimum delay values, measured in some defined coexistence test setup.

$$\text{Robustness} \quad (R) = \min \text{ delay}/\max \text{ delay}$$

$$R = 4 \text{ ms}/16 \text{ ms} = 0.25$$

In an existing system between two user interfaces under idealistic and realistic but more worse-case conditions, for example, the coexistence with other wireless systems in their typical channel occupation mode. The more close to unity the better is the robustness.

Spectral efficiency can be measured as the ratio of data rate divided by the used bandwidth.

$$\text{Spectral Efficiency} \quad (E) = D/B \quad (D, \text{ data rate in b/s; } B, \text{ bandwidth in Hz})$$

$$E = 1 \text{ Mbit/s}/1 \text{ MHz}$$

This is an implementation- and application-independent value that enables technology comparison.

A more practical performance figure when looking at implemented solutions would be the following:

$$\text{Performance} (P) = 1/(T_s/n_U \times B)$$

( $T_s$ , slot time in ms;  $n_U$ , number of parallel uplinks)  
= 4 for Wireless Interface,  
= 1 for symmetrical systems

$$P = 1/(0.064 \text{ ms}/4 \times 5 \text{ MHz})$$

$$= 12.5 \text{ nodes/ms/MHz}$$

The frequency usage can give an indication of the interference potential of a wanted system to other wireless systems. A simple practical value can be derived from multiplying the time/duty cycle and the bandwidth used:

$$\text{Frequency usage} (F) = T \times B \quad (T, \text{ fraction of time; } B, \text{ bandwidth})$$

$$F \sim 1 \times 1 \text{ MHz}$$

This gives a very practical figure of how much of the available frequency band, here, for example, the ISM band, as a very valuable resource is used for a certain implementation. The frequency usage should, of course, always be as small as possible; nevertheless, the resulting interference depends in practice mainly on the type of the other/victim system. Different victim systems react very different to frequency usage by a wanted system, dependent on if they had been designed for coexistence or not. The Wireless Interface, for example, uses in average not much more than 1 MHz of bandwidth continuously, for example, in an application as defined in Table 37.1.

Another practical aspect of coexistence is stability. The influence of one system on another should be as predictable as possible for automation systems. In practical applications it has a nearly constant

frequency usage, which is determined mainly by its downlink, thus making its effect on other systems relatively predictable. The short uplink telegrams generate on average only low traffic load (<10%), even with high number of nodes and events.

Other wireless systems used in industrial applications are as follows:

- IEEE802.11, WLAN:

In factory automation WLAN is applied in many plants for varying applications. There are two typical uses:

- Access of many different applications to the plant/IT network (scanners, order data transfer, production data transfer, network connection with, e.g., a notebook)
- Communication to AGV systems: automated guided vehicles that fulfill transport needs

WLAN has its strength as a widespread standard, allowing a large number of different clients to access the same network. Typically, delay times below 100 ms are not an issue here.

WLAN is very susceptible to disturbance as it has a large receiver bandwidth and its CSMA and CCA features—designed to enable other WLAN devices to access the same system—also react to narrow band frequency user inside the used band. Therefore, the latency of a WLAN system will have a large jitter in practical applications. Measurements have shown values to vary from 1 ms to sometimes over 30 ms in a coexistence situation with other low duty cycle users.

- Bluetooth: Bluetooth is implemented in many mobile phones and notebooks; therefore, it is likely to be present. Bluetooth was made for user device interaction and is a robust protocol. It is suited for HMI purposes in industrial applications. Bluetooth devices do not use CSMA and may thus have an effect on WLAN links (especially in the search/pairing mode).
- IEEE 802.15.4/Zigbee/WirelessHART: Such devices will be used to cover a larger area for condition monitoring or building automation use cases. They will typically have a low duty cycle and are not to be expected in large quantities in factory automation (have therefore not been considered as disturber for the Wireless Interface in more detail). Such devices might be disturbed by a WLAN with a high duty cycle if in close distance and with not enough frequency separation (except Wireless Hart with a FH-option).

In order to estimate distance-dependent interference effects, an empirical model for the path loss (PL) is often used for Bluetooth-type applications (e.g., [13]). In the near field of the transmitting antenna, this attenuation is proportional to  $d^2$ , where d is the distance (6dB additional PL if distance is doubled). For larger distances, the empirical formula stipulates attenuation proportional to  $d^{3.3}$  (10 dB additional PL if distance is doubled). This is a coarse model; hence, the distance values derived in the following should be considered only as indicative.

### 37.4.1.1 Interference from IEEE802.11b

Consider factory staff working in the vicinity of a Wireless Interface cell using a laptop computer to upload a large document from an 802.11b base station. The Wireless Interface transmission power is 0 dBm. Using the aforementioned PL model, this results in a carrier reception level C, at the base station at a distance of 5 m, of  $C = -54$  dBm. IEEE 802.15.1 receivers require a co-channel carrier-to-interference ratio of  $C/I > 14$  dB for adequate reception performance. Hence, the interferer level should be  $I < -54$  dBm  $- 14$  dB =  $-68$  dBm. The 802.11b transmitter power may be up to 100 mW in 22 MHz bandwidth, equivalent to 6.5 dBm per Wireless Interface/IEEE802.15.1 receiver bandwidth of 1 MHz. The required PL to ensure safe operation is therefore  $6.5$  dBm  $- (-68$  dBm) =  $74.5$  dB. This translates into a minimum safe distance requirement of 25 m for an 802.11b transmitter.

### 37.4.1.2 Interference from Bluetooth

Assume a factory worker using a Bluetooth phone headset. The typical Bluetooth transmitter power is 0 dBm at 1 MHz bandwidth and the required PL to ensure  $C/I > 14$  dB is therefore 68 dB, which corresponds to a minimum distance requirement of 16 m.

### 37.4.2 Performance Measurements

The typical Wireless Interface operation is at relatively short distances, with reception signal levels of about  $-60$  dBm, well above the sensitivity level. Hence, performance is in practice not limited by distance or fading effects, but mainly by robustness to external radio interference.

Performance evaluations were done by measuring the message delays. Any loss of message in the uplink (sensor status message) or in the downlink (BS acknowledgment) causes a retransmission in the next frame, resulting in an additional delay of  $2048\ \mu s$ . A measurement setup consisted of 60 nodes set to transmit at a rate of two messages per second over distances of about 70 cm. In the interference-free case, one in about 1000 uplink messages required a retransmission (marked as *reference* in Figure 37.9).

The effect on the transmissions due to interference from other base stations with Wireless Interface was also measured in a realistic scenario. The antennas of the interfering base stations are set to point toward the system under test, thus simulating multicell operation as shown in Figure 37.9 (top).

### 37.4.3 Industrial Electromagnetic Interference

Investigation of a number of potential industrial sources of interference showed that no interference is to be expected in the 2.4 GHz band from high power welding equipment or frequency converters. Figure 37.9 gives an overview of typical industrial devices, their basic frequency, and indications for their harmonics in the spectrum.

The only interference may come from legal ISM transmitters (Industrial Scientific and Medical). They are not widespread but have to be taken into account if unshielded. They can have very high power levels (e.g., microwave drying applications in the kW range).

A spot welding gun used in induction welding, for example, operates at up to  $20\ kA$  and generates very high electromagnetic field strengths. However, the majority of the high-frequency noise decays strongly above 1 GHz and therefore has a minimal impact on the Wireless Interface. The only

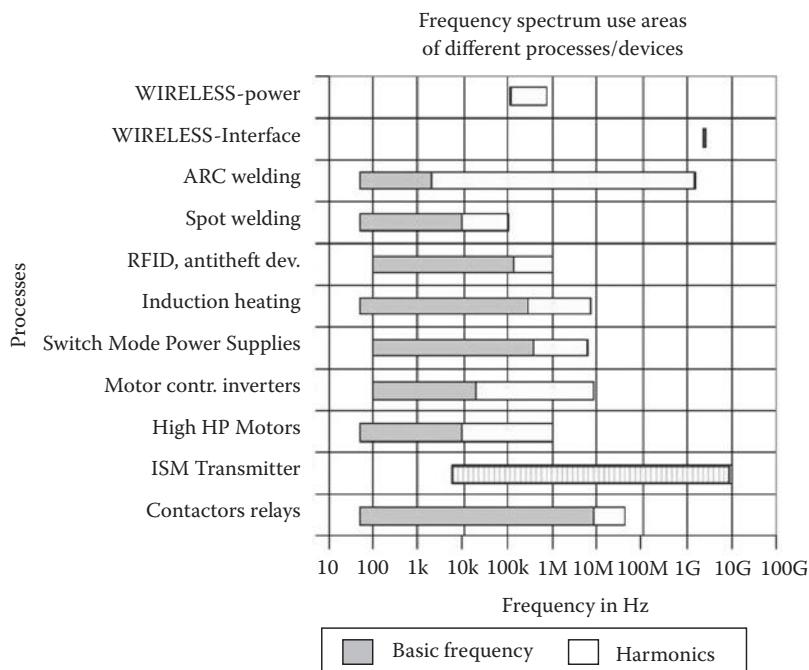

FIGURE 37.9 Electromagnetic interference from typical applications in the industry.

measurable interference with high frequencies (up to 1800 MHz) was identified as being generated by arc welding. Devices with Wireless Interface have been tested with positions only a few centimeters away from the welding spots.

### 37.4.4 Interference from Other Communication Systems

A number of measurements and tests have been conducted to quantify the effect of interference from other communication systems in the 2.4 GHz band. In a first scenario, interference was caused by a laptop PC with an IEEE 802.11g WLAN communicating to an access point (AP) transmitting at 54 Mb/s on channel 5 at 100 mW (Figure 37.11). Measurements were repeated at several distances ( $d = 7.5, 4$ , and  $1$  m) between the AP and the BS with Wireless Interface, and over 100,000 messages each were taken. Figure 37.11b shows the increased number of retransmissions due to the WLAN interference.

The effective data rate of the WLAN was reduced from 3.1 MB/s in the interference-free case to 2.8 MB/s ( $d = 7.5$  m), 2.25 MB/s ( $d = 4$  m), and 0.86 MB/s ( $d = 1$  m), respectively.

In the second scenario, a Bluetooth-equipped laptop continuously transmits toward a Bluetooth AP at 1 mW and 1 m distance (Figure 37.11c) shows that the effect of Bluetooth interference on the Wireless Interface retrasmssions is much smaller than the effect of WLAN interference. In the converse direction, the Bluetooth data rate was reduced from 29.2 to 25.6 kB/s by the interference from the Wireless Interface.

Further work on Wireless Interface is under way in the WSAN (Wireless Sensor Actuator Network) group of the Profibus International group on implementing, for example, WLAN options, which allow a blacklisting of WLAN Channels. As the dominant influence on WLAN is the continuous downlink (compare Figure 37.12, top and middle), just blacklisting the downlink is improving the WLAN statistic significantly (see Figure 37.12, bottom), where the downlink has been in a wire to verify uplink influence. This statistic is already very close to the reference measurement (top).

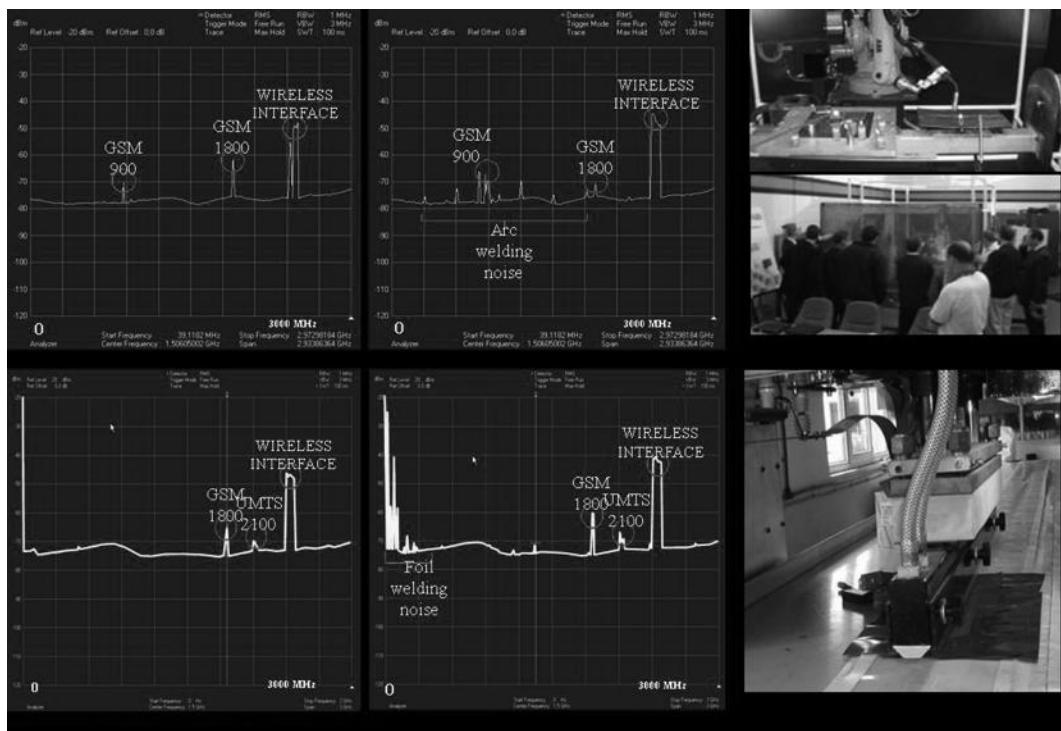

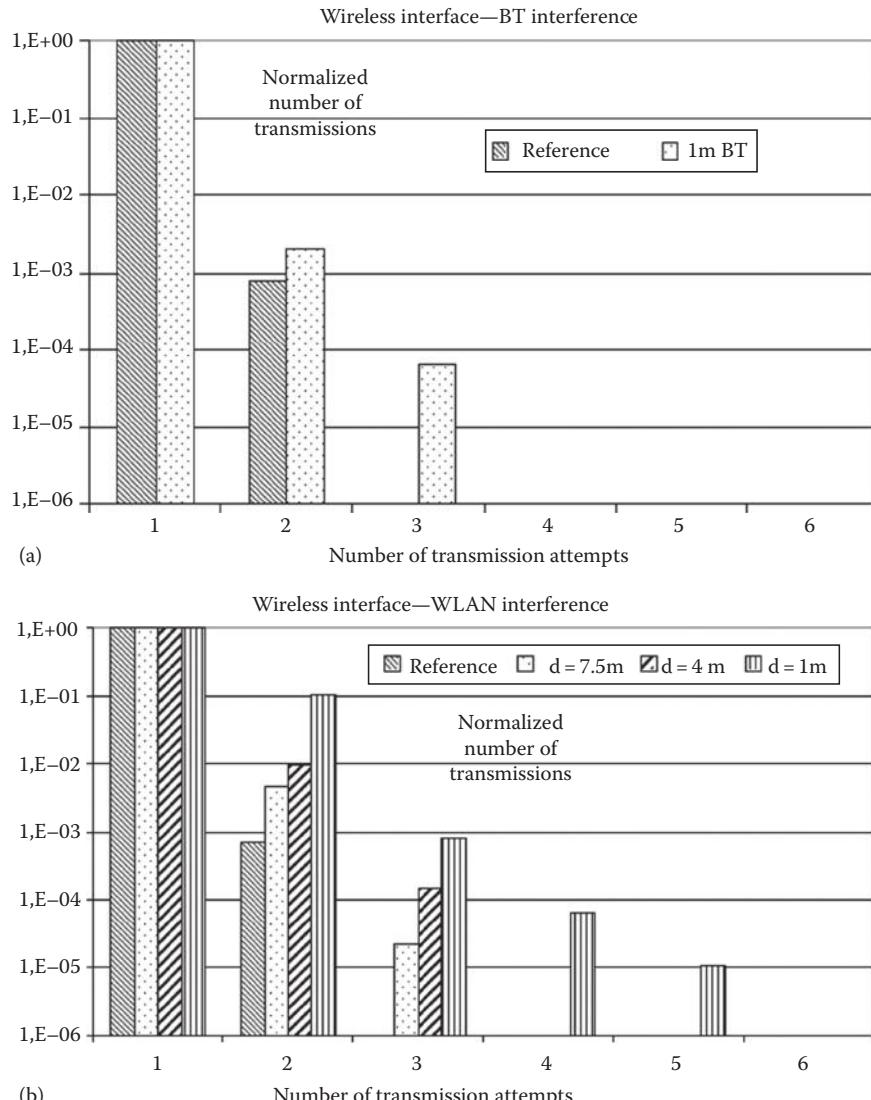

FIGURE 37.10 Frequency spectrum plots of electromagnetic noise of industrial welding equipment.

It has to be noted that generally the disturbance range of a system, outside which, for example, frequency can be reused, is significantly larger than the safe operation range. The disturbance range of a wanted system also varies with respect to a victim system, so it is not a wanted system property only.

## 37.5 Wireless Power Subsystem

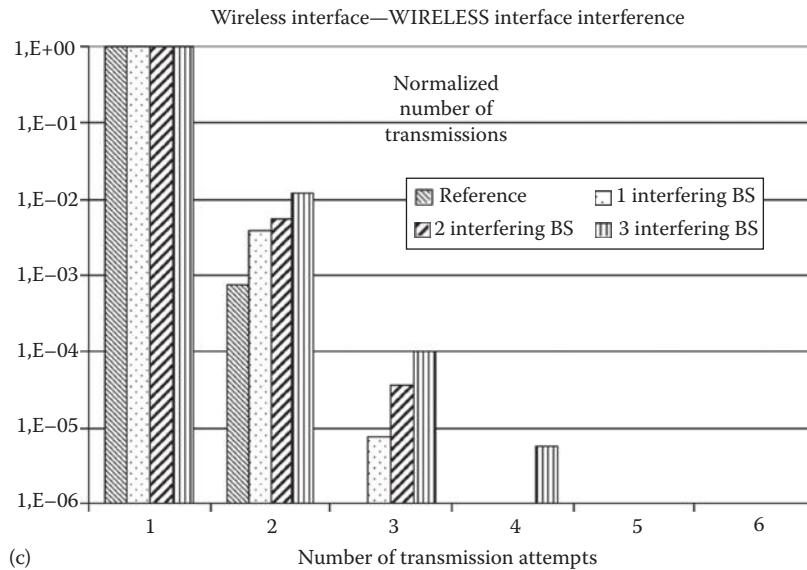

Wireless power in principle can be supplied by different concepts:

- Energy scavenging: Taken from the local environment in the form of light, heat, vibration/motion.
- Energy storage: Included in the system in the form of batteries, fuel cells, etc.
- Energy distribution: Transmitted to the system via optical or radio frequencies, sound, etc.

**FIGURE 37.11** Measured retransmission statistics for uplink messages due to interference. (1 retransmit = 2048 µs).  
 (a) Wireless Interface/Wireless Interface (1 m distance). (b) Wireless Interface/WLAN.

(continued)

**FIGURE 37.11 (continued)** Measured retransmission statistics for uplink messages due to interference. (1 retransmit = 2048 µs). (c) Wireless Interface/Bluetooth.

The use of battery power is considered acceptable in the consumer world. However, in general industrial applications, where hundreds of devices require constant, reliable power supply and run day and night, batteries are not an option. Their energy density (normally around 1.2 Wh/cm<sup>3</sup> for primary batteries) is still too low, or the other way round: The consumption of low power radios and sensors is still too high for general use. While for secondary batteries there has been quite some development their volumetric energy density is still significantly lower than for primary batteries, typically by at least a factor of 3–5. For primary batteries, there has not been a noticeable progress regarding energy density.

Fuel cells are potentially somewhat better, but even their realistic potential is little more than 2 Wh/cm<sup>3</sup> (petrol energy density would be around 10 Wh/cm<sup>3</sup>) and much development is still required before they could be envisioned to be used in everyday industrial installations [14]. Another fact is to be considered for fuel cells: Like human beings, they simply need air to breathe and evaporate water, a challenge for IP67 housings.

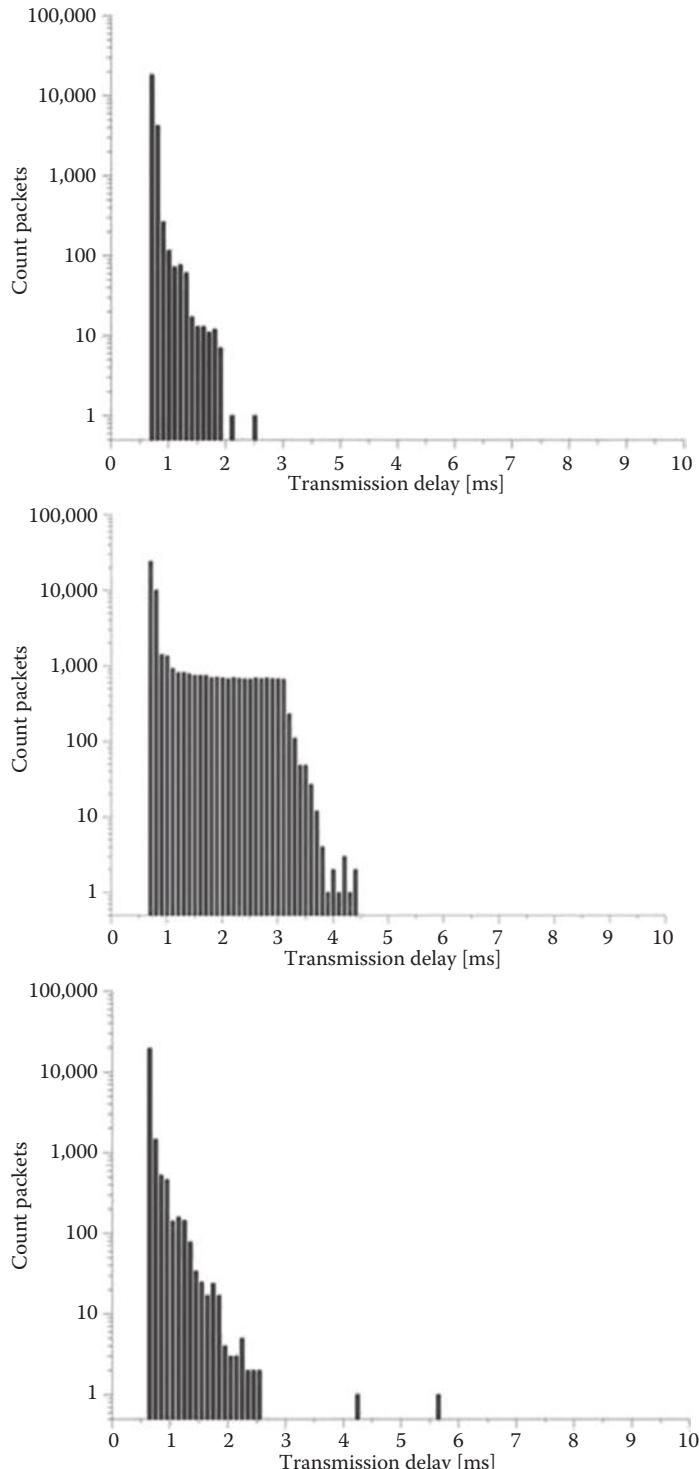

Environmental energy sources also fail to meet the needs of general industry applications, due to their unpredictable nature—both in terms of general usability without special engineering work and reliability. Such solutions would also incur considerable engineering and design costs for every single device. Nevertheless, for some niche applications, there are use cases, for example, vibration or high temperature monitoring (Figure 37.13).

Regarding the energy distribution concepts, only magnetic coupling in the near field can transfer enough power for general use. There are a number of possibilities to use magnetic coupling, depending on the transmission distance, a wide range of applications and power levels can be covered (mW at several meters of air gap up to tenth of kW at millimeters).

After a thorough evaluation of the various available options [14,15], it was concluded that the only viable, generally applicable solution for factory automation is based on long-wave radio frequencies, a form of inductive, magnetic coupling.

In Table 37.2, a comparison for a special use case of a wireless proximity switch is summarized. A figure of merit is defined, which summarizes the characteristic figures:

- Energy amount over 5 years (Wh)
- Energy cost over 5 years (USD)
- Risk of developing such a supply (factor)

**FIGURE 37.12** Measured WLAN-latency statistic (64 byte every 5 ms). Top: Reference measurement (no other frequency user). Middle: With Wireless Interface in parallel, +2 ms downlink influence visible (3 m). Bottom: Same, uplinks only (downlink in cable); 4 consec. Wireless Interface nodes (50 events/s simultaneously).

**FIGURE 37.13** Overview of wireless power concepts and technologies; power levels, deficiencies, and remark for general application in factory automation.

The figure of merit is computed by dividing energy by cost and by risk according to Table 37.2. Inductive energy transfer at low frequencies of around 100 kHz has clearly the highest figure of merit regarding the intended application.

This is the so-called Wireless-POWER approach. This wireless supply principle, described later in more detail, provides power supply across a distance of a few meters with the help of magnetic fields and is suitable for most sensors and electrical actuators (like pneumatic valves) in discrete factory automation.

### 37.5.1 The Magnetic Supply: Wireless-POWER

The basic principle of a magnetic field-induced power supply can be described by the well-known transformer principle. A power supply unit feeds a primary winding, a large coil, which can be arranged around a production cell. The secondary side consists of a practically unlimited number of small receiver coils (see Figure 37.7). Each receiver coil is equipped with a ferrite core to increase the amount of flux collected by the coil and to minimize effects of external conductive materials. For this type of *transformer*, magnetic coupling is very low (<0.1%). The receivable power is determined by the amplitude of the magnetic field at the location of the *receiver* (secondary) winding and its size.

Although human operators will rarely work continuously inside such an automated production cell, the strength of the magnetic field at all working positions (including within such a cell) complies with international occupational regulations and recommendations [16]. Wireless-POWER works at the frequency of 120 kHz. The distance to be observed by a pacemaker carrier to this setup would be 2.5 m at the maximum current of the WPU (24 A) according to strict German regulations.

Energy losses in such a wireless power system are surprisingly small and are mainly caused by skin and eddy current effects in the coil itself and in nearby metal objects, especially steel. In many different production cells in factory automation equipped with Wireless-POWER, energy losses have been measured to be around 10–15 W/m<sup>3</sup> of supplied cell volume.

The principle does not depend on the frequency, but the chosen frequency is a good balance between

- Higher amplitudes needed at lower frequencies (higher ohmical losses)
- High-frequency losses in a realistic environment, where always metal will be present to a certain degree (eddy current losses)

**TABLE 37.2 Example Power Supply Comparison for a Typical Autonomous Industrial Sensor Application by a Figure of Merit (One-Third of Sensor: 6 cm<sup>2</sup> Usable Surface, 2.5 cm<sup>3</sup> of Usable Volume)**

<sup>a</sup> Estimation.

- Semiconductor switching losses
- Capacitive dielectric losses
- Component sizes (larger at lower frequencies), which is especially an issue on the receiver side, where you need to have small devices

As the receivers will typically be designed to consume just 5–100 mW (sensors—small actuators) the aforementioned losses will clearly dominate the power consumption. Therefore, the amount of such wireless devices is practically not limited; several hundred or even 1000 can be supplied.

### 37.5.2 Resonant, Medium-Frequency Power Supply

These unconventional transformers have to be operated in a *resonant* mode, in order to compensate for the large leakage inductances of the transformer. The resonant principle allows the wireless power unit WPU to stimulate the resonant circuit at relatively low voltages (<60 V).

The WPU has to have a control circuit that must also be able to accommodate the following:

- Changes over time in the environment, for example, caused by the movement of large, metal objects such as robots
- Different *load* requirements, caused by differently sized and formed primary coils (inductance values), and losses, caused by factors such as eddy currents in adjacent metal objects
- Other nearby wireless supply systems, which may couple inductively

### 37.5.3 Rotating Field

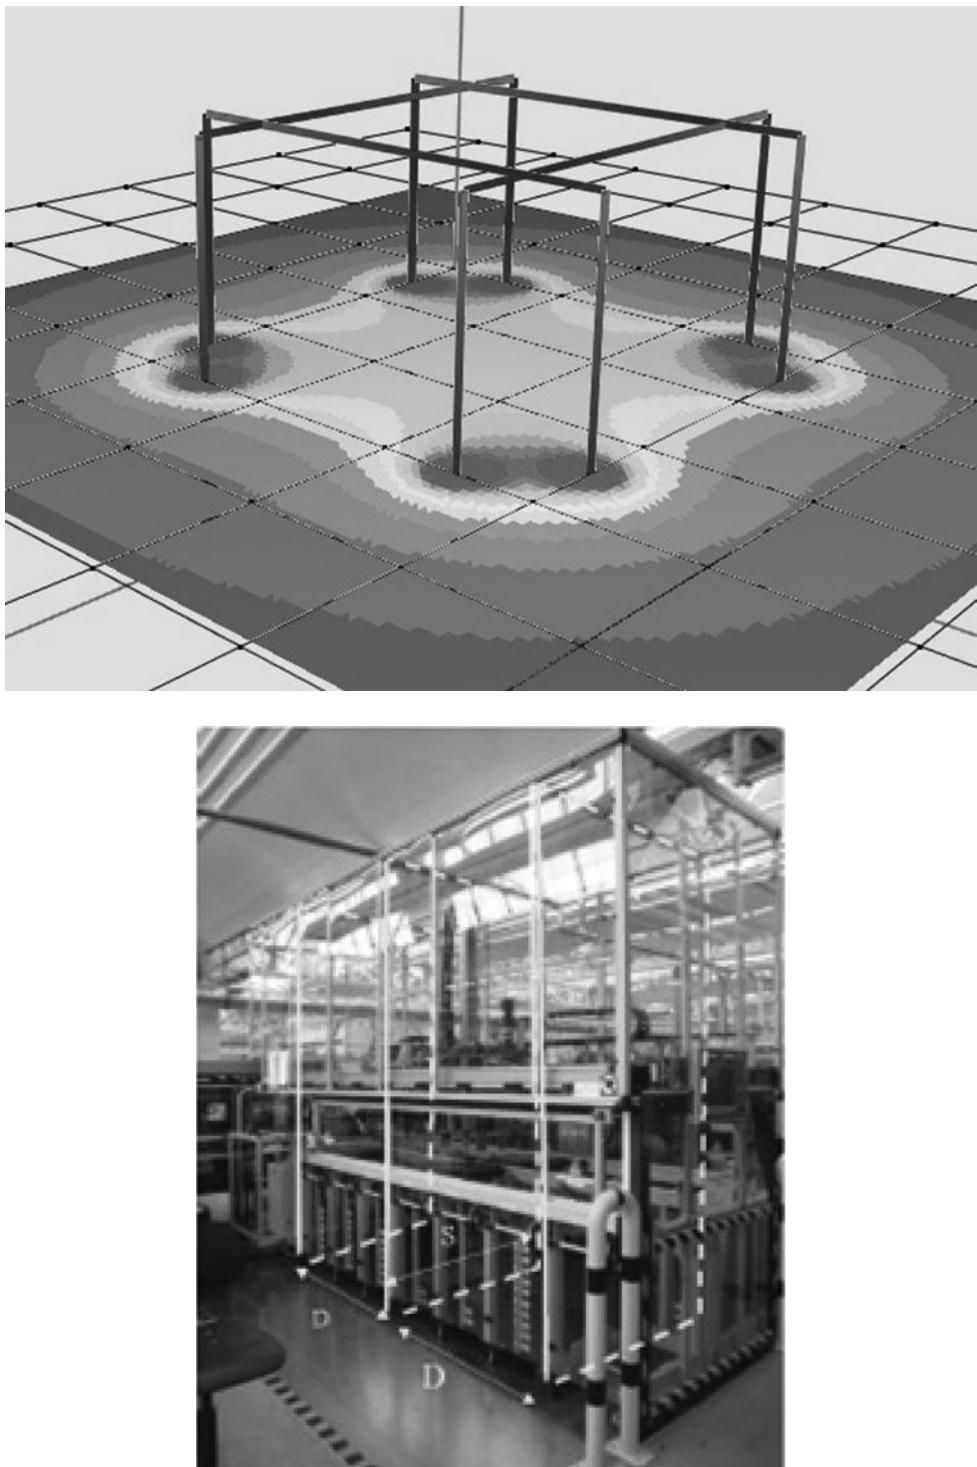

Unidirectional magnetic fields can be attenuated or blocked by metal objects, which is the case in applications where the devices have to be placed arbitrarily or are moved, for example, by a robot throughout the application. To minimize the shielding effects, two primary loops can be mounted orthogonally (see Figure 37.14, top). The loops are fed by separate power supplies, whose currents are phase-shifted by 90° with respect to each other. This creates a field vector that rotates at 120 kHz with a constant amplitude, which is sufficient for most practical applications. With a third loop also an undirected field could be created, by rotating the field vector evenly through the volume. Nevertheless, the additional benefit would have been small in the so far realized applications, but a much more complex control approach would be needed.

### 37.5.4 Omnidirectional Receiver Structure

For sufficient power output, the receiver side also has to be operated in resonant mode. To make the available power independent of the receiver's orientation with respect to the primary field vector, an orthogonal setup of three coils on a common core has been chosen (see Figure 37.7). The available power density for typical *worst-case* shielding conditions in real applications is on the order of 1.2 mW/cm<sup>3</sup>. Typically, it is a factor 2–4 higher. The absolute power level can be modified with the secondary coil size and shape (and the distance to the primary coil). With optimized Q-factors of the receiver coils, much higher levels could be transferred, nevertheless only under ideal, nonrealistic environmental conditions.

### 37.5.5 Example Setup

The resulting field distribution in an installation with rotating field to cover a larger volume is shown in Figure 37.14. The only design quantity needed for the coil placement is the distance D to the next parallel coil. This distance is optimal around two-third of the smallest dimension S of a loop. The smallest dimension S is defining the range of the loop antenna.

**FIGURE 37.14** Top: Simulated field distribution in an example  $3 \times 3 \times 3 \text{ m}^3$  setup. Bottom: Example installation with Wireless-POWER and communication showing some of the integrated power loops and the design parameter distance  $D$ , which depends on the smallest length  $S$  of the coil.

To reach the required minimum field strength for safe operation of the devices, a certain current has to be set at the WPU feeding the loops. A typical current is 24 A for loop with  $S = 3$  m, respectively, smaller in loops with a smaller dimension. If an application is larger, more loops can be cascaded. Also a number of simpler setups are possible for special cases (line and spot type primary loops) as often the range of movement of the devices is limited. A line type primary loop could be as long as 40 m per WPU unit.

## 37.6 Practical Application and Performance Comparison

Wireless technologies have led to a range of products. A fully wireless proximity switch and a sensor concentrator are using both wireless technologies and operate with special energy optimized sensor heads. To also allow the integration of other standard sensors and typically much more power hungry actuators, which might be needed for a complete automation application, a sensor/actor distribution box with up to 16 in.-/or outputs is available. For the Wireless communication two profiles (up to 32 bits in both directions) have so far been implemented, to accommodate the different payload data requirements of different devices (Figure 37.15).

Total power delivered even under worst-case conditions to the wireless proximity switch is 6 mW (sufficient for five events per second). The larger receiver in the sensor pad WSP100, which allows the connection and supply of up to eight sensor heads, can worst case provide approximately 50 mW continuously. Both values are two to four times higher in typical working positions.

Cell dimensions that can be covered with the WPU100 power supply devices are  $1 \times 1 \times 1$  m<sup>3</sup> to  $8 \times 8 \times 3$  m<sup>3</sup>, respectively, 1 m<sup>3</sup> to close to 200 m<sup>3</sup> in a single cell arrangement (without vertical conductors inside).

Integrated into industrial IP67 products, including filtering on the device side, the fieldbus timing uncertainty and the handling delays on the base station side of a field bus master, the performance stays within the specified limit.

The base station interface normally is a fieldbus that adds additional latency. The base station also supports over its built-in user interface a special configurable mapping mode, which can map signals, for example, of wireless sensors directly to other devices with outputs. In that mode very simple latency measurements can be done, without being delayed by the bus interfaces.

**FIGURE 37.15** Industrial automation devices with embedded Wireless-POWER and Wireless Interface-COM technologies (left side) and necessary infrastructure (right side).

Measurements published in Ref. [17] show for the mapping mode a delay statistics with values between 5 and 9 ms increasing in a coexistence setup with two WLAN networks to maximum 11 ms for a few telegrams out of 1 million measured. These latencies measurements were always for two acknowledged telegrams indicating that the Wireless Interface works with latencies of typically 4 ms (2.5–6 ms).

The machine shown in Figure 37.14 is in continuous shift operation since 2003. In total several Wireless Interface applications with several hundred devices have been monitored over several years. Therefore, up to date roughly 4 million device hours have been accumulated, giving a very good feedback of the achieved reliability in production. The main lessons learned were on mechanical issues (usability of housing and connector).

Applications with up to 156 independently rotating nodes in one machine (cable winding machine, Karlskrona Sweden) have been installed in 2005 with up to four colocated base stations. All the sensors are in cable drums, which continuously move in a Ferris wheel-type cage arrangement with multidimensional movement. Several more of such machines are installed or planned.

A further challenging application where the real-time properties are mission-critical is automotive stamping. The delays of the wireless system have to be within the mechanical limits of the press, otherwise drastic failures could occur. The wireless devices are installed in the press tools that are frequently exchanged, so also fast start-up and reconnection times are an issue here. A Wireless Interface device can, after start-up, be transmitting again already after few 100 ms, including internal secondary power supply start-up procedures.

To quantify the achieved performance, another figure of merit was defined (see right column in Table 37.3/I) as number of nodes divided by real-time limit and by power consumption. The empirical quantitative comparison of the technologies mentioned in Chapter 2 was done using the figures as given in Table 37.3. Assumed was the wireless connection of simple proximity switches (1 bit), the most widespread sensor in discrete factory automation.

Data as listed in Table 37.3 are often a subject of controversy and consistent practical data cannot be found in papers. Therefore, typical estimated values have been collected and taken to enable a comparison. Where values cannot be really guaranteed due to the technology, the figures in parentheses have

**TABLE 37.3** Empirical Comparison of Wireless Technologies in Discrete Factory Automation for Short Data Packet Applications (Sensors)

I	Nodes/ Network	Networks per Cell <sup>a</sup>	Cycle Time Air Interface in ms	Real Time Limit <sup>b</sup> in ms	Energy/Bit with Retransmits in mWs	Figure o. MERIT (Nodes per ms a. mWs)

<sup>c</sup> Not defined, value assumed for comparison.

<sup>d</sup> Usable volume: Assumed radius of range *r*, height 2 m.

been used to conduct the performance comparison. In Table 37.3, *Enocean* refers to a proprietary technology known for its low power consumption, developed for building automation.

The real-time limit in Table 37.3/I is the time delay, which can be *practically guaranteed* (very small failure probability, goal here at the mentioned number of nodes in operation:  $10^{-9}$ ).

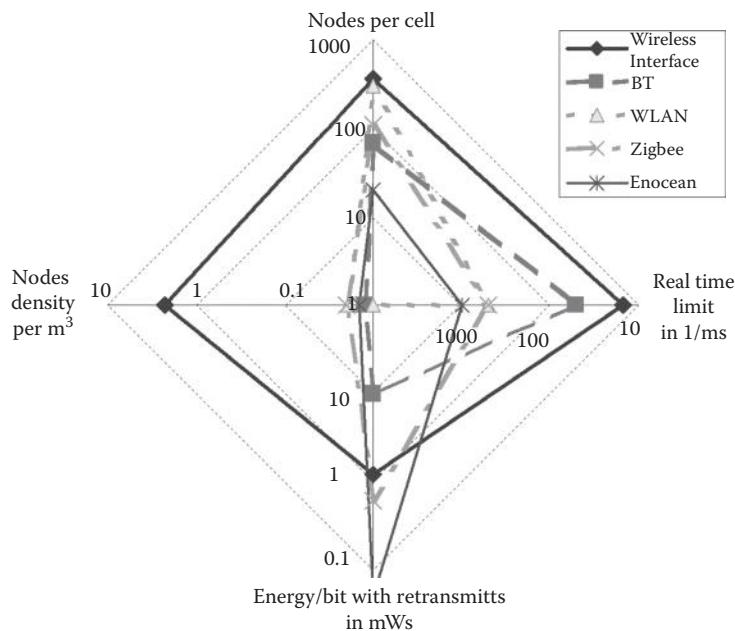

As an example, consider a Bluetooth pico-net having up to seven slaves. Ten Bluetooth networks have been reported to operate directly in parallel [3], without a significant decrease in performance. Assuming the typical range in industrial environment, for example, 30 m in for Bluetooth (100 mW class 1 version) and assuming a height of typical applications of 2 m a realizable average node density figure per  $\text{m}^3$  can be calculated (Table 37.3/II). This average figure is quite small for Bluetooth due to the longer range, compared with the requirement (0.25–2 wireless devices per  $\text{m}^3$  in factory automation applications; see Chapter 2). Bluetooth can operate with a cycle time of  $\sim 8.75$  ms, but under realistic conditions at high node densities, the maximum latency that can be practically guaranteed is much higher, figures of 50 ms have been reported by various groups. For Bluetooth, a power consumption of 50 mW has been estimated, assuming a certain duty cycle in use.

The resulting figure of merit (last column in Table 37.3/I) for the Wireless Interface is 20 (nodes per ms and mWs), roughly a factor of hundred higher than for any other technology. This relation changes somewhat on the energy per bit scale, with assuming a 32 bit payload, but will still be around a factor of 50 higher.

Looking at Table 37.3/II, it can be clearly seen from the achievable average node density in a factory hall, that only the Wireless Interface can achieve the requirements for a whole factory.

It is worth reminding that generally a smaller range allows a higher node density, due to lower interference between cells. A low range is typically acceptable in factory automation, where a given base station needs only to provide coverage for a manufacturing cell.

For technologies like Enocean, ZigBee, and WLAN, low failure probability is not generally possible due to the impact of, for example, a moving environment in machines within their long range  $r$  (see Table 37.3/II); therefore, the figures have been put in parentheses. Figure 37.16 visualizes the achieved match of performance of the Wireless Interface compared with the requirements and the discussed competing technologies.

**FIGURE 37.16** Visualization of comparison for the most important requirements in discrete factory automation (empirical, mind logarithmical scale).

It should be noted that despite the empirical approach, it is not changing the picture a lot, if a certain value would be differing by a factor of 2, due to the logarithmic scales chosen on each of the axes.

The characteristic figures defined in Chapter 4 coexistence can be used to help practically judge the coexistence behavior of the different in factory automation used systems/technologies. In order to do this, a fictive real-time system with a TDMA approach as implemented in the Wireless Interface on an IEEE802.15.1 physical layer has been assumed implemented with the different physical layers of IEEE802.15.4.-based systems (Zigbee, WirelessHART) and as comparison WLAN (IEEE802.11.g). To calculate a duty cycle for frequency usage, it has been assumed that 100 nodes should be covered as fast as possible, an application cycle time of 20 ms (e.g., PLC) has been assumed, in which all nodes should transmit one telegram correctly.

Table 37.4 shows the assumed realizations and the values used to calculate the characteristic figures. For the 15.4 PHY, it is visible that the resulting TDMA frame of 50 ms would be much larger as the anticipated applications cycle time of 20 ms; therefore, 15.4 would not be practically usable with such a number of wireless nodes. Table 37.5 calculates the characteristic figures defined in Chapter 3 for the three different physical layers.

**TABLE 37.4** Assumed Realizations of a TDMA Real-Time System, Based on Different Standard Physical Layers and Resulting TDMA Frame in Which All Nodes Could Transmit

Actual nodes	100	1 byte data		
MS application cycle (PLC)	20			
	Bandwidth MHz	Slot time in ms	Data rate Mbit/s	Resulting TDMA frame time in ms
IEEE 15.4 PHY	3	0.5	0.25	(50 <sup>a</sup> )
IEEE 15.1 PHY— WIRELESS Interface	5	0.064	5	1.6
IEEE 11.g PHY	22	0.04	54	4

<sup>a</sup> Longer than necessary application cycle: Not realizable.

**TABLE 37.5** Characteristic Figures for Three Different Physical Layers in an Assumed TDMA Real-Time Implementation (Empirical, Indicative Only)

Characteristic Figures	Performance		Coexistence	
	E = Spectral efficiency	P = performance	F = Frequency usage (@ max. nodes)	R = Robustness (empirical)
	Bit rate/bandwidth	Nodes/cycle time and per bandwidth	Bandwidth × (nodes × slot time/application cycle time)	Min. latency/max. latency
		Nodes/(ms × MHz)	(MHz)	Ideal/worst case
IEEE 15.4 PHY	0.083	0.67	7.5	~0 <sup>a</sup>
IEEE 15.1 PHY— WIRELESS Interface	1.0	12.5	1.32	0.25 <sup>b</sup>
IEEE 11.gPHY	2.45	1.14	4.4	0.02 <sup>c</sup>

<sup>a</sup> The worst-case latency for a 15.4 system is very large, as fading with a large bandwidth can frequently or even statistically occur; that is why normally a mesh layer should be used to find alternative routes then.

<sup>b</sup> WIRELESS Interface has been measured, for example, in [4] as WISA.

<sup>c</sup> A WLAN latency as, for example, measured in [16] in a very quiet environment can be as fast as 0.7 ms, but in a realistic environment, 100 nodes connected with parallel other WLANS and users, up to 35 ms can be frequently measured.

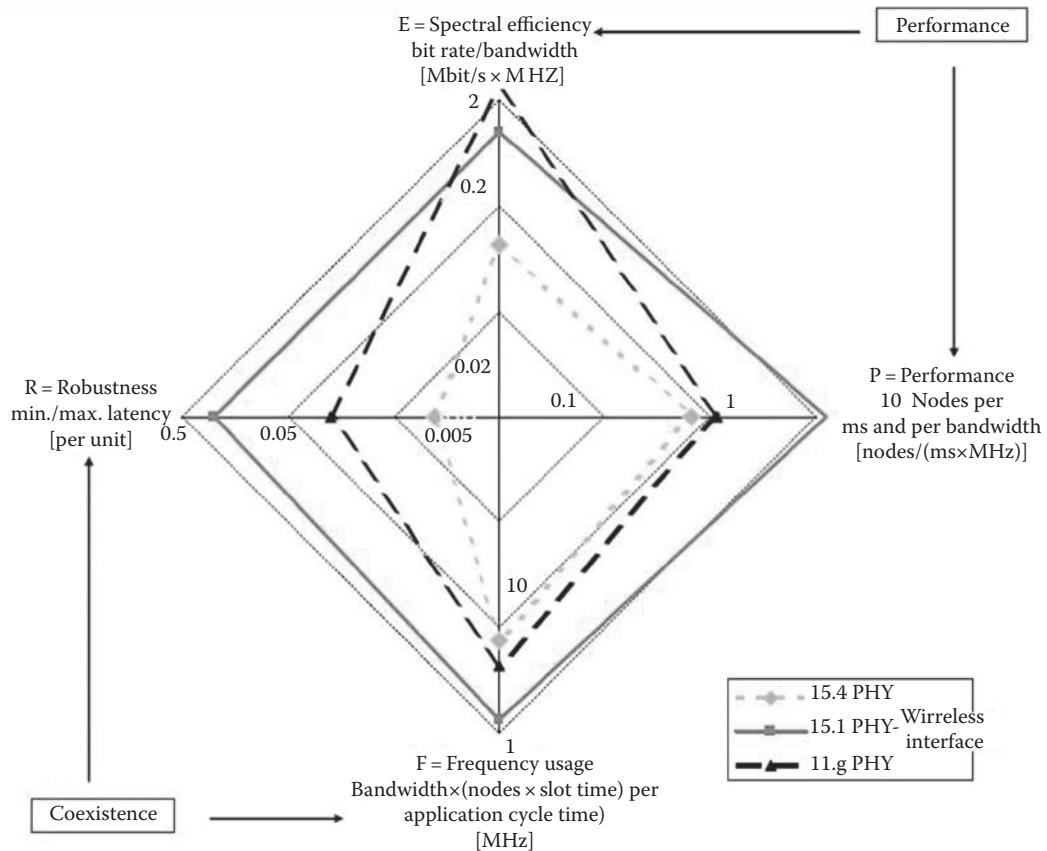

FIGURE 37.17 Characteristic figures for coexistence and performance according to Table 37.5.

The IEEE802.15.1 physical layer-based Wireless Interface implementation has, although it uses five 15.1 frequencies simultaneously, a lower frequency usage F compared with the much higher data rate WLAN, which, if used like that, suffers from its overhead at the assumed small data packet sizes of 1 byte (e.g., a typical simple binary sensor).

The values of Table 37.5 are plotted in Figure 37.17 to visualize again the different profiles of the technologies for short packages.

## 37.7 Summary

A truly wireless sensor/actuator interface with wireless power and wireless communication for real-time factory has been presented. The Wireless Interface uses IEEE 802.15.1 radio transceivers, but adds an optimized TDMA protocol to support a high number (120) of S/As per base station as well as short cycle times (2048 µs).

It is important to emphasize that Wireless Interface parameters differ significantly from the design goals of existing short-range wireless office systems such as Bluetooth or ZigBee. This difference has been verified graphically and by a figure of merit, which compares the performance to the most important requirements in discrete factory automation applications.

The FH sequences are constructed to guarantee adequate frequency separation between consecutive hops and low correlation (low interference) in the case of multicell operation. In combination with an

appropriate ARQ scheme, this provides reliable and low delay data transmission. All cells use the entire available ISM frequency band of 80 MHz at 2.4 GHz, without any requirement for frequency planning.

The effect of interference from other systems likely to operate in the same frequency band has been analyzed, and the Wireless Interface is designed to withstand such interference. For comparison of coexistence and robustness, new characteristic figures have been proposed to quantify discussions.

A wireless power supply system has been designed and verified together with the wireless devices in many practical installations.

The system has been implemented into products and its performance in real factory applications has been verified and more than 4 million node hours have been accumulated. Products based on it are commercially available and are used in a growing number of diverse applications in discrete factory automation [18], some of them already running for more than 5 years.

### 38.1 Introduction

---

In the past decade, a great deal of research has been conducted in the field of wireless sensor networks (WSNs). One important part of a WSN node is its communication interface. In the early days of WSN, these communication interfaces were not standardized. But today, standardized communication interfaces, which are in line with machine-to-machine (M2M) communication requirements (self-describing interfaces, self-organizing, and self-healing), are required to build the foundation of the Internet of Things (IoT) or Web of Things.

IEEE 802.15.4 defines physical and medium access control layer and is widely used in current WSNs. Recently, this standard was mainly the basis for proprietary protocols, like ZigBee, WirelessHART, and SP100. But today, IEEE 802.15.4 is also used as the basis for Internet Protocol (IP). With the availability and wide acceptance of 6LowPAN—an adaptation of the IP Version 6 for low-power networks with limited resources—the IP functionality is now available for distributed networks with very limited resources.

This chapter describes 6LowPAN—an adaption protocol—which brings IPv6 (IP version 6) protocol to WSNs using IEEE 802.15.4 communication standard. With 6LoWPAN, various challenges have been solved to integrate applications that used to rely on proprietary protocols into the global digital village.

Further, basic principles and features of CoAP, an emerging application protocol initially based on 6LoWPAN, are explained. CoAP forms the basis for RESTful embedded web services, which are often used in IP-based sensor networks for seamless integration.

## 38.2 IPv6 over Low-Power Wireless Personal Area Networks—6LoWPAN

---

On low-power wireless devices like WSN nodes and for Smart and Cooperating Objects (SCO), Zigbee over IEEE 802.15.4 is one of the predominating protocols today. Such WSNs lie on the edge of networks, or at the field level in process automation. Today, application layer gateway or proxy solutions are used to integrate WSNs, with their proprietary protocols, into enterprise systems, or higher level services in the IP-based networks. Changes in the application, the protocol data representation, or data encoding, impose high management and computational effort for the application layer gateways. In contrast to gateways, routers of IP-based networks with their end-to-end connectivity just forward packets and do not need to have a deep knowledge about the mission of the specific WSN and applied protocols.

Alternatively to proprietary solutions, for M2M communication and for integration purposes in enterprise systems, IP would be a suitable contributor. IP is the predominating protocol in network infrastructure for information and communication systems, ranging from local area to wide area networks. However, IPv4 is obsolete considering the envisioned trillions of devices, which will appear in the near future. IPv6, the next generation IP, expands address space of IP to  $2^{128}$  addresses and includes miscellaneous conceptual improvements based on experiences with IPv4.

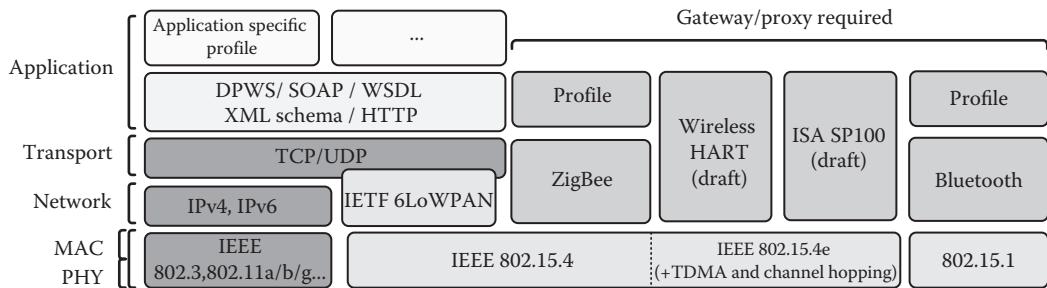

Until recently, IP was not an option for WSNs because there were no IP stacks available that would run on resource-constrained WSN nodes. However, latest developments have born IP stacks, which run on tiny 8-bit microcontrollers like TI's MSP 430—a commonly used microcontroller in WSNs. The footprint of such IP stacks for microcontrollers is around 12 kB (cf. uIPv6 [Dur08]).

Dependent on IP, other higher level protocols, tools, and applications have been established. Protocols like DNS, DHCP, Zeroconf, etc., can be used for naming, addressing, discovery, and configuration. Tools like SNMP, ping, arp, traceroute, etc. are usable for management purposes. Even at the application layer level, matured protocols, data models, and services such as HTTP, HTML, XML, SOAP, REST, etc. are well-established and essential for IT developments. With all these tools and protocols and decades of experience with them, designing and developing WSN becomes easier, more efficient, and thus less expensive.

Summing up, IP is supported by all classes of operating systems ranging from desktop operating systems, embedded and real-time operating systems, to operating systems for WSNs like Contiki [Dun04]. IP protocol stacks are available as an integral part of the operating system, as open source software stacks, and commercial solutions. The uIPv6 [Dur08] stack is an implementation of the 6LoWPAN protocols described in this section. For proprietary protocols, there are only few open source solutions available. They are limited to specific application areas and application niches. Future networks of smart and cooperating objects are not for niche markets only. They will pave the way for very new innovative and broad application areas. That said, IP radically helps to enforce that development, provides the basis for cross-domain interoperability, and will break through technology-specific boundaries.

### 38.2.1 Introducing IEEE 802.15.4

Based on IEEE 802.15.4 [IEEE154], which defines the physical (PHY) and medium access control (MAC) communication layers as depicted in Figure 38.1, various upper layer protocols have been defined by

**FIGURE 38.1** IEEE 802.15.4 in context.

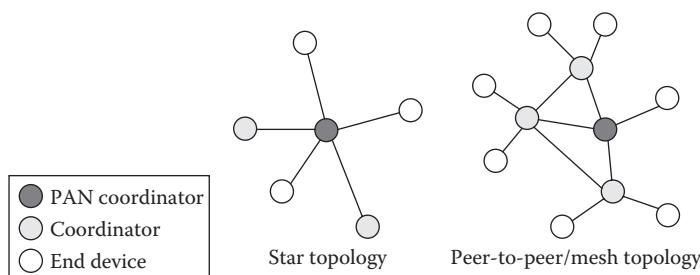

large industrial consortia; for example, WirelessHART, ISA SP100, and ZigBee. Open standards and proprietary industrial consortia standards will be in a close competition. Key features of all protocols are as follows:

- Long battery life through low-power consumption solutions
- Self-healing networks
- Scalability and support of large networks
- Low cost node
- Low data rate

IEEE 802.15.4 is a standard for wireless personal area networks with low data rates (LR WPAN). The wording “personal area networks” in the 802.15.4 standard is misleading at this point, because 802.15.4 networks are of course not limited to personal use. While technologies like WiFi (802.11) and Bluetooth have been developed for high data throughput, the focus of IEEE 802.15.4 networks was power awareness and low-cost design, which results in low data rates.

The IEEE 802.15.4 standard specifies two physical (PHY) layers—working in the 2.4 GHz and 868/915 MHz band PHY layers. The physical layer depends on local regulation and user preference. The unlicensed 2.4 GHz is valid worldwide and has a higher data rate (240 kbps) compared to 915 MHz band with 40 kbps (US) and 868 MHz (EU) band with 20 kbps data rate. The radio can operate on 16 channels in the 2.4 GHz band, 10 channels in the 915 MHz band, and 1 channel in the 868 MHz band.

IEEE 802.15.4 supports like other low-power link layer several topologies including star and peer-to-peer mesh as depicted in Figure 38.2. Within the topology, the device may form lightweight end points (leaves), which require a minimum of resources in terms of memory, computing power, or energy. With slightly more resources available, the devices may act as full function device (FFD) other endpoints named as reduced function devices (RFD) may connect to. These FFD also provide routing functionalities within the meshed topology. Most resources within the topology are required by the so-called PAN (personal area network) coordinator, which is in charge of managing the network.

**FIGURE 38.2** IEEE 802.15.4 topologies.

### 38.2.2 Introducing 6LoWPAN

The IETF has foreseen an urgent need for IP-based communication also on wirelessly connected resource-constrained network nodes using IEEE 802.15.4 communication systems. Thus, the 6LoWPAN working group was founded. The name of the working group is currently used widely as acronym for the specific protocol adaptations developed within the 6LoWPAN working group and thus also as name for WSNs using these 6LoWPAN protocols.

The goal of the 6LoWPAN working group was to develop a standard that allows IPv6-based communication over IEEE 802.15.4. In the process of developing the standard, most adaptations became agnostic from the specific 802.15.4 technology and therefore the 6LoWPAN protocols can also be used on top of other low-power links. For example, at the time of writing this section, 6LoWPAN over Bluetooth Low Energy is under development within the IETF.

It is important to notice though, that the 6LoWPAN protocols only describe adaptations and enhancements on the addressing layer. They form the glue between the physical layers and the upper application layer. For higher layers on top of 6LoWPAN, the adaptations and enhancements are transparent and provide identical functionalities as native IPv6, that is, full IPv6 address with global scope if required, end-to-end connectivity, etc. However, when 6LoWPAN nodes communicate with native IPv6 endpoints, the adaptations and enhancements have to be mapped into the corresponding IPv6 pendants. Thus, the 6LoWPAN networks are stub networks at the edge, with dedicated links to other networks and/or the backbone. These links are called border routers and are responsible for forwarding IPv6-only or 6LoWPAN-only communication.

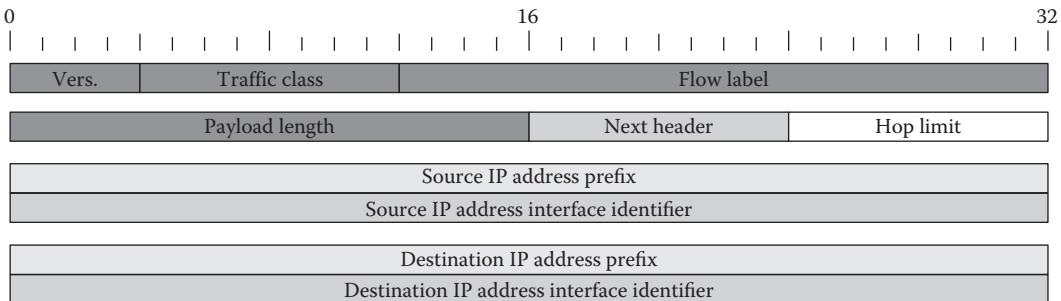

The mentioned adaptations and enhancements that transform native IPv6 to 6LoWPAN and thus to enable IP-based communication in highly resource-constrained networks can be separated in three major parts: (1) compression, (2) fragmentation, and (3) neighbor discovery. All of them are described in the remainder of this section before briefly covering routing.

### 38.2.3 Compression

Low-power link technologies like IEEE 802.15.4 are characterized by small frame sizes. A typical IEEE 802.15.4 frame is 127 bytes, leaving 81 bytes for upper layers if MAC header and security information are included (worst-case payload = 127–25 bytes MAC header – 21 bytes link layer security = 81 bytes). A native IPv6-header already has a size of 40 bytes, not taking IPv6 extension headers into account. To transport this IPv6 header and, for example, an additional UDP header would result in the remaining 33 bytes (remaining payload = 81–40 bytes IPv6 header – 8 bytes UDP header = 33 bytes).

To transmit IPv6 efficiently over low-power links, the IPv6 headers can be compressed. The objective of this compression is to avoid information carried inline, which is implicitly known or which can be retrieved differently. Examples for the compression of the IPv6 header fields are as follows (c.f. Figure 38.3):

- The protocol version is always IPv6. This field can be omitted.
- The fields Traffic Class and Flow Label are not applicable in meshed low-power networks and can be omitted.
- The field Payload Length is redundant and can be omitted, because this information is already carried in the IEEE 802.15.4 header.
- The Next Header field can be omitted if no next header is carried in the frame.
- The Hop Limit field cannot be compressed and must be carried fully inline.
- The IPv6 address prefixes of the source and the target endpoints may be already known and/or the same, for example, if both endpoints are in the same 6LoWPAN and for the entire 6LoWPAN one prefix is used. In this case, the prefix(es) can be omitted or compressed.

**FIGURE 38.3** Native IPv6 header.

- The IPv6 interface identifiers of the source or the target may also be redundant, if the IPv6 interface identifiers are generated from the MAC addresses of the endpoints. For communication within an IEEE 802.15.4, the MAC addresses thus are already carried in the 802.15.4 frames and can be omitted/compressed in the IPv6 headers.

Depending on the specific scenario, native IPv6 headers can be compressed down to a few bytes only. Similar to the IPv6 header compression, the 6LoWPAN protocols also describe a UDP header compression, whereby the UDP header can be compressed from natively 8 bytes down to 4 bytes in the best case.

### 38.2.4 Fragmentation

The IPv6 standard requires a minimum MTU of 1280 bytes to be supported by the link layer. But low-power link technologies like IEEE 802.15.4 are characterized by small frame sizes, which are typically far below the required MTU of 1280 bytes. Thus, a fragmentation layer is defined for the 6LoWPAN protocols. This layer is located at *layer 2.5*, that is, between MAC and addressing, and thus provides the addressing layer 3 transparently with the required MTU. By using such a dedicated and transparent fragmentation layer, lower layers still can exploit the energy efficiency of small data frames while upper layers can still benefit from the IPv6 compliant packet sizes.

### 38.2.5 Neighbor Discovery

While the enlargement of the address space is often considered as the major change from IPv4 to IPv6, this modification only affects the format. However, the Neighbor Discovery is the brains behind IPv6. The Neighbor Discovery of IPv6 replaces the mechanisms of IPv4 to retrieve a valid (global scope) IP address and further network configuration parameters such as the address of the default router, etc.

In native IPv6 networks, each endpoint is on the same link as the router that is responsible for the subnetwork. From that router, the endpoint retrieves the address information like network prefix, etc. But in meshed topologies like WSNs/6LoWPANs, the endpoints may not be in direct communication range with the border router that is responsible for the 6LoWPAN subnet. Between the border router and the endpoint, further 6LoWPAN devices acting as forwarding routers may be required. Thus, for 6LoWPAN networks, the Neighbor Discovery protocol has been changed to cope with the topology differences compared to native IPv6 networks (c.f. Figure 38.4).

### 38.2.6 Routing

Due to the emerging 6LoWPAN protocols, the IETF had to also provide a proper routing solution to be used in such meshed low-power IP networks. Therefore, the ROLL (Routing over Low-Power

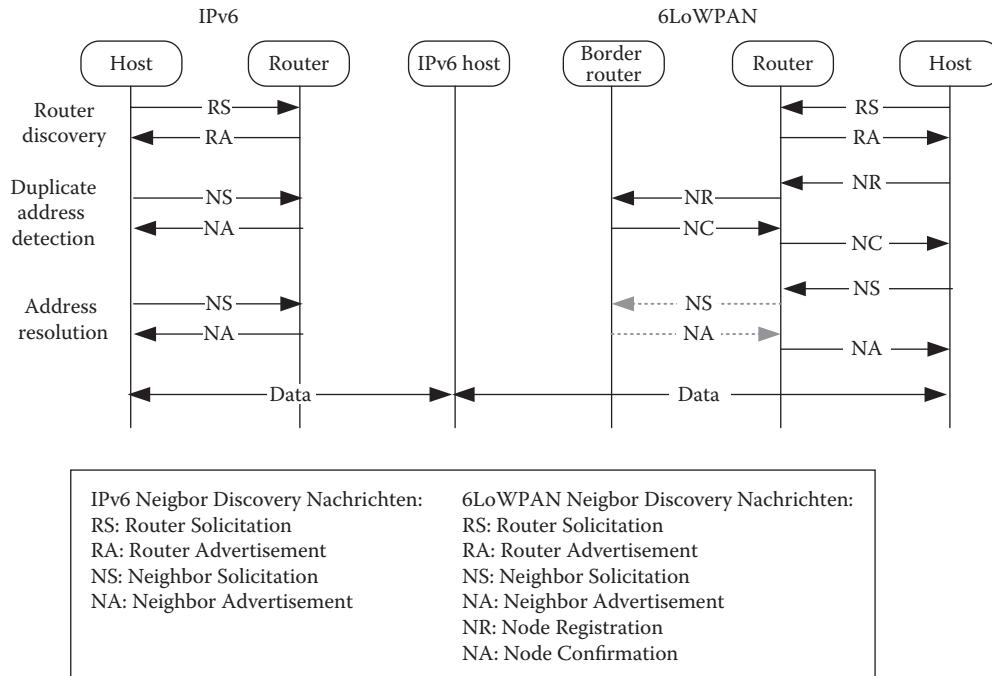

FIGURE 38.4 IPv6 Neighbor Discovery vs. 6LoWPAN Neighbor Discovery.

and Lossy Networks) working group has been formed. Within ROLL, the IPv6 routing protocol RPL (IPv6 Routing Protocol for Low-Power and Lossy Networks; spoken *Ripple*) has been developed. RPL is located on top of IPv6. Thus, it can be used in 6LoWANs as well as in other IPv6-based networks and is agnostic of the link layer. Nevertheless, RPL is optimized for usage in 6LoWPAN networks.

RPL is optimized to pull or push data from the 6LoWPAN into other unconstrained backbone networks. Therefore, RPL establishes a directed, acyclic graph toward a sink. The sink will be the border router of the 6LoWPAN in many use cases, but RPL is not limited to this. The graph (routing tree) can be optimized for several metrics like minimizing energy consumption along the path, minimal hop counts, or spreading traffic load depending on the resources (CPU, RAM, energy) of the routers along the routing path. It is even possible to have more than one such graph in a 6LoWPAN, whereby different routes with different characteristics and metrics may exist from a source to the sink (c.f. Figure 38.5).

Within the routing topology, each endpoint is assigned to one or more routers, whereby one router is the default router. The routers in turn are assigned to routers closer to the sink, or directly to the sink of the routing topology, whereby closer means less costly regarding the used metric and does not necessarily refer to physical distance. Each router informs the sink about its presence and which further endpoints or routers are connected to it. As a result, the sink has knowledge of the whole RPL network. For the communication down the routing topology (i.e., starting from the sink toward the leaves), a source routing is used. In this source routing, all intermediate routers to be traversed are included in the packet by the sink. For communication upward of the topology (i.e., starting in the network and toward the sink) or communication between endpoints in the topology, two different modes exist (c.f. Figure 38.6). To avoid each router to maintain heavyweight and storage-intensive routing tables, the routers may forward all traffic to the sink and from the sink again source routing is used. This mode is called nonstoring mode. To avoid data packets to travel all the way up to the sink and afterward again down, the routers may maintain own routing tables, whereby the packets only have to travel up to the first common ancestor of source and target. This mode is called storing mode.

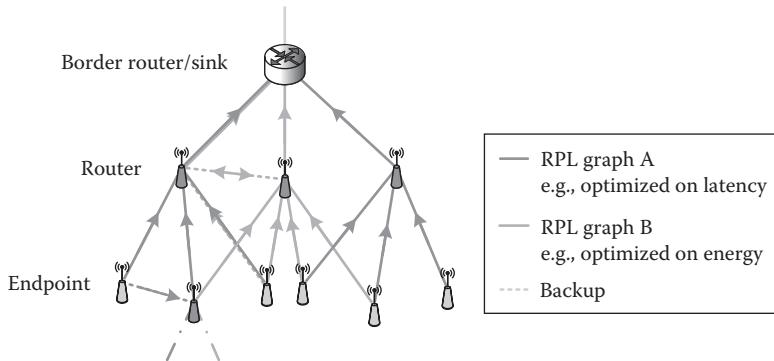

FIGURE 38.5 RPL routing topology.

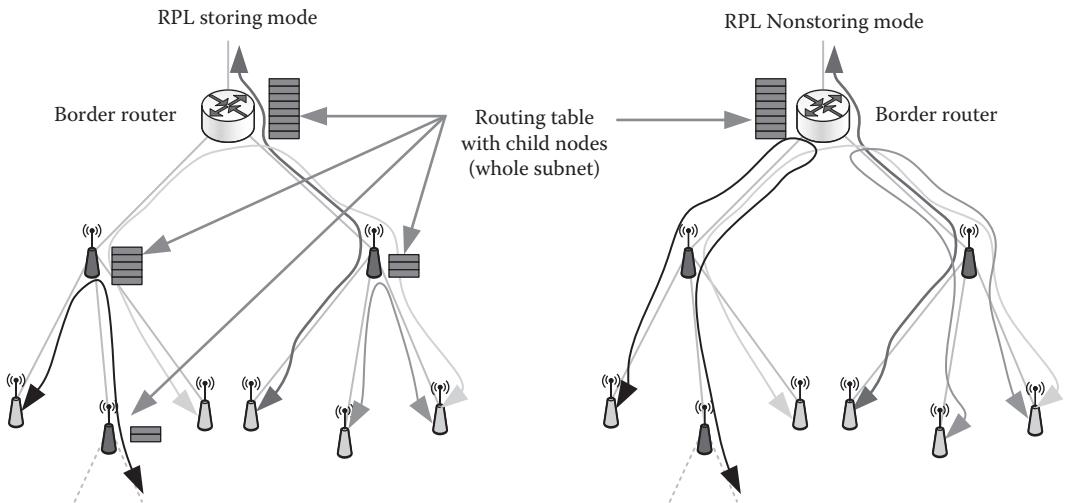

FIGURE 38.6 RPL storing vs. nonstoring mode.

At the time of writing this section, further stateless routing solutions are being developed by the ROLL working group at the IETF. These stateless routing solutions are, for example, based on the well-known Trickle algorithm [RFC2606] and are capable of realizing a so-called controlled flooding behavior. Due to this behavior, such solutions may be more efficient, for example, for IP-Multicast communication in meshed low-power networks.

### 38.2.7 Closing Remarks

The herein described header compression, fragmentation, Neighbor Discovery, and routing give only a very brief overview about the general concepts. However, the overall solution is more complex. The newest protocols and their different operational modes are not well-established today and not used widely. For example, neither Contiki nor TinyOS, which are the two major operating systems for wireless sensor networks, support the storing mode of RPL.

Thus, many of the protocols and protocol components still have to ensure efficient IP-based communication in WSNs. A good example is the group communication via IP-Multicast, which requires a close cooperation of several layers to be efficient. The IETF copes with this fact by producing documents that will not describe further protocols, but which will have a tutorial characteristic and thus describe how to

use the specific protocols. But these documents are still under development, for example, in the Light-Weight Implementation Guidance (LWIG) working group.

A more in-depth overview of the dedicated protocols in general is required only if developers are planning to implement an own 6LoWPAN stack. In this case, readers interested in further details should refer directly to the RFCs produced by the working groups 6LoWPAN and ROLL.

### 38.3 Constrained Application Protocol

---

The previous section discussed how IPv6 packets can be transferred efficiently over wireless links with limited bandwidth. Complementary to the efficient transportation, an equally efficient (M2M) application layer protocol is needed that can be used to realize novel and innovative applications. The CoAP protocol can be used to control resource-limited devices via embedded web services. It is an alternative to SOAP web services, which are mainly used on devices with much more resources available as in WSNs. Bear in mind though that research work showing the feasibility of running SOAP web services on wireless sensor nodes does exist.

#### 38.3.1 Introducing CoAP

The Constrained Application Protocol (CoAP) is a comparatively new application layer protocol. CoAP is currently under development by the IETF Constrained RESTful Environments (CoRE) working group, and is designed for the resource-constrained environments such as 6LoWPANs. Nevertheless, CoAP is independent of 6LoWPAN and may also be used, for example, in existing IPv4 networks.

CoAP is designed in its many parts as lightweight alternative to HTTP. Even though there is more to CoAP than merely being binary HTTP, thinking like that makes it easier to understand CoAP. The major common ground for both CoAP and HTTP are the REST design principles described by Fielding in [Fie00]. In a nutshell, REST is about the following:

- Stateless request/response interaction model between application endpoints
- Addressing resources through URIs
- Representation of the resources and resource states through Internet Media Types
- Uniform and well-defined CRUD (Create, Read, Update, Delete) operations on the resources
- Caching and proxying to allow for scalability

It is important to notice at this point that neither HTTP is REST nor REST is HTTP, but HTTP is a protocol that can be mapped on the design principles of REST and so is CoAP. Readers interested in this discussion should refer to Pautasso, who discusses this issue in [Pau08]. Pautasso also pays attention to the *SOA vs. REST* discussion. While REST is often considered to be more lightweight than SOA, mostly the protocols HTTP and SOAP and/or their implementations are compared, but not the architectural styles. It is important not to confuse the design principles, protocols following these principles, and implementations.

To tailor CoAP for bandwidth-limited networks, the protocol headers of CoAP are encoded binary in contrast to the ASCII encoded HTTP headers. Thereby, a typical CoAP header is about 4–20 bytes, while an average HTTP header is about 700–800 bytes in size. Another major difference of CoAP and HTTP is the usage of UDP at transport layer instead of TCP. TCP performs poorly when used for short-lived request/response exchanges, and the SYN/ACK handshake causes a significant overhead when using a low-power link with comparatively long duty cycles. Thus, UDP is the preferred transport protocol for WSNs. Because UDP is not reliable by default, CoAP adds own mechanisms to ensure reliability and for duplication detection and fragmentation by a dedicated CoAP Messaging layer. These features are not implemented in HTTP since TCP takes care of them. An overview about the differences and commonalities of CoAP and HTTP is given in Table 38.1.

**TABLE 38.1** Comparison of HTTP and CoAP

	HTTP	CoAP
Role model	Client/server	Client/server
Communication pattern	Request/response	Request/response
Transport	TCP	UDP reliability optional via CoAP messages
Transmission	Unicast, point-to-point	Unicast, multicast, point-to-point, point-to-multipoint
Exchange pattern	Mainly synchronously	Synchronously, asynchronously
Service-/data modeling	Resources	Resources
Service-/data addressing	URI	URI
Methods	GET, PUT, POST, DELETE, TRACE, HEAD, OPTIONS, CONNECT	GET, PUT, POST, DELETE
Media-types	Text, JSON, XML, EXI,...	Text, JSON, XML, EXI,...
Response-codes	Informational 1xx Successful 2xx Redirection 3xx Client Error 4xx Server Error 5xx	Success 2.xx Client Error 4.xx Server Error 5.xx
Header-coding	ASCII	Binary
Proxy und caching	HTTP to HTTP	CoAP to CoAP HTTP to CoAP CoAP to HTTP
Formal description	WADL	WADL
Resource-description	HTTP link header format	CoRE link format
Resource-discovery	None	CoAP, CoAP link format
Eventing (c.f. Push)	Long polling/comet, web sockets, BOSH ...	CoAP observe
Security	SSL/TLS	DTLS

### 38.3.2 CoAP/HTTP Proxy and Caching

CoAP provides Caching and Proxy features that are similar to HTTP to ensure the required scalability in large-scale networking environments. In that context, caching means that some of the CRUD style interactions with the resources (e.g., GET, PUT, and DELETE) may result in reproducible results or in the delivery of resource representations with a given time of validity and thus a known expiration time. With such information, clients are able to avoid polling of data if it is known that no changes of the resource representations have occurred since the last request. But furthermore, third-party intermediary caches may respond instead of the originally requested endpoints if the result for this request is already known through former interactions with this endpoint. Such intermediary caches are a key enabler for scalability of the Internet applications and are also available for CoAP.

Due to the significant overlapping of the CoAP and HTTP protocols and due to the REST principles both protocols are based on, in major parts, it is even possible to map CoAP seamlessly to HTTP and vice versa. This mapping is already an integral part of the CoAP specifications which is a major difference compared with other binary field bus protocols.

A full deployment, as exemplary depicted in Figure 38.7, may consist of proxies mapping HTTP in to CoAP and vice versa. Thereby, external implementations and deployments are not required to be changed, and native HTTP over TCP still can be used. But in resource-constrained environments like 6LoWPAN networks, the much more tailored CoAP protocol over UDP can be used. Caches can provide the required scalability of the overall architecture for all four possible combinations of endpoints (c.f. Figure 38.8): HTTP/HTTP, CoAP/CoAP, HTTP/CoAP, and CoAP/HTTP. For the CoAP/HTTP and HTTP/CoAP

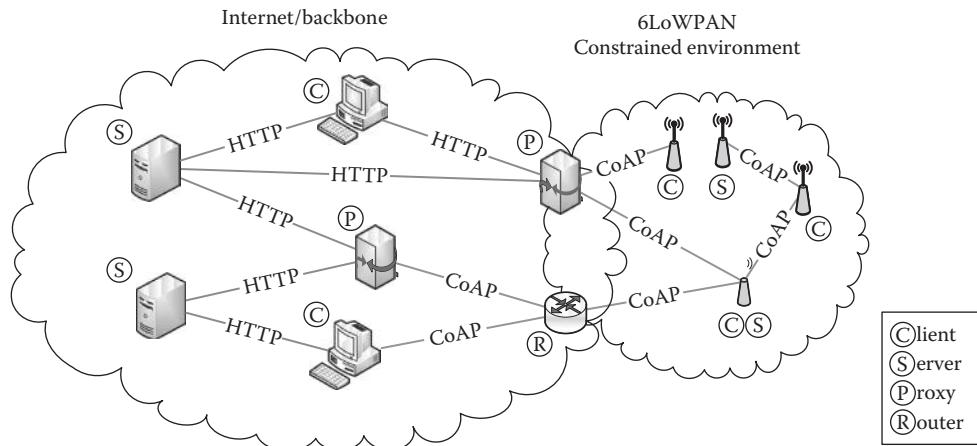

FIGURE 38.7 HTTP + CoAP deployment.

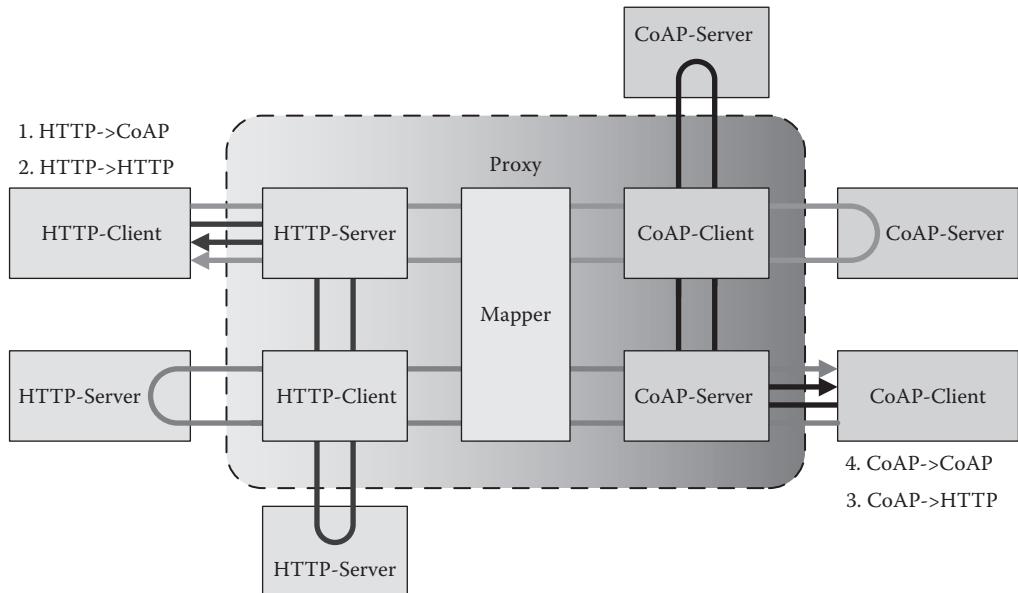

FIGURE 38.8 HTTP/CoAP Proxy.

interactions, the caches may be integrated directly into the proxies but do not have to. Also, even though it appears reasonable to locate the proxies and the caches at the border routers of the 6LoWPANs, the architecture is not bound to such specifics. This is an important aspect and only possible through the usage of the link layer encapsulating IP-based infrastructure.

### 38.3.3 CoAP Enhancements to Binary HTTP

While HTTP was developed for browser interaction and thus human-to-machine (H2M) communication scenarios, CoAP was designed for M2M applications. Hence, CoAP is not only a binary HTTP but extends HTTP by essential features required in the M2M environments.

While HTTP mainly realizes pull communication, CoAP also features push notifications through a publish/subscribe mechanism. Thereby, clients can *observe* resources for state changes. If subscribed to

a specific resource, the server autonomously pushes state changes to the clients, potentially decreasing traffic dramatically since active polling is avoided.

While HTTP uses TCP on transport layer and thus is limited to unicast point-to-point connections, CoAP uses UDP on transport layer. UDP is capable of IP–Multicast communication. Against this background, CoAP interactions with resources are not limited to single nodes, but clients can also interact with a group of devices with one request.

For autonomous M2M environments, a discovery mechanism of endpoints and the provided services/resources is an essential requirement. To provide this feature, CoAP defines two different mechanisms. First, a description format for resources of a device is defined and called CoAP link format. This link format forms a list of available resources at a well-known URI path and uses attributes for each resource to provide information, for example, on the content formats, the expected resource representation size, and further semantic information like the resource type. Second, several mechanisms are defined to retrieve the resource list. Clients may use unicast or multicast requests to retrieve this information from each device in the network. But for CoAP also a central entity called resource directory can be used, where devices register at and upload their resource descriptions. Using such a central entity is a huge advantage in deployments where devices may reside in power-saving sleep states most of the time and wake up only in given time slots for possible client interactions.

## 38.4 Related Work

---

Based on the presence of IP in WSNs (through the 6LoWPAN protocols) in research, development, and standardization, further activities have been initiated to benefit from the new infrastructure and possibilities offered.

While HTTP is widely used for H2M communication, and CoAP is designed as a proper M2M alternative for resource-constrained environments, SOAP-based web services are another candidate for M2M applications as they are used widely in the web and in enterprise IT. With the OASIS standard Devices Profile for Web Services (DPWS), a SOAP web services profile dedicated to device-centric communication has been developed. While the WS-\* specifications had to be extended to ensure secure M2M communication, DPWS is still based on the WS-Architecture and is thus compliant with existing WS-\* specification framework, deployments, and implementations. Nevertheless, SOAP web services are by default too heavy weight and too verbose to be applied to resource-limited systems such as WSNs [Nix09, ABG13].

Moritz et al. [Mor13] have developed a DPWS architecture that pushes DPWS onto WSNs. Therefore, three major extensions were made to the original DPWS: First, DPWS and its mechanisms for discovery and eventing (c.f. push notifications) can be adopted carefully to be a better fit for WSN-typical applications like monitoring temperatures or other environmental parameters. Second, the verbosity of the XML-based message representation had to be removed. Moritz et al. have developed a solution based on the Efficient XML Interchange (EXI) format of the W3C. Third, the compressed SOAP messages need to be transported efficiently. Based on the existing SOAP-over-HTTP transport mechanism and due to the similarities of HTTP and CoAP, Moritz et al. have developed and specified a novel SOAP-over-CoAP transport mechanism to be used in networks such as 6LoWPANs. In contrast to other similar approaches as the one described by Samaras et al. [Sam13], the solution by Moritz et al. is fully compliant with the WS-Architecture and can benefit from several stateless mappings like CoAP in HTTP (for the SOAP transport mechanisms) and EXI in XML (for message encoding).

A completely different application layer protocol was proposed by Hornsby et al. in [Hor09]. The Extensible Messaging and Presence Protocol (XMPP), formerly named Jabber, was originally developed for instant messaging purposes. Nevertheless, over time and through several enhancements to the core protocol, XMPP can also be used for general message exchange and is often described as application layer or XML routing protocol. The reason is the dedicated XMPP infrastructure. Clients connect to servers through long-living TCP connections and the servers are connected to each other. Messages

in the form of XML fragments from one client to the other are thus forwarded by the XMPP servers until they reach the final destination. Hornsby et al. have implemented  $\mu$ Xmpp, an XMPP client for WSN node class devices.

The earlier mentioned ZigBee protocol was originally developed completely independently of IP and other Internet protocols. The only common basis with 6LoWPAN was the usage of IEEE 802.15.4 as the link layer. Nevertheless, ZigBee does not have a monolithic protocol stack but has a strong separation between the application layer and the lower layers. At the application layer, the so-called ZigBee Application Profiles (ZAP) are defined that consist, for example, of data models including semantics and grouping of data bulks for device types (e.g., lamp and temperature sensor). With the emerging ZigBee Smart Energy 2.0 (SE 2.0), the ZigBee consortium now combines the defined and self-contained ZAP with the IP-based infrastructure. Because ZigBee was designed for low-power and low-cost devices, the 6LoWPAN protocols are of course a major part of the evolving SE 2.0 profile.

## 38.5 Conclusion

---

6LoWPAN and CoAP are important protocols used in WSNs. They offer the technological basis for massively scalable networking, and bridge the gap between enterprise networks and the Internet-of-Things (IoT) or Web-of-Objects (WoO).

6LoWPAN ensures applicability of IPv6 to low-power, low-rate wireless radio communication based on the IEEE 802.15.4 standard. It provides protocols for IP header compression, address autoconfiguration, adoption layer to fit IPv6-specific MTU requirements, etc.

CoAP is an application layer protocol that helps integrate wirelessly connected sensors, devices, things, or objects. Beyond that, it can be used in various other scenarios and help downsize huge data sets. By means of those kinds of application layer protocols, system engineers and developers can focus on development of applications and products, instead of putting too much effort on the communication technology and its protocols, as it is today.

Both, 6LoWPAN and CoAP, are completely independent technologies. However, they both are rapidly gaining momentum as they complement each other, making a powerful toolset for integrating formerly separated proprietary networks into our global IP-based infrastructure, and thus enable concepts such as the IoT.

### 39.1 Time-Triggered and Event-Triggered Communication

---

It has been recognized that communication protocols fall into two general categories with corresponding strengths and deficiencies: event-triggered and time-triggered control. Event-triggered protocols (e.g., TCP/IP, CAN, Ethernet, ARINC629) offer flexibility and resource efficiency. Time-triggered protocols (e.g., TTP/C, FlexRay) excel with respect to predictability, composability, error detection, and error containment.

In event-triggered architectures, the system activities, such as sending a message or starting computational activities, are triggered by the occurrence of events in the environment or the computer system. In time-triggered architectures, activities are triggered by the progression of global time. The major contrast between event-triggered and time-triggered approaches lies in the location of control. Time-triggered systems exhibit autonomous control and interact with the environment according to an internal predefined schedule, whereas event-triggered systems are under the control of the environment and must respond to stimuli as they occur.

The time-triggered approach is generally preferred for safety-critical systems [Rus01, Kop95]. For example, in the automotive industry, a time-triggered architecture will provide the ability to handle the communication needs of by-wire cars [Bre01]. In addition to hard real-time performance, time-triggered architectures help in managing the complexity of fault-tolerance and corresponding formal dependability models, as required for the establishment of ultrahigh reliability (failure rates in the order of  $10^{-9}$  failures/h). The predetermined points in time of the periodic message transmissions allow error detection and establishing of membership information. Redundancy can be established transparently to applications, that is, without any modification of the function and timing of application systems. A time-triggered system also supports replica determinism [Pol96], which is essential for establishing fault-tolerance through active redundancy.

Furthermore, time-triggered systems support temporal composability [KO02] via a precise specification of the interfaces between subsystems, both in the value domain and temporal domain. The communication controller in a time-triggered system decides autonomously when a message is transmitted. The communication network interface is a temporal firewall, which isolates the temporal behavior of the host and the rest of the system.

## 39.2 Fundamental Services of a Time-Triggered Communication Protocol

---

In the following, four fundamental services of a time-triggered communication protocol are explained, namely, clock synchronization, the periodic exchange of state messages, fault isolation, and diagnostic services.

### 39.2.1 Clock Synchronization

Due to clock drifts, the clock times in an ensemble of clocks will drift apart, if clocks are not periodically resynchronized. Clock synchronization is concerned with bringing the values of clocks in close relation with respect to each other. A measure for the quality of synchronization is the precision. An ensemble of clocks that are synchronized to each other with a specified precision offers a global time. The global time of the ensemble is represented by the local time of each clock, which serves as an approximation of the global time [KO87].

Two important parameters of a global time base are the granularity and horizon. The granularity determines the minimum interval between two adjacent ticks of the global time (also called macrogranule), that is, the smallest interval that can be measured with the global time. The horizon determines the instant when the time will wrap around.

The reasonableness condition [Kop97] for a global time base ensures that the synchronization error is bounded to less than one macrogranule. However, due to the synchronization and digitalization error, it is impossible to establish the temporal order of occurrences based on their timestamp, if timestamps differ by only a single tick. A solution to this problem is the introduction of a sparse time base [Kop92].

### 39.2.2 Periodic Exchange of State Messages

A time-triggered communication system is designed for the periodic exchange of messages carrying state information. These messages are called *state messages*.

Information with state semantics contains the absolute value of a real-time entity (e.g., temperature in the environment is 41°C). The self-contained nature and idempotence of state messages eases the establishment of state synchronization, which does not depend on exactly-once processing guarantees. Since applications are often only interested in the most recent value of a real-time object, old state values can be overwritten with newer state values. Hence, a time-triggered communication system does not require message queues.

The periodic transmission of state messages is triggered by the progression of the global time according to a time division multiple access (TDMA) scheme. TDMA statically divides the channel capacity into a number of slots and assigns a unique slot to every node. The communication activities of every node are controlled by a time-triggered communication schedule. The schedule specifies the temporal pattern of messages transmissions, that is, at what points in time nodes send and receive messages. A sequence of sending slots, which allows every node in an ensemble of n nodes to send exactly once, is called a TDMA round. The sequence of the different TDMA rounds forms the cluster cycle and determines the periodicity of the time-triggered communication.

The a priori knowledge about the times of message exchanges enables the communication system to operate autonomously. The temporal control of communication activities is within the sphere of control of the communication system. Hence, the correct temporal behavior of the communication system is independent of the temporal behavior of the application software in the host computer and can be established in isolation.

### 39.2.3 Fault Isolation Mechanisms

A time-triggered communication protocol and the corresponding system architecture need to provide rules for partitioning a system into independent FCRs. In a system with active redundancy, the dependencies among FCRs (i.e., correlation between failure probability of FCRs) have a significant impact on the system reliability [OKS07]. The independence of FCRs can be compromised by shared physical resources (e.g., hardware, power supply, time-base), external faults (e.g., electromagnetic interference, heat, shock, spatial proximity), and design faults.

In a time-triggered communication protocol, the error containment mechanisms for timing message failures can be enforced transparently to the application. Using the a priori knowledge concerning the global points in time of all intended message sent and receive instants, autonomous guardians can block timing message failures. For this purpose, node-local and centralized guardians have been developed and validated for different time-triggered communication protocols (e.g., [BKS03, Gua05]). For example, in TTP, a guardian transforms a message that it judges untimely into a syntactically incorrect message by cutting off its tail [Kop03a].

Error containment for value message failures is generally not part of a time-triggered communication protocol but within the responsibility of the host computers. For example, value failure detection and correction can be performed using N-modular redundancy (NMR). N replicas receive the same requests and provide the same service. The output of all replicas is provided to a voting mechanism, which selects one of the results (e.g., based on majority) or transforms the results to a single one (average voter). The most frequently used N-modular configuration is triple-modular redundancy (TMR). By employing three components and a voter, a single consistent value failure in one of the constituting components can be tolerated.

Although not natively provided by time-triggered communication protocols, N-modular redundancy is enabled by time-triggered communication protocols by supporting replica determinism [Pol96]. Fault-free replicated components exhibit replica determinism, if they deliver identical outputs in an identical order within a specified time interval. Replica determinism simplifies the implementation of fault-tolerance by active redundancy, since failures of components can be detected by carrying out a bit-by-bit comparison of the results of replicas. Replica nondeterminism is introduced either by the interface to the real world or the system's internal behavior.

### 39.2.4 Diagnostic Services

Diagnostic services are concerned with the identification of failed subsystems. Diagnostic services can trigger the autonomous recovery of a system in case of a transient subsystem failure. In addition, diagnostic services can support the replacement of defective subsystems if a failure is permanent.

An example of diagnostic services that can be found in time-triggered communication protocols is a solution to the membership problem. The membership problem is a fundamental problem in distributed computing, because it allows solutions to other important problems in designing fault-tolerant systems [GP96]. The membership problem is defined as the problem of achieving agreement on the identity of all correctly functioning processes of a process group. A process is correct, if its behavior complies with the specification. Otherwise the process is denoted as faulty.

In the context of integrated architecture, it makes sense to establish membership information for FCRs, since FCRs can be expected to fail independently. Depending on the assumed types of faults, an FCR is either an entire system component or a subsystem within a component (e.g., a task) dedicated to a function.

A service that implements an algorithm for solving the membership problem and offers consistent membership information is called a membership service. A membership service simplifies the provision of many application algorithms, since the architecture offers generic error detection capabilities via this service. Applications can rely on the consistency of the membership information and react to detected failures of FCRs as indicated by the membership service.

A membership service also plays an important role in controlling application-level fault-tolerance mechanisms that deal with failures of functions. If a function fails—since more FCRs have failed than can be tolerated by the given amount of redundancy—all that an integrated architecture can do is to inform other functions about this condition so they can react accordingly by application-level fault-tolerance mechanisms.

In a time-triggered communication system, the periodic message send times are membership points of the sender [KGR91]. Every receiver knows a priori when a message of a sender is supposed to arrive, and interprets the arrival of the message as a life sign at the membership point of the sender. From the arrival of the expected messages at two consecutive membership points, it can be concluded that the sender was operational during the interval delimited by these membership points.

## 39.3 Properties of Time-Triggered Communication Systems

---

### 39.3.1 Composability

In many engineering disciplines, large systems are built from prefabricated components with known and validated properties. Components are connected via stable, understandable, and standardized interfaces. The system engineer has knowledge about the global properties of the components—as they relate to the system functions—and of the detailed specification of the component interfaces. Knowledge about the internal design and implementation of the components is neither needed nor available in many cases. *Composability* deals with all issues that relate to the component-based design of large systems. Composability refers to an architectural framework that supports the smooth integration and reuse of independently developed components in order to increase the level of abstraction in the design process. Architecture instantiations that are derived from a generic platform must support the constructive composition of large systems out of components and subsystems without uncontrolled emerging behavior or side effect. Composability is a concept that relates to the ease of building systems out of subsystems [ART06, p. 24]. An example is the deadlock-freedom of a component-based system.

An architecture must enable the precise specification of the linking interface (LIF) [Kop02] of a node in the domains of value and time. This is a necessary prerequisite for the independent development of nodes on one side and the reuse of existing nodes that is based solely on their LIF specification on the other side. While the operational specification of the value domain of interacting messages is *state-of-the-art* in embedded system design, the temporal properties of these messages are often not considered with the appropriate care. The global time, which is available in time-triggered systems, is essential for the precise specification of the temporal properties of the LIF messages. In the time domain, time-triggered protocols specify the periods and phases of message exchanges with respect to a global time base with a specified precision.

Furthermore, composability requires the stability of prior services upon integration. Services of a node that have been validated in isolation (i.e., prior to the integration of the node into the larger system) remain intact after the integration. This concept is also known as compositionality. The analysis of the component properties can be performed independently for each component. Compositionality avoids exponential analysis complexity. Temporal compositionality is an instantiation of the general

notion of compositionality. A communication system supports temporal compositionality, if temporal correctness is not refuted by the system integration [KO02].

Another necessary condition of composability is the support for noninterfering interactions. If there exist two disjoint subgroups of cooperating nodes that share a common communication infrastructure, then the communication activities within one subgroup may not interfere with the communication activities within the other subgroup. If this principle is not satisfied, then the integration within one node-subgroup will depend on the proper behavior of the other (functionally unrelated) node-subgroups. These global interferences compromise the composability of the architecture. Time-triggered communication systems provide predictable message transport latency that is not influenced by the behavior of other, functionally unrelated messages.

Finally, composability requires the preservation of the node abstraction in the case of failures. In a composable architecture, the introduced abstraction of a node must remain intact, even if a node becomes faulty. It must be possible to diagnose and replace a faulty node without any knowledge about the node internals. This requires a certain amount of redundancy for error detection within the architecture. This principle constrains the implementation of a node, because it restricts the implicit sharing of resources among nodes. If a shared resource fails, more than one node can be affected by the failure. In time-triggered communication systems, the communications system contains redundant information about the permitted temporal behavior of nodes and disconnects nodes that violate their temporal specification in order to avoid error propagation from a faulty node (a babbling idiot) into the communication system.

### 39.3.2 Independent Fault Containment Regions

A fault containment region (FCR) is the boundary of the immediate impact of a fault [LH94]. In conformance with the fault-error-failure chain introduced by Laprie [ALR01], one can distinguish between faults that cause the failure of an FCR (e.g., design of the hardware or software of the FCR, operational fault of the FCR) and faults at the system-level. The latter type of fault is a failure of an FCR, which could propagate to other FCRs through a sent message that deviates from the specification. If the transmission instant of the message violates the specifications, we speak of a *message timing failure*. A *message value failure* means that the data structure contained in a message is incorrect.

Such a failure of an FCR can be tolerated by distributed fault-tolerance mechanisms. The masking of failures of FCRs is denoted as error containment [LH94] because it avoids error propagation by the flow of erroneous messages. The error detection mechanisms must be part of different FCRs than the message sender [Kop03b]. Otherwise, the error detection mechanism may be affected by the same fault that caused the message failure.

For example, a common approach for masking node failures is *N-Modular Redundancy (NMR)* [LA90].  $N$  replicas receive the same requests and provide the same service. The output of all replicas is provided to a voting mechanism, which selects one of the results (e.g., based on majority) or transforms the results to a single one (average voter). The most frequently used  $N$ -modular configuration is triple-modular redundancy (TMR).

We denote three replicas in a TMR configuration a *Fault-Tolerant Unit (FTU)*. In addition, we consider the voter at the input of a node and the node itself as a self-contained unit, which receives the replicated inputs and performs voting by itself without relying on an external voter. We call this behavior *incoming voting*.

Common-mode failures are failures of multiple FCRs, which are correlated and occur due to a common cause. Common-mode failures occur when the assumption of the independence of FCRs is compromised. They can result from replicated design faults or from common operational faults such as a massive transient disturbance. Common-mode failures of the replicas in an FTU must be avoided, because any correlation in the instants of the failures of FCRs significantly decreases the reliability improvements that can be achieved by NMR [HTH97].

The definition of FCRs needs to take into account shared resources that could be affected by a fault. Typically, shared resources include the computing hardware, the power supply, the timing source, the clock source, and the physical space. For example, if two subsystems depend on a single power supply, then these two subsystems are not considered to be independent and therefore belong to the same FCR. Since this definition of independence allows that two FCRs can share the same design, design faults are not part of this fault-model. Diversity is a method to avoid common design faults in FCRs by using different designs that perform the same function.

### 39.3.3 Strict Control on Node Interactions

A distributed system uses shared networking resources in order to support the interaction between nodes. In order to preserve the independence of FCRs, strict control on the node interactions and the use of these shared resources is required. Based on the specification of the permitted behavior of a node at its linking interface, a time-triggered communication protocol can isolate nodes that violate the linking interface specification. Thereby, the time-triggered communication protocol realizes *temporal partitioning* and *spatial partitioning* [Rus99] at the network-level:

- *Temporal partitioning*: Media access control is concerned with the assignment of time intervals to each node for the transmission of the node's messages. A node that sends untimely messages has the potential of disrupting the communication abilities of the other nodes by delaying their messages. The media access control mechanisms of a time-triggered communication system can be designed to prevent this interference between nodes in the temporal domain. A time-triggered communication system is autonomous and has a priori knowledge of all intended message sent and receive instants. This knowledge can be used by local or central guardians [BKS03, Gua05] in order to block untimely messages.
- *Spatial partitioning*: Spatial partitioning ensures that one node cannot alter the code, private data, or messages of another node. Spatial partitioning must ensure that no messages with corrupted data or wrong addresses are delivered. A message with a wrong address or identification—also called a masquerading failure—could cause correct messages of other nodes to be overwritten at the recipient. Faults occurring at the communication channel can be detected using CRC checks. For faults that occur within the sender, an unforgeable authentication mechanism is necessary. Depending on the failure assumptions, an authentication mechanism can be implemented with simple signature schemes or cryptographic mechanisms [GMR88].

### 39.3.4 Replica Determinism

Replica determinism has to be supported by the architecture to ensure that the replicas of an FTU produce the same outputs in defined time intervals. A time-triggered communication system addresses key issues of replica determinism. In particular, a time-triggered communication system supports replica determinism by exploiting the sparse global time base in conjunction with preplanned communication and computational schedules. Computational activities are triggered after the last message of a set of input messages has been received by all replicas of an FTU. This instant is a priori known due to the predefined time-triggered schedules. Thus, each replica wakes up at the same global tick, and operates on the same set of input messages. The alignment of communication and computational activities on the sparse global time base ensures temporal predictability and avoids race conditions.

### 39.3.5 Performance

Important performance attributes in real-time communication networks are the bandwidth, the network delay, and the variability of the network delay (i.e., communication jitter).

The bandwidth is a measure of the available communication resources expressed in bits/second. The bandwidth is an important parameter as it determines the types of functions that can be handled and the number of messages and nodes that can be handled by the communication network.

The network delay denotes the time difference between the production of a message at a sending node and the reception of the last bit of the message at a receiving node. At some instant  $t_{\text{request}}$ , the sending node requests the transmission of a message by invoking a send operation at the node's communication controller. Depending on the communication protocol and the current traffic on the communication channel, the transmission of the message will start after the *access delay* at the send instant.

Depending on whether the communication protocol is time-triggered or event-triggered, the access delays exhibit different characteristics. In a time-triggered system, the send instants of all nodes are periodically recurring instants, which are globally planned in the system and defined with respect to the global time base. The access delay of a message in a time-triggered system is thus locally determined at the sending node. The access delay is independent of the traffic from other nodes and depends solely on the relationship between the request instants and the preplanned send instants. Furthermore, since the next send instant of every node is known a priori, a node can synchronize locally the production of periodic messages with the send instant and thus minimize the access delay of a message.

In addition, the TDMA scheme of a time-triggered communication protocol can contain periodic communication slots for the transport of sporadic and periodic messages. In case of a transmission request, the message is transmitted during the next communication slot in the TDMA scheme. The period of the communication slots can be determined by the maximum permitted network delay, the bandwidth requirements, and knowledge about the message interarrival times (e.g., minimum and average values). Sporadic and aperiodic messages incur a delay depending on the (stochastic) time of the request instant relative to the preplanned send instants of the time-triggered communication protocol. In the worst case, the transmission of a sporadic or aperiodic message is requested immediately after a send instant, thereby incurring a delay equal to the period of the communication slot. At the cost of additional communication resources, this network delay can be reduced by increasing the frequency of the communication slots reserved for sporadic and aperiodic messages. In order to reduce the consumption of communication resources, several time-triggered communication protocols have been extended with means for the event-triggered communication of sporadic and aperiodic messages such as time intervals with dynamic arbitration.

In an event-triggered system, the access delay of a message depends on the state of the communication system at the send instant. If the communication network is idle, the message transmission can start immediately, leading to an access delay close to zero. If the channel is busy, then the access delay depends on the media access strategy implemented in the communication protocol. For example, in the CSMA/CD protocol of Ethernet [IEE00], nodes wait for a random delay before attempting transmission again. In the CSMA/CA protocol of CAN [Int93], the access delay of a message depends on its priority relative to the priorities of other pending messages. Hence, in an event-triggered network the access delay of a message is a global property that depends on the traffic patterns of all nodes.

A bounded network delay with a minimum variability is important in many embedded applications. For example, achievement of control stability in real-time applications depends on the completion of activities (like communicating sensor and control values) in bounded time. Hard real-time systems ensure guaranteed response even in the case of peak load and fault scenarios. Guaranteed response involves assurance of temporal correctness of the design without reference to probabilistic arguments. Guaranteed response requires extensive analysis during the design phase such as an off-line timing and resource analysis [ABG98]. An off-line timing and resource analysis assesses the worst-case behavior of the system in terms of communication delays, computational delays, jitter, end-to-end delays, and temporal interference between different activities.

In hard real-time systems, missed deadlines represent system failures with the potential of consequences as serious as in the case of providing incorrect results. For example, in drive-by-wire applications, the dynamics for steered wheels in closed control loops enforce computer delays of less than 2 ms [HT98]. Taking the vehicle dynamics into account, a transient outage-time of the steering system must

not exceed 50 ms [HT98]. In the avionic domain, variable-cycle jet engines can blow up if correct control inputs are not applied every 20–50 ms [LH94].

While control algorithms can be designed to compensate a known delay, delay jitter (i.e., the difference between the maximum and minimum value of delay) brings an additional uncertainty into a control loop that has an adverse effect on the quality of control [Kop97]. Delay jitter represents an uncertainty about the instant a real-time entity was observed and can be expressed as an additional error in the value domain. In case of low jitter or a global time-base with a good precision, state estimation techniques allow to compensate a known delay between the time of observation and the time of use of a real-time image. State estimation uses a model of a real-time entity to compute the probable state of the real-time entity at a future point in time.

The Time-Triggered Protocol (TTP) is a communication protocol for distributed fault-tolerant real-time systems. It is designed for applications with stringent requirements concerning safety and availability, such as avionic, automotive, industrial control, and railway systems. TTP was initially named TTP/C and later renamed to TTP. The initial name of the communication protocol originated from the classification of communication protocols of the Society of Automotive Engineers (SAE), which distinguishes four classes of in-vehicle networks based on the performance. TTP/C satisfies the highest performance requirements in this classification of in-vehicle networks and is suitable for network classes C and above.

TTP provides a *consistent distributed computing base* [Kop03] in order to ease the construction of reliable distributed applications. Given the assumptions of the fault hypothesis, TTP guarantees that all correct nodes perceive messages consistently in the value and time domains. In addition, TTP provides consistent information about the operational state of all nodes in the cluster. For example, in the automotive domain, these properties would reduce the efforts for the realization of a safety-critical brake-by-wire application with four braking nodes. Given the consistent information about inputs and node failures, each of the nodes can adjust the braking force to compensate for the failure of other braking nodes. In contrast, the design of distributed algorithms becomes more complex [LSP82], if nodes cannot be certain that every other node works on the same data. In such a case, the agreement problem has to be solved at the application level.

TTP has been integrated into a number of commercial applications. In the railway domain, Thales Rail Signalling Solutions has used TTP for realizing the electronic interlocking system *LockTrac 6131 ELEKTRA* [KK95]. This system has been certified according to CENELEC standards with Safety Integrity Level 4 (SIL4). The ELEKTRA system supports the basic interlocking functions, as well as additional features such as local and remote control, automatic train operation, blocking functionality, and diagnosis capabilities.

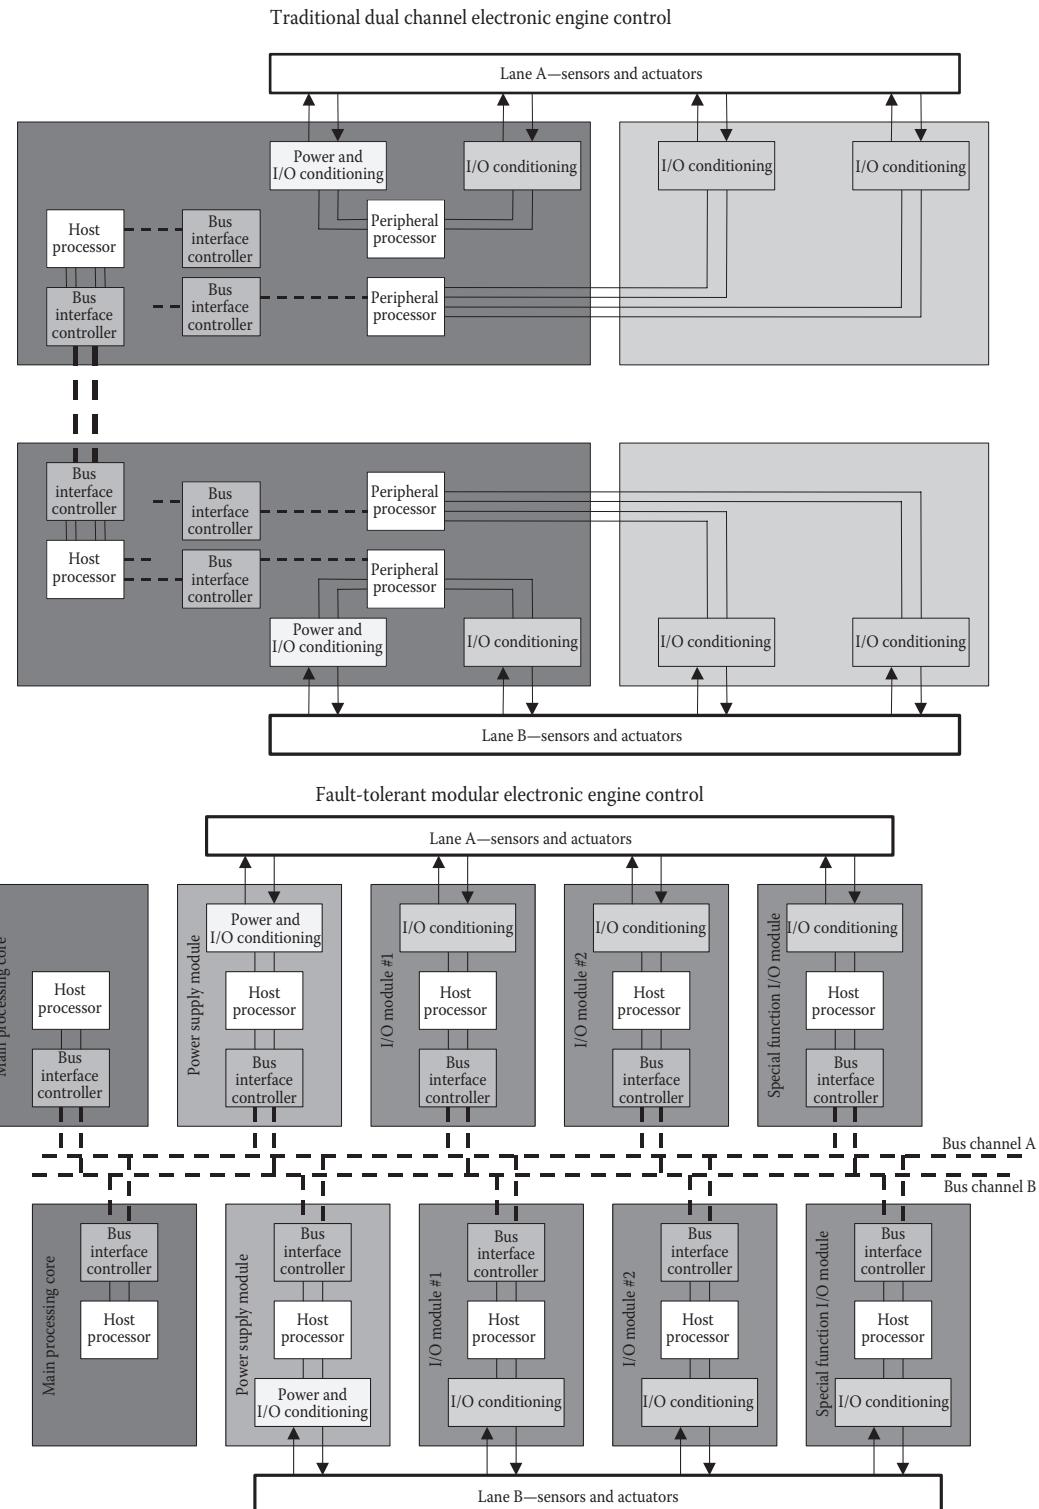

**FIGURE 40.1** Concept behind Modular Aerospace Control (MAC) [Tus03]. (Courtesy of Honeywell.)

In the aerospace domain, the Honeywell Modular Aerospace Control (MAC) has been developed using TTP as a backplane databus for intermodule communication. For engine control, MAC facilitates simplified overspeed and uncommanded thrust protection. Honeywell has created the MAC platform having reusable modules in mind. Module functions are scaled to the control needs of multiple applications. Furthermore, reduced development cycle times are possible due to reuse. This reduces nonrecurring cost by reuse of modules. The core architecture comprises multiple modules (i.e., cards) connected by TTP scalable within a wide range of anticipated use cases. The replication level for each module is scalable to the needs of the application for this one module. If one compares this to the most prevalently existing dual-lane engine control dependability paradigm where everything is deployed at the same dual replication needs, this can be more efficient. In addition, this reduces recurring cost. Figure 40.1 depicts the concept behind MAC. Figure 40.2 compares traditional dual-lane and the MAC distributed engine control.

MAC modules are partly prequalified and, hence, decrease certification cost. Furthermore, MAC supports proactive obsolescence management by enabling a building block approach where obsolete modules can easily be redeveloped and exchanged due to well-defined interfaces. Furthermore, TTP should ensure not only proper communication but also partitioning between modules. This supports deterministic integration and keeps efforts low.

MAC is deployed in the FADEC of F124 used, for example, on Alenia Aermacchi's M-346. M-346 is an advanced/lead-in fighter trainer. MAC is also used for the engine control of General Electric's F110 Turbofan deployed, for example, on newer generations F-16 Fighting Falcon.

In the following, protocol services of TTP are described. The *communication services* support the predictable message transport with a small variability of the latency. The *fault-tolerant clock synchronization* maintains a specified precision and accuracy of the global time base, which is initially established by the *restart and start-up services* when transitioning from asynchronous to synchronous operation. The *diagnostic services* provide the application with feedback about the operational state of the nodes and the network using a consistent membership vector. The diagnostic services in conjunction with the a priori knowledge about the permitted behavior of nodes are the basis for the *fault isolation services* of TTP. Finally, *configuration services* offer flexibility by switching between predefined modes or programming new communication schedules into the system.

## 40.1 Temporal Structuring of Communication

---

The smallest unit of transmission and media access control on the TTP network is a *TDMA slot*. A TDMA slot is a time interval with a fixed duration that can be used by a node to broadcast a frame to all other nodes. A frame is a transmission of defined length on a TTP channel containing both application and protocol data. The application data within a frame represents a message, which possesses corresponding semantics for the host (e.g., a speed value in a control loop).

A sequence of TDMA slots is called a *TDMA round*. The *cluster cycle* defines a pattern of periodically recurring TDMA rounds. Although the sequence and the length of the TDMA slots in every TDMA round are equal, the frame communicated in a TDMA slot can differ between TDMA rounds. A TDMA slot in two TDMA rounds can be used for the exchange of frames with different sender nodes, content, and size. The fixed duration of the TDMA slot limits the maximum size of a frame.

While a TDMA slot is defined within the TDMA round, a so-called *round slot* uniquely identifies a slot within the entire cluster cycle. A round slot possesses a unique sender node. In addition, the content and size of the frame communicated in the round slot is known.

If two TDMA rounds have two different sender nodes for a TDMA slot, the nodes are called *multiplexed nodes*. Multiplexed nodes can improve the use of communication bandwidth. If no multiplexed nodes are used, TTP possesses a unique mapping between TDMA slots and sender nodes. Otherwise, the sender is only known at the level of round slots.

Figure 40.3 depicts the structuring of the communication activities on a TTP network. This TDMA scheme is used after the completion of the start-up and the establishment of synchronous operation.

A node that does not send during any slot is called a *passive node*. A node can be passive by design, if it is only required to receive frames (e.g., a bus sniffer for diagnosis). A failure can also lead to a passive node, such as the absence of the timely update of the life-sign or isolation performed by the bus guardian.

### 40.1.1 Timing of a TDMA Slot

The constituting elements of a TDMA slot are depicted in Figure 40.4. The TDMA slot begins with the *transmission phase*, which is used for sending a frame on the bus. The *postreceive phase* (PRP) is reserved for the protocol execution, for example, updating the membership vector and writing the status information in the Communication Network Interface (CNI). The *idle interval* allows to stretch a TDMA slot in case a specific duration of TDMA slots and TDMA rounds is required in an application. The *presend phase* serves for the preparation of the transmission phase of the next TDMA slot. In this time interval, the communication controller loads the information about the next slot from the Messenger Descriptor List (MEDL).

The durations of the postreceive phase and the presend phase depend on the controller implementation, namely, the number of instructions for the protocol execution, the clock rate of the communication controller, and the memory access times of the CNI memory.

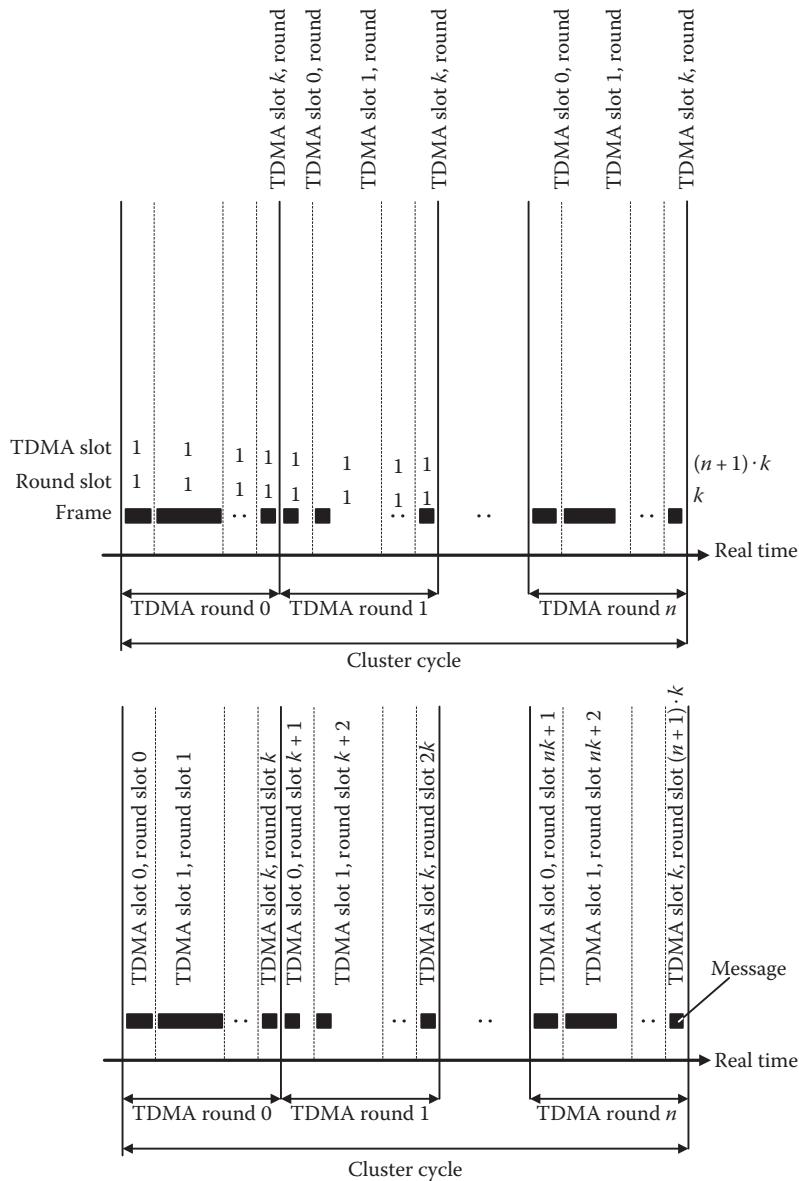

The transmission phase duration in macroticks is computed using the following formula:

$$\text{Transmission phase} = \left\lceil \frac{4\Pi + d_{\text{correction}} + n_{\text{frame}} / f_{\text{bitrate}} + d_{\text{processing}}}{g} \right\rceil + 1 \quad (40.1)$$

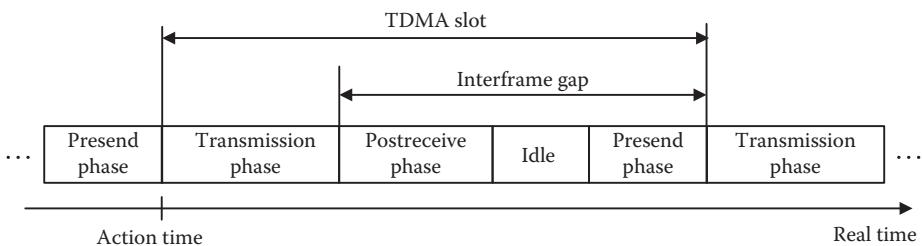

where

$\Pi$  is the precision of the clocks in the cluster

$g$  is the granularity of the global time base

**FIGURE 40.3** TDMA scheme.

**FIGURE 40.4** Timing of a TDMA slot.

The computation of the transmission phase must take into account a maximum deviation of  $\Pi$  between the clocks of different TTP nodes.  $d_{\text{correction}}$  is the maximum delay correction of all receiving nodes to the sender node of the round slot. The time required for the transmission on the bus is the quotient of the frame length in bits  $n_{\text{frame}}$  and the bitrate of the TTP bus  $f_{\text{bitrate}}$ .  $d_{\text{processing}}$  denotes the number of instructions in the communication controller required for the transmission or reception (e.g., 280 instructions at a clock rate of 40 MHz in the C2 controller [TTC02, p. 21]).

#### 40.1.2 Frame Types and States

The TTP protocol distinguishes two main types of frames (cf. Figure 40.5): *cold start frames* are sent during the unsynchronized operation at start-up, while *normal frames* are used in the synchronous operation. In addition, *download frames* can be used to parameterize the TTP protocol or to write an application image into a node.

A cold start frame contains a frame identifier that marks the frame as a cold start frame, the global time of the sender, the current round slot of the sender, and a cyclic redundancy check (CRC). With the knowledge about the current global time and round slot, receiving nodes are enabled to integrate and transit from asynchronous to synchronous operation.

A normal frame consists of a frame type field, information about mode change requests, an optional controller state, application data, and a CRC. If the controller state is included, one speaks of a frame with explicit controller state. Such a frame serves for the integration of nodes during synchronous operation (i.e., no cold start frames are exchanged).

The controller state encompasses internal variables of the TTP communication controller, which are required to be globally consistent among all correct nodes in the TTP cluster. The controller state consists of the global time, the round slot position, the current mode of the cluster, information about pending mode changes, and the membership vector.

Regardless of the inclusion of the controller state in a frame, the controller state is always used in the CRC calculation of the frame. The TTP protocol introduces the notion of *frames with an implicit controller state*, if the state is not contained in a frame. An implicit controller state reduces the protocol overhead and allows a more efficient use of the communication bandwidth at the cost of higher computational complexity.

A divergence of the controller state between receiver and sender is always detected by a CRC error. In particular, this information is used to establish agreement on a consistent view concerning the membership.

After each round slot configured for reception, a node classifies the received frames depending on detected errors:

- *Null frames*. If a receiver observed no transmission activity on a communication channel, the expected frame is called a null frame. A null frame occurs in case of a crash failure of a node.
- *Invalid frames*. A frame is received within the expected time interval of the round slot and the coding rules are satisfied. For example, the Modified Frequency Modulation (MFM) encoding, which is supported by existing TTP communication controllers, imposes limits on the minimum and maximum number of 0 bits that may appear between consecutive 1 bits. A frame that violates these constraints is called an invalid frame.

Normal frame

Frame type	Mode change request	Controller state (optional)	Application data	CRC
------------	---------------------	-----------------------------	------------------	-----

Cold start frame

Frame type	Global time	Round slot of sender	CRC
------------	-------------	----------------------	-----

FIGURE 40.5 Frame formats.

- *Incorrect frames.* An incorrect frame is a valid frame with an incorrect CRC. The CRC error indicates a disagreement of the controller states or a transmission error (e.g., bit flip during the transmission).
- *Tentative frames.* As long as the controller state agreement and acknowledgment is in progress, a frame is tentative. In order to perform this agreement, the membership views of successor nodes in the TDMA round are evaluated.
- *Correct frames.* A correct frame is a valid frame, which has passed the CRC check and the acknowledgment.

## 40.2 Clock Synchronization

---

The fault-tolerant average (FTA) algorithm [KO87] is used for clock synchronization in TTP. The FTA algorithm computes the convergence function for the clock synchronization within a single TDMA round. It is designed to tolerate  $k$  Byzantine faults in a system with  $N$  nodes. Therefore, the FTA algorithm bounds the error that can be introduced by arbitrary faulty nodes. These nodes can provide inconsistent information to the other nodes.

Each node collects the  $N - 1$  measured time differences between the node's clock and the clocks of the other nodes. The time differences are determined by the difference of the actual arrival time of a frame and the expected arrival time of frames (as defined by the time-triggered communication schedule). These time differences, which indicate the deviations of the local times of sender and receiver, are sorted by size. The  $k$  largest and the  $k$  smallest time differences are discarded. The average of the remaining time differences is the correction term for the node's clock.

Using the FTA algorithm, a faulty time value is discarded if it is larger or smaller than the other time values. Otherwise, a faulty time value must be within the precision window. As discussed in [KO87], the worst-case scenario occurs if all correct clocks are at opposite ends of the precision window and the Byzantine clock is seen at different corners by two nodes. In this case, each Byzantine clock will cause a difference of  $\Pi/(N - 2k)$  in the calculated averages at two different nodes in an ensemble of  $N$  clocks. In the worst case, a total of  $k$  Byzantine errors will thus cause an error term of  $k\Pi/(N - 2k)$ .

Considering the jitter  $\epsilon$  of the synchronization frames and the drift offset  $\Gamma$ , the convergence function of the FTA algorithm is as follows:

$$(\epsilon + \Gamma) \frac{N - 2k}{N - 3k} \quad (40.2)$$

In the TTP protocol, the MEDL controls which TDMA slots are used for clock synchronization. The slots at which new correction terms are calculated are marked consistently at all receivers in the MEDL in order to ensure that all nodes correct their clocks at the same time.

In addition to internal clock synchronization, the TTP protocol supports external clock synchronization using a time reference such as GPS. For this purpose, a host acts as a time gateway and possesses a connection to GPS or to another cluster with a different time base. The time gateway periodically computes a correction term and provides this term to its communication controller using the external rate correction field in the CNI. The external rate correction term denotes the number of microticks that need to be corrected in the next synchronization interval.

If the absolute value of the external correction or the absolute value of the total correction term is larger than  $\Pi/2$ , a node freezes due to a synchronization error.

## 40.3 Restart, Reintegration, Integration

---

*Cluster start-up* is the process of establishing a synchronized cluster after power-on. After power-on, a node listens on the communication channels for a *cold start frame*. A cold start frame consists of a frame type field (identifying the frame as a cold start frame), the global time at the send instant of the frame,

a sender round slot position in the MEDL, and a CRC. If the frame is received, then the node sets its controller state accordingly. The node adopts the global time and the round slot position in the MEDL.

If no cold start frame is received within the *listen timeout* and the cold start allowed flag is set in the MEDL of the node, then the node sends a cold start frame itself. The sending of a cold start frame can be repeated until a maximum number of allowed cold starts are reached (as defined in the MEDL). This limit is introduced in order to prevent a node with an incoming link fault to interfere with the synchronization of the other nodes in the cluster.

During start-up, the nodes perform asynchronous access to the communication medium controlled by the *start-up timeout*. This parameter is unique for each node in a cluster. For a given node, it denotes the number of TDMA slots prior to the sending slot of the node. The listen timeout introduced earlier is the sum of the node's controller start-up timeout plus two TDMA rounds. Hence, the duration between two cold starts is always shorter than the listen timeout.

In case of a collision of the cold start frames of two nodes, TTP performs the so-called *big bang mechanism*. In case of large propagation delays, a collision can be perceived inconsistently. Only a subset of the nodes could receive a correct cold start frame, thereby leading to the formation of cliques. All nodes can detect this situation based on the transmission phases of two cold start frames in relation to the sum of the maximum propagation delay and the frame duration. In order to prevent cliques, nodes will not integrate on cold start frames once a big bang scenario has been detected. Thereby, cold starting nodes will not detect traffic and they will restart their start-up timeouts again. Because of the unique start-up timeouts, no second collision will occur between the nodes.

If a node joins a cluster, which is already synchronized, this process is called the *integration* of the node [SP02]. In order to support integration, the MEDL must contain at least one frame with the controller state within the minimum listen timeout (i.e., two TDMA rounds). This constraint ensures that an integrating node does not initiate a cold start.

In order to avoid the integration on faulty frames, an integrating node maintains an *integration counter*. The MEDL contains a parameter called *minimum integration value*, which specifies the number of correct frames that need to be received before a node considers itself integrated and may start to send.

## 40.4 Diagnostic Services

---

The TTP protocol detects the crash failure of a host based on a periodic *host life-sign*. In every TDMA round, the host of a node must provide a *life-sign* to the communication controller. More precisely, a host needs to set the life-sign after the start of the node's transmission slot and before the beginning of the presend phase of the node's transmission slot in the next TDMA round. The communication controller verifies whether the host has set the life-sign during the node's transmission slot.

If the life-sign is not set by the host, the communication controller does not send frames and transits into passive mode. Frame transmission is only continued when the host updates the life-sign again. The life-sign is used both during normal operation and at start-up. The set life-sign is also a prerequisite for sending cold start frames to start up the cluster.

In addition to the host life-sign, the updating of the global time and schedule position by the communication controller serves as a *controller life-sign*. Thereby, the host can react to a crash failure of a communication controller in an application-specific way (e.g., enter a safe state).

The TTP protocol informs nodes about the operational state of every other node in the TTP cluster using a membership vector. The membership vector is a vector with a bit for every node, denoting whether the respective node is operational.

A node *A* considers another node *B* as operational, if node *A* has correctly received the frame that was sent by node *B* prior to the membership point. In case redundant communication channels are used, the reception on one of the channels is sufficient in order to consider a sender to be operational.

The delay between the failure of a node and the indication in the membership vector is bounded by the duration of two TDMA rounds. The points in time for establishing the membership information are called *membership points*. In TTP, the PRP of a sending node serves as a membership point.

The *clique detection and avoidance* in TTP [BP00] has the goal of avoiding the partitioning of a cluster into cliques that are not able to communicate with each other. The clique avoidance algorithm selects the largest partition (clique) as a winner, while the nodes of other partitions are shut down by entering the freeze state.

In every TDMA round, the communication controller determines whether it is in agreement with the majority of the other nodes concerning the controller state. For this purpose, the communication controller counts the number of round slots where the frame status is correct, as well as the number of round slots where the frame status is incorrect or invalid. In the present phase of its own transmission slot, a node checks whether the value of the failed slots counter is larger than the agreed slots counter. In this case, a clique error is detected and the communication controller transits into the freeze state.

## 40.5 Fault Isolation

---

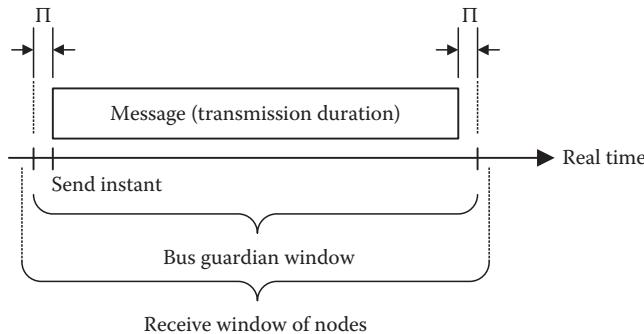

The TTP protocol was designed to isolate and tolerate an arbitrary failure of a single node during synchronized operation [KBP01]. After the error detection and the isolation of the node, a consecutive failure can be handled. Given fast error detection and isolation mechanisms, such a single fault hypothesis is considered to be suitable in many safety-critical systems [OP06]. The fault hypothesis assumes an arbitrary failure mode of a single node. TTP does not guarantee to tolerate two independent node failures, that is, a second failure before the detection and isolation of the first failure. Such a scenario is considered very unlikely and addressed by the so-called *Never-Give-Up (NGU) strategy* [Kop04]. If failures outside the fault hypothesis are detected, the communication system informs the application. Depending on the application, a safe-state can be entered (e.g., setting all signals to red in a railway application). Assuming transient faults, a restart of the TTP cluster can be performed in a fail-operational system.

In order to tolerate timing failures, a TTP cluster uses local or central *bus guardians*. In addition, the bus guardian protects the cluster against slightly-off-specification faults [Ade02], which can lead to ambiguous results at the receiver nodes.

A *local bus guardian* is associated with a single TTP node and can be physically implemented as a separate device or within the TTP node (e.g., on the silicon die of the TTP communication controller or as a separate chip). The local bus guardian uses the a priori knowledge about the time-triggered communication schedule in order to ensure fail-silence of the respective node. If the node intends to send outside the preassigned transmission slot in the TDMA scheme, the local bus guardian cuts off the node from the network. In order to avoid common mode failures of the guardian and the node, the TTP protocol suggests the provision of an independent external clock source for the local bus guardian.

The *central bus guardian* is always implemented as a separate device, which protects the TDMA slots of all attached TTP nodes. An advantage compared to the local bus guardians is the higher resilience against spatial proximity faults and the ability to handle slightly-off-specification faults.

In safety-critical systems, a TTP cluster is deployed with two independent bus guardians for the two redundant TTP channels. The failure mode of a central bus guardian is assumed not to be arbitrary. According to the fault hypothesis of TTP, the failure of a central guardian only leads to the transmission of frames that are detectably faulty at the receivers. In the time domain, a failure of a guardian can lead to untimely frames that are perceived at the receiving nodes outside the slots defined by the TDMA scheme. In the value domain, a faulty guardian can produce frames with an invalid CRC. According to the fault hypothesis, the guardian may not generate incorrect frames with valid CRCs and correct timing. The reason for this assumption is that nodes would receive two different frames from the redundant communication channels with correct CRCs and timing. Hence, the receiving nodes would be

**FIGURE 40.6** Bus guardian window and nodes' receive window.

unable to determine which frame is the correct one and should be provided to the application. In order to justify this fault assumption, implementations of the central bus guardian contain no logic for the generation of CRC codes. TTP addresses the replaying of old frames by including the global time in controller state, which is used together with the application data in the CRC calculation.

Both central and local guardians use a *bus guardian window* in order to ensure timely frames (cf. Figure 40.6). The bus guardian window enables access to the communication system for the node at the specified time and for the complete slot duration, but prevents any transmission from the node for the remaining duration of the TDMA round. The start instant and the end instant of the bus guardian window take into account the different views on the global time, which are bounded by the precision of the clock synchronization.

In order to avoid slightly-off-specification failures, the bus guardian uses a bus guardian window that is shorter than the receive windows used by the receiver nodes. This means that the bus guardian is more restrictive concerning the time of a frame transmission than any receiver node. The bus guardian limits the frame transmission in such a way that frames transmitted too early or too late are blocked or truncated, thus resulting in an invalid transmission for all receivers. Thereby, the bus guardian protects the communication system from a node transmitting a correct frame with a temporal deviation close to the precision. Such a transmission can result in an inconsistently perceived failure (i.e., so-called Byzantine fault) when the frame is received correctly by some nodes and incorrectly by other nodes. A detailed discussion of the dimensioning of bus guardian windows can be found in [Rus01].

## 40.6 Configuration Services

TTP supports the switching between predefined static configurations called *cluster modes*. The rationale for this protocol service is that many applications exhibit mutually exclusive modes of operation. For example, the flight control system of an airplane can support different modes such as on-ground, takeoff, low-altitude, and landing [BM00]. Likewise, cars can exhibit different modes of operation such as a normal mode and a limp-home mode [BP96, TNBM05].

At any time, all nodes of the cluster must be in the same cluster mode. The cluster mode is part of the controller state, thus a divergence of cluster modes is detected by the CRC calculation. Every cluster mode must also possess the same sequence of TDMA slots.

A host can request a mode change using the control area of the CNI. In the next presend phase, the communication controller checks this request against the mode change permissions in the MEDL. If the mode change is permitted by the MEDL, information about the new mode is included in the next sent frame.

Receiving nodes act on this mode change information in the postreceive phase. The communication controller of a receiver node also checks whether the sender is allowed to request the new mode according

to the mode change permissions in the MEDL. If the request is permitted, the new mode will become active at the beginning of the next cluster cycle. The ongoing cluster cycle is not preempted.

If another mode change request arrives before the end of the cluster cycle, then the new one overwrites the previous one. Nodes can also cancel a pending mode change request by sending a special value for the mode change request. In this case, the mode of the current cluster cycle remains in place.

### 41.1 Protocol Overview

---

Controller area network (CAN) [Int93a] provides an inexpensive and robust network technology, which is widely deployed in many application domains such as automotive, avionic, and industrial control systems. For example, present-day cars contain multiple CAN buses deployed for different domains such as comfort or powertrain subsystems [ES09,HB08]. Properties of CAN that have led to its success include its simplicity, high flexibility, efficiency, and low cost. Adversely, CAN exhibits limitations with respect to reliability, diagnosis, and scalability.

In classic CAN networks, the communication has two main characteristics: the communication is event-triggered, and the shared medium is a bus. Both these properties lead to limitations of the conventional CAN protocol in the context of dependable embedded systems. An example of a hazard to reliability is the missing fault isolation for babbling idiot failures [TH94]. A faulty CAN node can disrupt the communication abilities of all other nodes by continuously transmitting high-priority messages. Besides these limitations, which have their origin in the bus-based topology, conventional CAN does not provide time-triggered concepts like dedicated communication slots for real-time communication, because conventional CAN does not make use of a priori knowledge about communication activities.

Due to the event-triggered nature of CAN, peak loads can occur if nodes in the network try to send messages at the same point in time. The arbitration mechanism of CAN performs sequential transmission of all messages according to their *identifier priority*. This arbitration makes a scheduling analysis of the whole system difficult because worst-case peak loads have to be considered for the analysis. Additionally, the temporal behavior of sending nodes is often unknown or not defined.

Time-Triggered CAN (TTCAN) [Int93b] uses the concept of cyclic communication, divided into slots to implement time-triggered behavior. The standard requires that all activity assigned to one slot (including interrupt handling) be finished until the next slot starts, whereas one message can be assigned to several slots.

It is important to note that TTCAN adds an *additional layer* before the existing standard CAN layers. The physical layer and data link layer of CAN (specified in [Int93cl]) are kept unchanged. Mapped to the ISO-OSI model, TTCAN resides on layer 5, the session layer. Within this layer, TTCAN is divided into two different modes of operation. While level 1 and level 2 both support time-triggered behavior, the capabilities of these levels differ in key properties. The most outstanding difference is the notion of a *global time*, which only exists in level 2, and allows a much more fine-grained synchronization of the nodes in a TTCAN network.

The following sections discuss the key properties of the TTCAN protocol, where both levels of TTCAN are taken into consideration.

## 41.2 Protocol Services

### 41.2.1 Communication Services

According to the standard [Int93b], TTCAN specifies a serial communication protocol that supports distributed real-time control and multiplexing for use within road vehicles. The underlying CAN-protocol is unchanged; therefore, TTCAN uses the same arbitration and medium access control mechanisms (MAC) as conventional CAN.

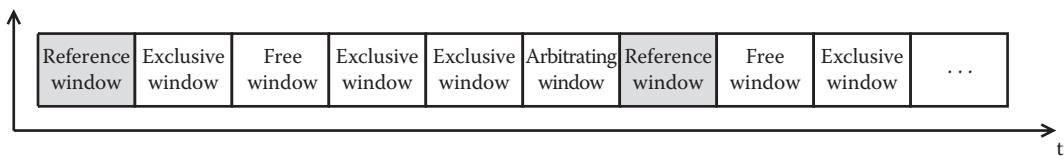

TTCAN level 1 provides cyclic message transfer, while level 2 adds the notion of a global time. The key element for the periodic and cyclic communication is the *reference message*, which is sent by a *time master*. TTCAN supports up to eight alternative time masters, where only one is allowed to be the current time master. The reference message is sent by the current time master at the beginning of each *basic cycle*. Figure 41.1 shows the execution of basic cycles over time.

Every basic cycle is divided into windows of communication activity. The sum of all basic cycles forms a *system matrix*. Basic cycles are the rows of the system matrix. Additionally, note that the number of basic cycles in the system matrix shall be a power of 2. The variable *Cycle\_Count* refers to the current basic cycle in the system matrix. *Cycle\_Count* starts from zero and has a maximum value of *Cycle\_Count\_Max*.

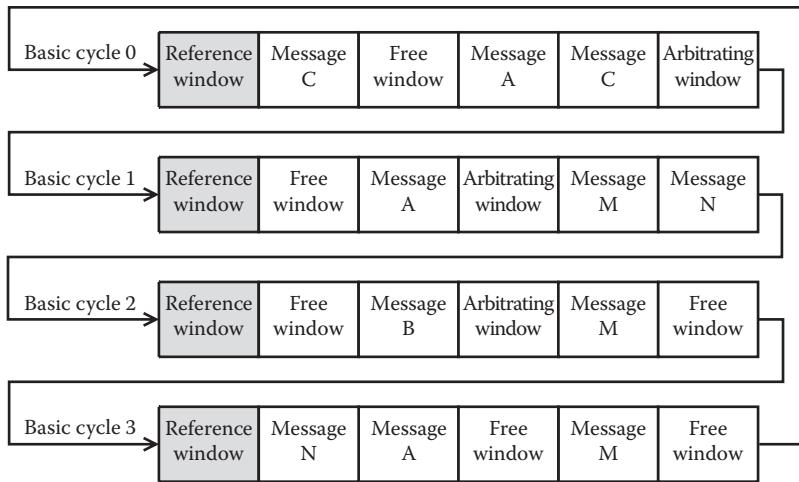

Figure 41.2 gives an overview about the communication matrix used in TTCAN. A message (e.g., message C in basic cycle 0) can be assigned to one or more time windows. The columns in the system matrix form the so-called *communication columns*, which are important for the periodicity of a message. The two important factors for the periodicity of a message are the number of basic cycles and the number of communication columns.

As shown in Figure 41.2, TTCAN supports different types of communication windows:

- Reference window
- Exclusive window
- Arbitrating window
- Free time window

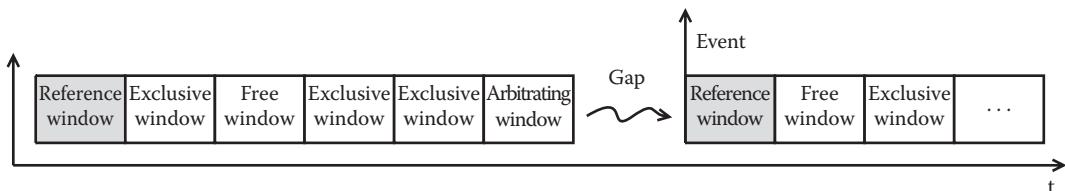

**FIGURE 41.1** Basic cycle in TTCAN. (From International Standardization Organisation (ISO), Road vehicles—Controller area network (CAN)—Part 4: Time-triggered communication, ISO 11898-4, 1993.)

**FIGURE 41.2** Communication matrix in TTCAN. (From International Standardization Organisation (ISO), Road vehicles—Controller area network (CAN)—Part 4: Time-triggered communication, ISO 11898-4, 1993.)

*Reference windows* are used to flag the start of a basic cycle. The format of reference messages and their importance for TTCAN are discussed in Section 41.2.2. *Exclusive windows* are assigned to specific, periodic messages where no other communication is allowed in the same window. There is no competition on the CAN bus within an exclusive window. *Arbitrating windows* are slots where all CAN nodes are allowed to communicate. Conflicts are resolved by the conventional CAN identifier arbitration mechanism (e.g., the message with the highest priority will be transferred). It is important to note that CAN nodes may not start a communication if the bus is not idle. To guarantee that nodes finish their transmission within their assigned window, there is a *time window* (Tx\_Enable) at the start of the arbitrating window where nodes are allowed to start their communication. If the attempt to send fails, nodes are not allowed to automatically retransmit their message and have to wait for another arbitrating window. *Free time windows* are reserved slots that will be eventually used in future network extensions.

TTCAN supports two different methods of basic cycle synchronization, namely, time-triggered and event-synchronized. In time-triggered synchronization, the time master sends the reference messages in equidistant time slots. Additionally, TTCAN supports an event-synchronized transmission of reference messages. In this case, the start of a basic cycle is synchronized to a specific event in the current time master. The gap is allowed only between the end of one basic cycle and the start of the next basic cycle (i.e., its reference message). If there is a gap between basic cycle  $n$  and basic cycle  $n + 1$ , the time master has to announce the gap in the reference message of basic cycle  $n$ . For this purpose the reference message, which will be described in detail in Section 41.2.2, contains a single-bit flag *Next\_is\_Gap*. Event-synchronized transmission is shown in Figure 41.3.

**FIGURE 41.3** Event-synchronized basic cycles in TTCAN.

### 41.2.2 Clock Synchronization

The key element for synchronization in TTCAN is the *reference message* that is sent at the beginning of every basic cycle. The following section discusses the structure and the relevance of the reference message and the achieved synchronization quality for both levels of TTCAN.

The TTCAN standard [Int93b] states that a reference message shall be a data frame characterized by a specific CAN identifier that shall be received and accepted by every FSE\* (frame synchronization entity) except the time master, which is the sender of the reference message. For reasons of simplification, FSEs are simply called nodes in the following. Level 1 and level 2 differ in the length of their corresponding reference messages. For level 1, the data length shall be at least 1 byte; for level 2, it shall have a length of at least 4 bytes. All bits of the identifier field, except three, are used to characterize the reference message itself. The three least significant bits are used to define the priority of up to eight ( $2^3$ ) time masters. The reference messages of both levels have in common, that they shall include the number of the current basic cycle (Cycle\_Count) and one bit that signals that there will be a gap between the current and the next reference message (Next\_is\_Gap), which is used for event-synchronized communication. In general, the reference message is transmitted periodically, with the exception of event-synchronized communication, or if the transmission of a reference message is disturbed. In the latter case, the time master is allowed to retransmit the reference message. In both levels, the reference message may be extended to 8 CAN data bytes. Reserved bits shall be transmitted as logical zero and shall be ignored by the receivers. Additionally, both levels have in common that the most significant bit (bit 7) is transmitted first.

The format of reference messages for level 1 and level 2 is shown in Figures 41.4 and 41.5, respectively. In both figures, grayed boxes represent optional bits in the reference message, which shall be transmitted as logical zero.

All timing in TTCAN, for level 1 and level 2, is controlled by the local clock, where the resolution for time is the network time unit (NTU). For the simpler level 1 the NTU is the nominal CAN bit time. The local time is implemented as a simple incrementing counter that contains 16 bits. In level 1, this counter is increased by one every NTU.

FIGURE 41.5 Reference message in TTCAN level 2.

\* Every CAN controller in a time-triggered CAN network has its own FSE.

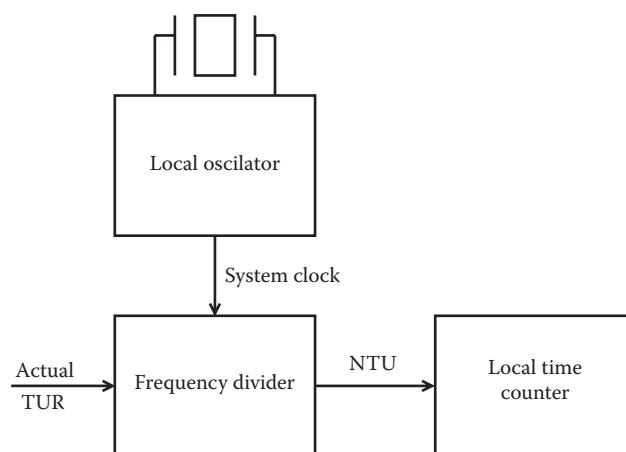

For level 2 communication, the reference message contains two additional fields, namely, Master\_Ref\_Mark (MRM), which is a time-stamp measured in global time, and Disc\_Bit, which flags that there is a discontinuity in the global time. If the transmission of a reference message is disturbed, the time master shall retransmit the message and the Master\_Ref\_Mark is updated. The structure of the reference message for TTCAN level 2 is shown in Figure 41.5.

The first byte of a reference message in level 2 contains the same bits as the reference message for a level 1 message. The second byte contains the Disc\_Bit, which flags a discontinuity in the global time and the NTU\_Res, which is the resolution of the NTU. TTCAN supports four additional bits for a more fine-grained specification of the NTU\_Res. If a node does not support these additional bits, they shall be transmitted as logical zero. The third and fourth bytes contain the low and high byte of the Master\_Ref\_Mark.

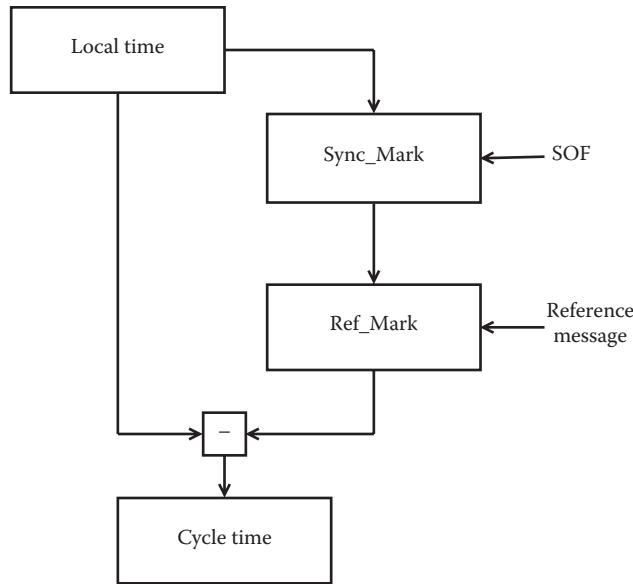

In TTCAN, there are three different notions of time [HMFH03], namely, local time, cycle time, and global time. Each of these times and their importance for TTCAN will be discussed in the following.

#### 41.2.2.1 Local Time

As in level 1, the time in level 2 is measured in NTUs. In contrast to level 1, the NTU in level 2 is a fraction of the physical second. This is required to correct the slight differences in the local clock oscillators of the nodes and to synchronize them to the global time. For level 2, the counter for the local time shall contain at least 19 bits, where the 16 most significant bits represent whole NTU ticks. The rest of the counter bits are reserved for the fractional parts of the NTU. Therefore, the counter counts in units of  $NTU/2^n$  if NTU\_Res contains  $n$  bits. If the counter is incremented  $2^n$  times, this is equivalent to 1 NTU. For example if 3 bits are reserved for the fractional part of the NTU, the counter has to increment  $2^3$  times, to increment one NTU. Every node has a basic time unit (e.g., the frequency of its local clock oscillator). To set this basic time unit in relation to the NTU, there exists the *time unit ratio* (TUR). This usually noninteger value specifies the ratio between the length of an NTU and the length of a basic time unit. The current value of TUR (TUR\_Actual) is responsible for the velocity of the NTU counter. The TTCAN standard does not specify the implementation or the data representation of the TUR. The TUR has an essential role for clock synchronization in level 2. Whenever there is a difference between the local time and the global time transmitted by the time master, the TUR gets adjusted. The generation of the *Local\_Time* is shown in Figure 41.6

**FIGURE 41.6** Local time generation in TTCAN. (From Hartwich, F. et al., Timing in the TTCAN network, Technical report, Robert Bosch GmbH, 2003.)

**FIGURE 41.7** Cycle time generation in TTCAN. (From Hartwich, F. et al., Timing in the TTCAN network, Technical report, Robert Bosch GmbH, 2003.)

#### 41.2.2.2 Cycle Time

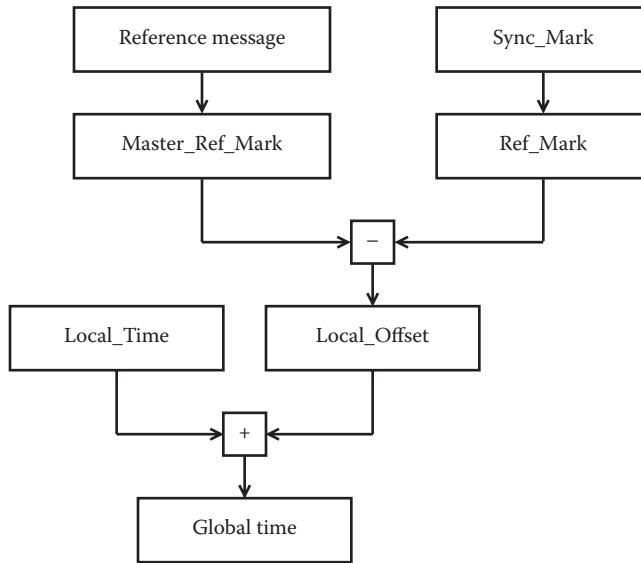

The time within one basic cycle is measured in the *Cycle\_Time* parameter. At each start of a data frame (SOF) or remote frame, the node saves its current value of the local time to *Sync\_Mark*. Whenever the node receives a reference message, it saves the current value of *Sync\_Mark* to *Ref\_Mark*. Therefore, the value of *Ref\_Mark* contains the time stamp of that point in time of the start of the last reference message. The *Cycle\_Time* is the difference between the local time of the node and its *Ref\_Mark*. *Cycle\_Time* has no fractional part, therefore only the 16 most significant bits contribute to the *Cycle\_Time*. The generation of the *Cycle\_Time* is shown in Figure 41.7.

#### 41.2.2.3 Global Time

In TTCAN level 1, the common time base is the *Cycle\_Time*, which is restarted at each basic cycle. In this sense, level 1 has a global time with the horizon of one basic cycle. Level 2 adds a more fine-grained concept of global time, which is used to calibrate the local time base of each node in the TTCAN network. To compensate a clock drift in the nodes in level 2, the TUR value is adjusted to the current time master's view of the global time at every reception of a reference message. At a pulse of frame synchronization, a node stores its local view of the global time as its *Global\_Sync\_Mark*, which has at least 19 bits. The current time master transmits its *Global\_Sync\_Mark* (i.e., its view of the global time) as the bits reserved for *Global\_Ref\_Mark* in its reference message. Whenever a node receives a reference message, it calculates a local offset:

$$\text{Local_Offset} = \text{Master_Ref_Mark} - \text{Ref_Mark}$$

The generation of the global time in TTCAN is shown in Figure 41.8. The current time master's view of *Local\_Offset* remains constant. Every node starts with a *Local\_Offset* of zero. Changes in the value of the

**FIGURE 41.8** Global time generation in TTCAN. (From Hartwich, F. et al., Timing in the TTCAN network, Technical report, Robert Bosch GmbH, 2003.)

Local\_Offset show that there is drift between the local view of time and the global view, which has to be corrected. This clock rate correction is done by adjusting the NTU value according to the following formula [HMFHO3]:

$$df = \frac{Ref\_Mark - Ref\_Mark_{previous}}{Master\_Ref\_Mark - Master\_Ref\_Mark_{previous}}$$

$$TUR = df * TUR_{previous}$$

TTCAN considers the 16 most significant bits of local time and local offset of the current time master as its *global time*. The local time and local offset of a node are an approximation of the global time.

The time master in TTCAN is allowed to use *external clock synchronization*. The TTCAN standard describes the following three means:

1. *Frequency adjustment*: In this method, the external time period is used as the base for the NTU. To adapt the NTU, the length of the external time period is used as the TUR value. First the time master writes the new value to TUR\_Adjust. At the beginning of the next basic cycle, TUR\_Actual gets overwritten by TUR\_Adjust.
2. *Phase adjustment*: Phase adjustment can be done by continuous frequency adjustment or by inserting a discontinuity in the global time. In the latter case, the time master has to set the Disc\_Bit to inform the nodes that a discontinuity has to be expected. At the beginning of next basic cycle, the time master adds the difference between the desired global time and the actual current time to its local offset to influence the global time.
3. *Adjustment of Cycle\_Time*: If this synchronization scheme of external clock synchronization is applied, the time master sets the Next\_is\_Gap flag in its reference message to inform the nodes that the next basic frame will be event-synchronized. After that, the time master waits as long as required by the external clock before it starts sending the next reference message.

### 41.2.3 Sending and Receiving Messages in TTCAN

As described before, the communication in TTCAN is organized with the help of the system matrix. Within the system matrix the rows form the basic cycles, where each of these basic cycles starts with a reference message. When it comes to sending and receiving of messages, two parameters are of utmost importance: *Cycle\_Time* and *Tx\_Trigger*. A basic cycle is divided into columns that form the time slots when a message shall be sent. Time within a basic cycle is measured in *Cycle\_Time*. *Tx\_Trigger* specifies that instant in time when a message corresponding to a time slot shall be sent. A *Tx\_Trigger* contains the following information:

- A reference to a message that shall be sent.
- Activation time mark, which is the column of the system matrix.
- Row of the system matrix measured in *Cycle\_Count*.
- Repeat factor: Position of the same column in which it will be sent next. The value is a power of 2.

A vital parameter for TTCAN and the sending of messages is the *Tx\_Enable* parameter. A message has to be sent within a specific time window after the start of its corresponding time slot. If the transmission would start too late, the message would overlap with the start of the next slot. To avoid this erroneous behavior, there exists the *Tx\_Enable* parameter. It specifies a window from the start of the corresponding time slot (*Tx\_Trigger*) within which the transmission of a message is allowed and safe. This window is specified as a number of nominal CAN bit times with a range from 1 to 16. If a node cannot start the transmission of a message within the *Tx\_Enable* window, the transmission may not be started at all. In this case, the node has to wait for the next *Tx\_Enable* to send the message.

The concept of the *Rx\_Trigger* is related to the *Tx\_Trigger*. It contains the same information as a *Tx\_Trigger*, but specifies the point in time when a received message has to be completed and verified.

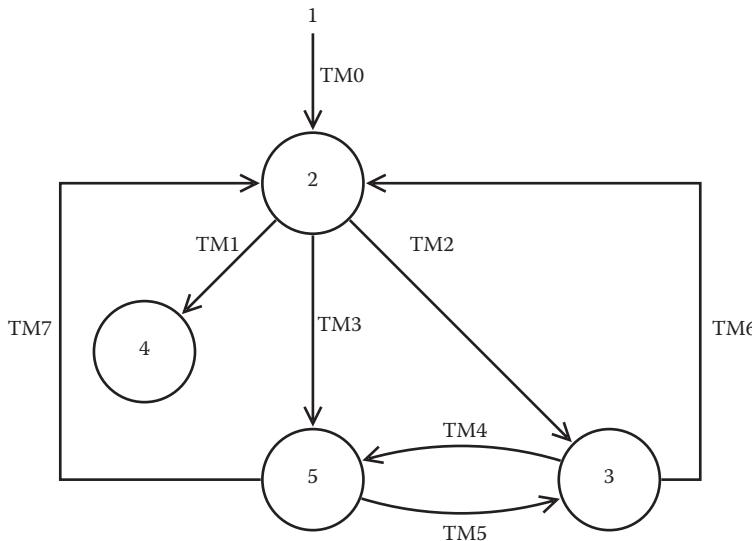

There are two additional triggers that are important in a TTCAN system: *Tx\_Ref\_Trigger* and *Watch\_Trigger*. *Tx\_Ref\_Trigger* is a special *Tx\_Trigger* that refers to reference messages and is only used in potential time masters. Whenever this trigger is reached, a potential time master tries to send a reference message. Within a strictly time-triggered TTCAN system (no *Next\_is\_Gap* bits) one *Tx\_Ref\_Trigger* is enough. If event-synchronized transmission of basic cycles is planned, a second *Tx\_Ref\_Trigger* is used. The first trigger is used for the periodic transmission of reference messages, where the second restarts the first one whenever the event that was flagged with the *Next\_is\_Gap* bit did not occur or was missed.

*Watch\_Trigger* is also used by nodes that are not potential time masters. These nodes will be called slave nodes in the following. *Watch\_Trigger* is reached if there is no reference message on the bus longer than a specified threshold. This could be the case on a disturbed bus. Like the *Tx\_Ref\_Trigger*, there shall be two *Watch\_Triggers* to support event-synchronized communication. When a *Watch\_Trigger* is reached, the application shall be informed about the erroneous behavior in the system. During start-up, the *Watch\_Trigger* is disabled until the first successful transmission or reception of a reference message.

### 41.2.4 Restart, Reintegration, Integration

TTCAN differentiates between the start-up behavior of a time master and its fault-tolerance capabilities. This section describes the start-up, whereas Section 41.2.6 gives an overview about fault tolerance in TTCAN.

At system start-up (or a reset), all potential time masters try to become the current time master and all of them try to send a reference message. There are two parameters that influence the decision which potential time master becomes the current time master. The potential time master with the highest priority shall use the CAN ID with the highest priority (in relation to the other potential time master). As specified by the TTCAN protocol, CAN IDs of time masters only differ in the three least significant bits.

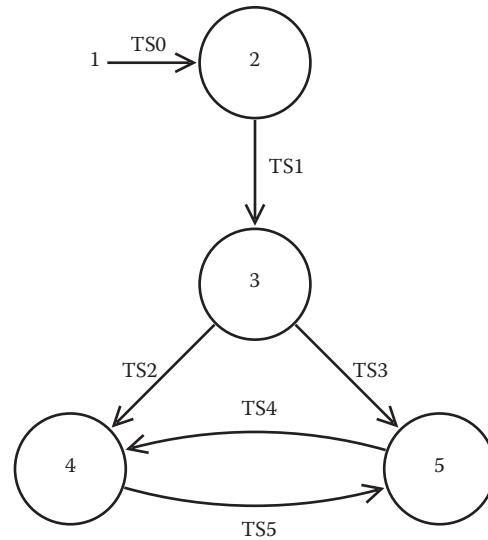

**FIGURE 41.9** Master/slave relation in TTCAN. (From International Standardization Organisation (ISO), Road vehicles—Controller area network (CAN)—Part 4: Time-triggered communication, ISO 11898-4, 1993.)

The rest of the bits reserved for the CAN ID are equal for all potential time masters. Additionally, there is a parameter that specifies how long a potential time master is idle before it tries to send a reference message. The potential time master with the highest priority has the shortest delay before it tries to send its initial reference message.

Both of these parameters, the priority of a potential time master and the time a potential time master waits for its initial transmission, influence the decision which potential time master will become the current time master and how long it takes to establish a new time master.

Figure 41.9 shows a state machine of the start-up protocol and the establishment of a new time master. State 1 is the initial state, which is reached for example after a hardware reset. Transition 0 is always taken. State 2 is reached by slaves as well as potential time masters. If the node is a slave, and it receives a reference message on the bus, transition 1 is taken and the node is in state 4, the slave state. If the node is in state 2 and it is a potential time master, two transitions may be taken. First of all, a potential time master will try to send its own reference message. The best case for the potential time master is that it reads its own reference message on the bus. In this case, the potential time master takes transition 3 and becomes the new time master (state 5). On the other hand, a potential time master in state 2 can read a reference message that contains an ID that is not equal to its own. In this case, the potential time master takes transition 2 and becomes a *backup time master* (state 3). From this state a potential time master can become the current time master with transition 4 whenever it reads its own ID in the reference message. This can happen if the prior time master fails and a backup time master can now successfully transmit its own reference message. However, a current time master can also be degraded to a backup time master. This happens if it is the current time master (state 5) and reads a reference message with a higher priority on the bus. In case of an error, the time master as well as backup time masters can be reset to state 2.

After the initialization, but before the synchronization has finished, each node refers to its local time as the global time of the system. The parameter Local\_Offset is initially set to zero. The actual time master tries to establish its view of the global time as the global time in the TTCAN system. Therefore, it sends its own Global\_Sync\_Mark as the Master\_Ref\_Mark in its reference message. An important fact is that a potential time master that becomes the actual time master (e.g., when the old time master fails) keeps its value for the Local\_Offset. This is used to avoid discontinuities of the global time.

**FIGURE 41.10** Synchronization in TTCAN. (From International Standardization Organisation (ISO), Road vehicles—Controller area network (CAN)—Part 4: Time-triggered communication, ISO 11898-4, 1993.)

The synchronization of a node can also be described with the help of a state machine (refer to Figure 41.10). A node is in state 1 after a hardware reset. From this state transition 0 always occurs. In state 2, the node is not yet synchronized (Sync\_Off). After leaving an internal configuration mode and setting Cycle\_Time to zero, the node is in state 3. From state 3, the node can either take a transition 2 to state 4, where it is In\_Gap, or transition 3 to be in schedule (In\_Schedule). For both transitions, TS2 and TS3, the node has to receive two successive reference messages where the last of the two did not contain a Disc\_Bit. For TS2 the last reference message has to contain a set Next\_is\_Gap bit, whereas for TS3 Next\_is\_Gap has to be unset. A node can leave the In\_Schedule state with transition TS4 whenever a reference message contains a set Next\_is\_Gap bit. When a node is in the In\_Gap state (state 4), it can reach a synchronized state (state 5) whenever it receives a reference message where the Next\_Is\_Gap bit is unset.

### 41.2.5 Diagnostic Services

TTCAN provides simple means for diagnosing the communication on the CAN bus. A *Watch\_Trigger* is used to monitor the reception of reference messages. TTCAN uses two different Watch\_Triggers, one for the reception of periodic messages and one for event-synchronized messages. If there is no reference message for a specified time, the Watch\_Trigger is activated and an error handling procedure is started. Additionally, the application shall be notified. During initialization, the Watch\_Trigger is disabled and gets activated upon a successful reception of a reference message.

As stated before, TTCAN provides an additional layer above the conventional CAN protocol. All means of CAN bus error handling support the error handling of TTCAN.

#### 41.2.5.1 Error Counters in CAN

CAN provides a receive error counter as well as a transmit error counter that can be used also in TTCAN. The values of these counters are vital for the CAN node because they define the error state of the node. CAN defines the following three error states for a node:

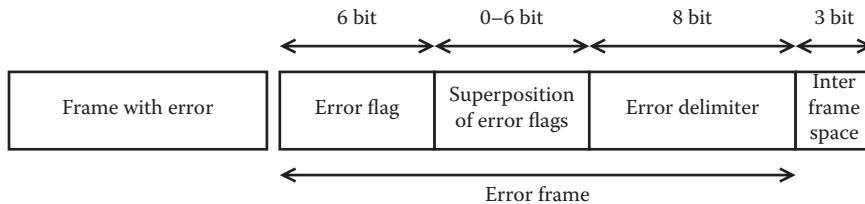

1. Error active: The node is allowed to send active error frames
2. Error passive: The node sends passive error frames
3. Bus off: The node does not take part in bus communication

According to the state of the error counter of the CAN node, it can send active or passive error frames. When a node is highly disturbed, and therefore has a high error count, it is only allowed to send passive error frames. Within these frames, the node is only allowed to send recessive error flags. Therefore, a node in passive error state cannot disrupt the communication of the bus, because its recessive error flags cannot disturb the communication of working nodes.

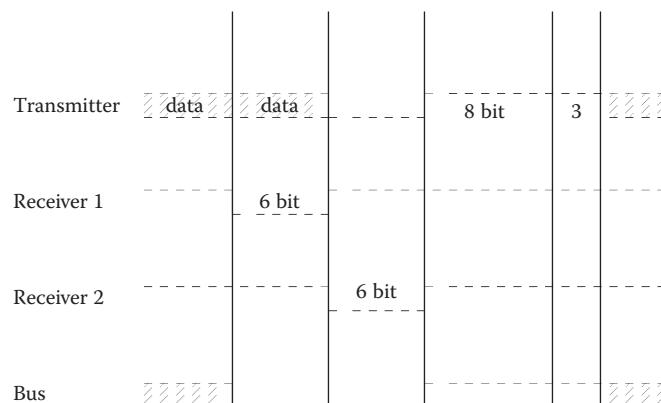

When the corresponding error counter has a value between 0 and 96, the node is in *error active state*. If the error counter exceeds 96, it reaches a *warning limit*, where the node sets an error flag and generates an interrupt. Between 97 and 127, the bus is heavily disturbed and the node is still in error active state. Between 128 and 255, the node is in *error passive state* and above 255 the node reaches *bus off* state.

#### 41.2.5.2 Error Frames in CAN

Whenever a node detects an error on the bus, it sends an error frame on the bus. These error frames contain a 6-bit error flag. Additional 0–6 bits are reserved for the superposition of further error flags. After the error flags, an error frame contains 8 bits used for the error delimiter. The delimiter contains 8 recessive bits to allow a restart of the communication after the superposition of error flags. After the delimiter, 3 bits are reserved for an interframe space. The fields of an error frame are shown in Figure 41.11. Superposition of error flags occurs in the following situation: A receiver detects an error on the bus and starts to send an error frame. Within this error frame, the other receivers will detect a violation in the bit stuffing of CAN. Therefore, the other receivers will send error frames themselves, and their first 6 bits will lead to a superposition of error flags in the first error frame. Figure 41.12 shows the superposition of error flags. In this case, receiver 1 detected the error on the bus first and started to send its error frame. After the first 6 bits, receiver 2 also detected an error and started to send its error frame with its error flags. This shows one important mechanism of CAN, the *globalization of local errors*. Whenever a node detects an error on the bus, it will try to establish a global error state on the bus.

**FIGURE 41.11** Error frame in CAN. (www.softing.com. CAN, CANOpen, DeviceNet. Website, August 2010.)

**FIGURE 41.12** Error handling in CAN. (www.softing.com. CAN, CANOpen, DeviceNet. Website, August 2010.)

#### 41.2.5.3 Bit Stuffing in CAN

Bit stuffing is used in CAN whenever 5 consecutive bits of the same polarity occur in the CAN bit stream. In this case, one bit of the opposite polarity will be inserted. In CAN, there are fields with a fixed bit pattern, which are not part of the bit stuffing. In CAN, the fields for start of frame (SOF), the arbitration field, the control field, the data field, and the CRC field are part of the bit stuffing area. The bit stuffing property of CAN is used to flag errors on the bus, because whenever 6 consecutive bits of the same polarity are read on the bus, all nodes will interpret this as an error.

#### 41.2.6 Error Detection and Fault Isolation

Fault isolation and tolerance is of utmost importance whenever a network is used in a safety-relevant context. For traditional CAN, it is possible to retransmit a message if an error occurs during the transmission of the message. This simple mechanism cannot be used for TTCAN because it has to follow the schedule for its messages. Therefore, in TTCAN, the automatic retransmission of messages is turned off.

The TTCAN standard itself provides error detection mechanisms and a classification of error severity. It also states that active fault confinement shall be left to a higher layer or to the application. The node shall provide error detection and fail-silence [Int93b].

TTCAN defines the following errors and their severity. Note that the standard does not specify where these bits should be saved (i.e., this could be in registers of a node).

- Scheduling\_Error\_1 (S1): An error of this kind is flagged whenever the difference between the highest message status count (MSC) and the lowest MSC of all messages is larger than 2. Additionally a scheduling error is flagged if the MSC of an exclusive receive message object is 7. The MSC is used for periodic messages in exclusive time windows. The MSC has a range from 0 to 7. The MSC is updated at the Rx\_Trigger event that corresponds to that specific message. If the message is successfully received, the MSC is decremented by 1, else it is incremented by 1.
- Tx\_Underflow (S1): This bit is set whenever the count for transmitted messages is lower than its expected value.
- Scheduling\_Error\_2 (S2): Whenever an MSC of a transmit message object reaches 7, this error bit will be set.
- Tx\_Overflow (S2): This flag will be set whenever the expected maximum value (Expected\_Tx\_Trigger) is reached and there are still Tx\_Trigger events.
- Application\_Watchdog (S3): The application watchdog gets reset by the application itself via a Host\_Alive\_Sign. If the application fails to set this sign, an error will be flagged.
- CAN\_Bus\_Off (S3): This error is flagged whenever the node went off the bus due to CAN-specific errors.
- Config\_Error (S3): Slots in TTCAN have a specific time window where the transmission of the data has to start. If the actual point in time exceeds this specified limit, a Config\_Error will be flagged.
- Watch\_Trigger\_Reached (S3): This error flag will be set whenever a reference message is missing.

The TTCAN standard specifies the following severity classes:

- S0: No error.
- S1: Warning—The application will be informed; the reaction is application specific.
- S2: Error—The application will be informed, and all transmissions in exclusive and arbitrating windows will be disabled. Potential time masters are still allowed to transmit reference messages with the maximal allowed offset.
- S3: Severe—The application will be informed, and all bus activities will be stopped. In this case an update of the configuration is required.

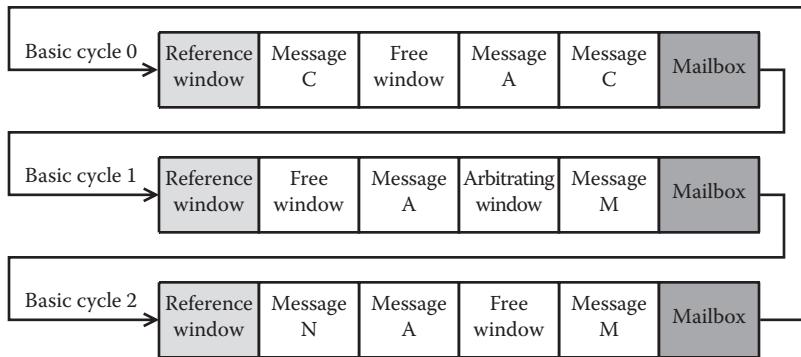

FIGURE 41.13 System matrix with mailbox.

In addition to the fault handling specified by the TTCAN standard itself, there are several approaches as to how to add fault tolerance to TTCAN. One simple approach is described in [BBRN04], where each frame is sent twice.

A different approach is to add a *mailbox system* to TTCAN [MA05]. This is done by reserving an exclusive window, the mailbox, at the end of each basic cycle to retransmit messages that could not be sent in their dedicated slot, as shown in Figure 41.13. The basic idea is to add a software supervisor layer above the TTCAN controller that manages additional send and receive queues. Whenever a message cannot be transmitted in its dedicated slot, this message is scheduled to be transmitted in the mailbox slot at the end of the basic cycle. This solution assumes that bit error rates occur in the magnitude of  $10^{-7}$ . Therefore, a basic cycle would have to be  $2 \times 10^7$  messages long to corrupt two messages within one basic cycle. This would require a basic cycle of about 2.2 h. The authors conclude that one mailbox is enough to provide sufficient fault tolerance. Whenever an error occurs, the supervisor sends an error frame on the bus. After that, it enqueues the failed message to the send queue and transmits the message in the mailbox slot. At the start of the system matrix (and at every iteration), the send queue gets flushed to prevent queue overflows.

TTCAN provides fault tolerance by combining two (or more) TTCAN buses [MFH<sup>+02</sup>]. A system of two TTCAN buses is considered a *coupled TTCAN pair* if there is at least one *gateway* node connected to both TTCAN buses. A system of TTCAN buses is considered as coupled if there exists a path from the start bus via coupled nodes to the end bus. More formally [MFH<sup>+02</sup>]:  $bus_a$  and  $bus_b$  are TTCAN coupled if there exists a sequence  $(bus_1, \dots, bus_n)$  of TTCAN buses with  $bus_1 = bus_a$  and  $bus_n = bus_b$  where  $(bus_i, bus_{i+1})$  are coupled TTCAN pairs  $\forall i = 1, \dots, n - 1$ . Now a fault-tolerant TTCAN network is a system of TTCAN buses where every two of them are TTCAN-coupled. Figure 41.14 shows a coupled TTCAN system where  $bus_a$  and  $bus_c$  are coupled.

The main problem of providing a coupled, and therefore fault-tolerant, TTCAN system is the synchronization between the different buses. [MFH<sup>+02</sup>] states three different problems of synchronization,

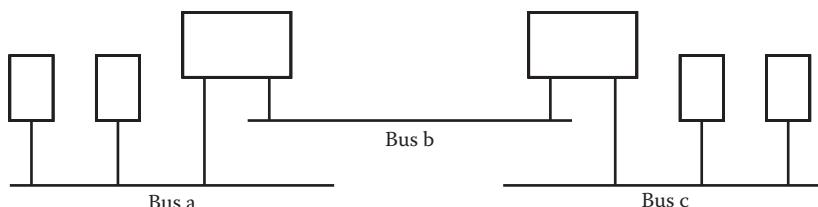

FIGURE 41.14 Coupled TTCAN buses. (From Müller, B. et al., Fault tolerant ttcan networks, Technical report, Robert Bosch GmbH, 2002.)

which are related to the different times used in TTCAN. With the synchronization mechanisms described in the paper, it is possible to synchronize a system of two or more TTCAN buses and therefore provide fault tolerance in the system: phase synchronization of cycle time, phase synchronization of global time, and rate synchronization.

#### 41.2.6.1 Phase Synchronization of Cycle Time

To recapitulate, the cycle time is used to measure the time between two successive reference messages. At every start of a basic cycle a reference mark is saved and *cycle time = local time – local reference mark*. All points in time in TTCAN are specified according to the cycle time. The simplest solution to phase synchronize two (or more) buses is to use one bus as a *master bus* and synchronize the second bus to the first one. The situation can further be simplified if the *gateway node*—the node connected to both buses—is a time master for the second bus. To initiate the desired phase relation, the time master has to set its *Next\_Is\_Gap* bit and stall the next reference message until the desired offset. This is the simplest method to solve this issue. If the gateway node is not a time master on the second bus, a simple metaprotoocol can be used. In this case, the gateway node transmits the desired phase shift in a TTCAN message to its time master and the time master will take care of the rest. This method of *master buses* can be extended to  $n$  TTCAN buses, where the first bus is the master bus and every bus  $i$  for  $i = 2, \dots, n$  synchronizes to bus  $i - 1$ .

#### 41.2.6.2 Phase Synchronization of Global Time

To synchronize the phase of the global time of two time masters on distinct buses, the same methods as for the phase synchronization of the cycle time can be used. The gateway node calculates the desired phase for the slave global time and informs the master node. As well as for the synchronization of the cycle time this can be simplified if the gateway node is the time master of the slave bus. The new global time can then be announced to the slave bus. This is done by setting the *Disc\_Bit* to flag a discontinuity in the global time.

#### 41.2.6.3 Rate Synchronization

To synchronize the rates of two TTCAN buses, first the rates of the two (or more) buses have to be measured. One option is to measure the same physical time interval on both buses. From this measurement the ratio for the slave bus can be calculated. This value will then be sent to the local time master. This time master will then update its TUR value and within the next basic cycle the TTCAN bus will be rate-synchronized.

For details about the different synchronization methods please refer to [MFH\*02].

In addition to the presented TTCAN specific methods of fault isolation, classical CAN error detection mechanisms of CRC-checksums can be used in TTCAN networks.

#### 41.2.6.4 CRC in CAN

CAN uses a 15-bit cyclic redundancy check for its messages. The generator polynomial used for CAN is  $x^{15} + x^{14} + x^{10} + x^8 + x^7 + x^4 + x^3 + 1$ . The polynomial has a guaranteed minimal hamming distance of 6, which means that up to 5 random bit failures can be detected. Due to bit stuffing, there can be the situation that only two disturbed bits lead to a situation that cannot be detected by the CRC check. For an example refer to Table 41.1.

### 41.2.7 Configuration Services

The TTCAN standard specifies three main configuration interfaces, where each of these interfaces is divided into subinterfaces that allow the configuration of protocol settings. The TTCAN standard demands that all interfaces shall be lockable against random changes, whereas reading settings is always possible. The following paragraphs provide an overview about the configuration interfaces and their most important

**TABLE 41.1** CRC—Hamming Distance Shortfall

*Source:* Müller, B. et al., Fault tolerant TTCAN networks, Technical report, Robert Bosch GmbH, 2002.

variables. For a complete list, refer to the corresponding section of the TTCAN standard [Int93b]. Note that the standard does not specify the location of these interfaces or how to access these interfaces. One practical solution is to store the values into registers and provide an API to access these interfaces.

#### 41.2.7.1 General Configuration Interfaces

As the name states, this interface is used to set general protocol parameters for a TTCAN node. Settings include the configuration of the TUR, the operation mode of the node (configuration, CAN communication, time-triggered communication, and event-synchronized time-triggered communication), its role as a slave or a potential master, if external clock synchronization shall be used, which interrupt sources shall be masked, and an 8-bit value for the application watchdog limit.

The main role of the interface is the configuration of the system matrix. With this interface, the system engineer can specify message objects, and the corresponding triggers. The triggers contain a reference to a valid message, a time mark when it should be activated, the position in the transmission column with its first activation, and its repeat factor. The standard states that the configuration can be read and written during the initialization phase, and shall be locked during the time-triggered communication activity.

#### 41.2.7.2 Application Interfaces

The application interfaces provide information about the current state of the node to the application.

Accessible information includes the priority (3 bits) of the current time master, the master state, the current value of the global time in NTUs, the Cycle\_Time, the number of the current basic cycle, and the actual value of the TUR (TUR\_Actual), which is read-only. Additionally, the interface is used to configure operational and error detection interrupt sources. Operational interrupt sources are, among others, the start of a basic cycle, the start of the system matrix, an interrupt that occurs if the global time wraps, or a change in the local master state. Error detection interrupt sources are, for example, over- and underflows of the Tx-Counter, the application watchdog, or a CAN\_Bus\_Off interrupt.

#### 41.2.7.3 Optional Interfaces

Optional interfaces are not required to comply with the TTCAN standard. Examples are interfaces that signal that the node is out of synchronization, or that the Disc\_Bit should not be used and to prevent a discontinuity in the global time. Additionally, there could be an interface to specify the maximum synchronization deviation.

### 41.3 Flexible Time-Triggered CAN

Flexible Time-Triggered CAN (FTT-CAN) [PA00] is a CAN-based master/slave protocol for building a predictable time-triggered communication service on top of CAN, while also allowing for slots with conventional event-triggered CAN communication.

FTT-CAN distinguishes two types of traffic, namely, synchronous and asynchronous traffic. The synchronous traffic consists of periodic time-triggered messages. Time windows not used by these periodic messages are available for the asynchronous traffic. Contention of the asynchronous traffic is resolved by the arbitration mechanism of CAN. FTT-CAN structures communication into communication rounds called *elementary cycles*. The master node initiates an elementary cycle by generating a periodic message used to synchronize all other nodes. This periodic message is referred to as *elementary cycle trigger message*. In addition to marking the beginning of a new elementary cycle, the trigger message conveys the identification of synchronous messages that are exchanged within this elementary cycle. Every node participating in synchronous communication is equipped with a local table that contains information about the synchronous messages transmitted and received during the elementary cycle.

FTT-CAN supports two modes. In *controlled mode*, a node may only send an asynchronous message, if the remaining time window before the next synchronous message has a sufficient length for preventing any interference of synchronous and asynchronous messages. The major disadvantage of controlled mode is the introduction of bus idle-time at the end of asynchronous windows, although messages are waiting for transmission. Hence, controlled mode decreases the network utilization. In *uncontrolled mode* nodes can start with the transmission of asynchronous messages at arbitrary points in time. Through assigning higher priorities to synchronous messages, it is ensured that synchronous messages always win in the arbitration process. Nevertheless, the nonpreemptive nature of CAN results in transmission jitter of synchronous messages, in case an asynchronous message is being transmitted when a synchronous message transmission is scheduled.

The advantages of FTT-CAN are as follows:

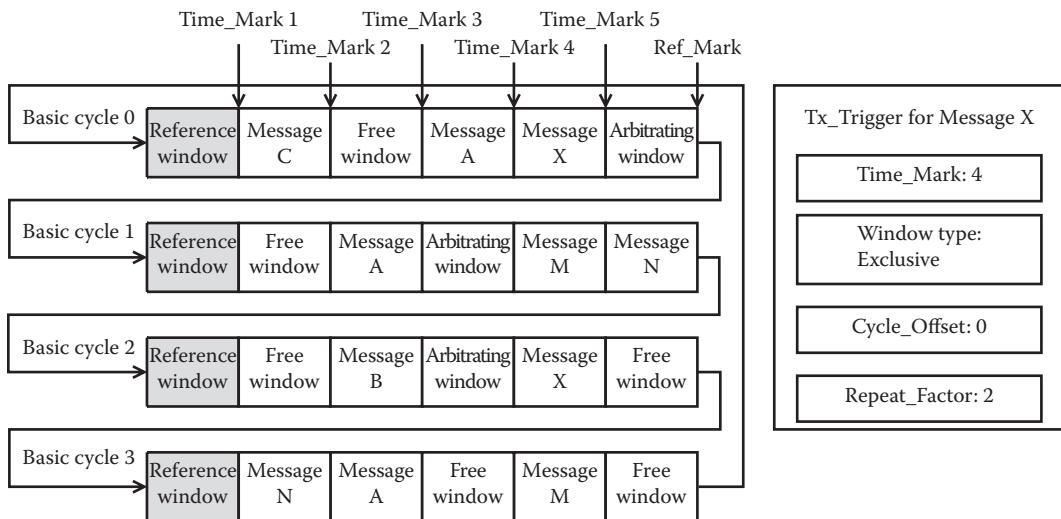

- *Low jitter mode*: The controlled mode of FTT-CAN ensures predictable communication with low jitter in the absence of faults.
- *Software upgrades for existing systems*: FTT-CAN can be installed in existing systems without involving modifications to hardware. However, in order to reach a fault-tolerant FTT-CAN [FPAF02] communication service, dedicated hardware (bus guardians) are required.
- *Coexistence with conventional CAN*: In uncontrolled mode, synchronous communication can coexist with standard CAN communication. Hence, no changes to the CAN protocol are required in legacy nodes and nodes with application software that does not require deterministic message exchanges.

A major drawback of FTT-CAN is the mutual exclusion of low jitter and support for legacy nodes. The uncontrolled mode of operation offers support for the integration of legacy CAN nodes with an unmodified CAN protocol stack. However, the support for legacy nodes comes at the price of increased transmission jitter due to the inability of CAN to preempt asynchronous messages after the transmission has been started. The controlled mode offers lower jitter, but it restricts the transmission of asynchronous messages to asynchronous windows. At the end of the asynchronous window, transmissions must not be started if an intersection with the synchronous window could take place. These restrictions with respect to the temporal behavior of message transmissions are not part of the CAN protocol specification and exceed the capabilities of standard CAN controllers. Hence, either legacy software has to be modified or CAN communication controllers must be replaced in order to support the controlled mode in existing systems.

## 41.4 Commercial or Prototypical Components

---

TTCAN controllers are available both as IP cores and as part of microcontrollers. For example, the TTCAN IP module is available from Bosch [Bos06]. This IP module is described in VHDL and can be integrated as a stand-alone device or as part of an ASIC. The IP module realizes a state machine for the ISO 11898-4 time-triggered communication. The state machine uses the reference messages of the

CAN bus as a synchronizing event to establish a global time base and perform message transmissions according to the a priori known communication schedule.

Another IP module supporting TTCAN is the MultiCAN IP of Infineon Technologies [Kel03], which is deployed in several Infineon devices (e.g., TC1130 [Inf03]). Like the TTCAN IP module, the MultiCAN IP performs clock synchronization and offers a scheduler to trigger the predefined message transmissions.

In addition, microcontrollers are available that support the implementation of TTCAN. For example, Atmel provides microcontrollers (e.g., T89C51CC01, T89C51CC02 [Atm08a,Atm08b]) that permit the implementation of TTCAN using higher software layers. In particular, these microcontrollers offer a single-shot transmission mode in order to prevent automatic retransmission upon errors. This transmission mode is required for the implementation of TTCAN.

In academics, the GAST (General Application Development Boards for Safety Critical Time-Triggered Systems) project\* provides a controller board that features a TTCAN controller card. The setup was used in a master thesis to evaluate the performance of TTCAN [FU06].

### 42.1 General Overview

Ethernet is the dominant network standard for local area networks (LAN). While originally designed for classic office applications, the growing communication demands in real-time systems led to adapting Ethernet for time-critical applications. Today, we can find Ethernet variants everywhere: in industrial applications (EtherCat, Ethernet Powerlink, ProfiNet, Ethernet IP), in aerospace applications (ARINC 664-p7, ASCB/D), in military naval applications (Gigabit Ethernet Data Multiplex System), in consumer audio/video systems (AVB), as well as in datacenters and cloud computing (DCB). All of these Ethernet variants aim to achieve a certain degree of quality of service (QoS) such that end-to-end transmission guarantees can be ensured. In this multitude of Ethernet-variants, TTEthernet introduces the deterministic time-triggered communication paradigm in an Ethernet flavor, which allows the use of standard Ethernet in safety-critical systems and systems with applications of mixed-criticality.

TTEthernet is the continued industry development of the academic TT-Ethernet research [KAGS05], conducted within a joint research project\* between the Vienna University of Technology and TTTech Computertechnik AG. The main objective of the academic project has been the integration of time-triggered with event-triggered messages on a single physical Ethernet network: as event-triggered messages are not synchronized, they typically result in conflicts with time-triggered messages at the outgoing ports in a network switch. The solution proposed within the academic TT-Ethernet project has been a preemptive switch. This TT-Ethernet switch [Ste06] identifies the reception of a time-triggered message based on an identifier within the message and preempts all event-triggered messages under transmission to free the outgoing ports for the time-triggered message. The merit of this solution is two-fold: first, the switch latency for time-triggered messages is constant with negligible error and, second, the switch can be kept almost free from additional configuration data.

The academic TT-Ethernet research has been continued within a joint industrial development between TTTech and Honeywell. Here, the objectives have been extended toward scalable fault tolerance and a finer

---

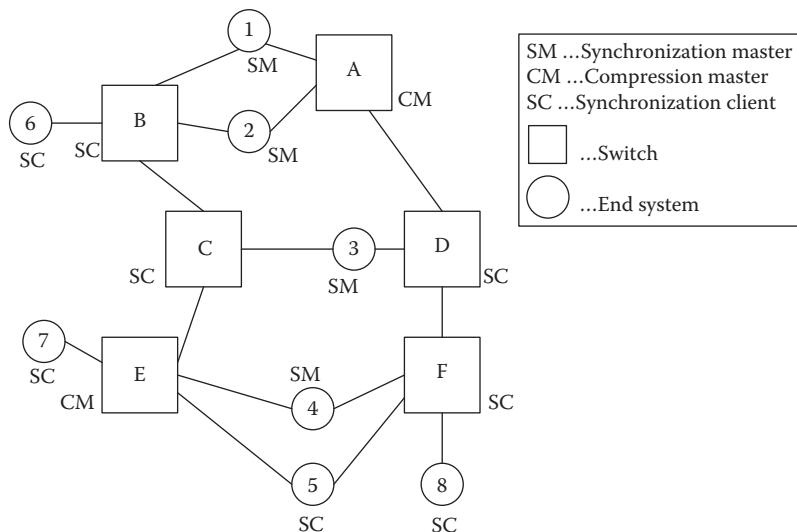

\* The FIT-IT project TT-Ethernet has been funded by the Austrian ministry for transport, innovation, and technology (BM-VIT) under contract No 808197.

classification of event-triggered messages into rate-constrained and best-effort traffic classes. The main driver for these additional objectives has been a shift in the target application domain toward safety-critical applications, in particular civil aerospace. Fault tolerance is a standard requirement in these applications and the rate-constrained traffic class has been intended as a compatible communication mode to ARINC 664 part 7, which specifies an unsynchronized real-time Ethernet variant for airborne applications. Another key differentiator to the academic version is a nonpreemptive integration mode of event-triggered and time-triggered messages to minimize the number of damaged Ethernet frames on the network, thereby easing diagnosis.

More recently, TTEthernet has been extended toward compatibility with the AVB (audio/video bridging) standard and TSN (time-sensitive networks) prestandard, which are the IEEE 802.1 real-time and robustness evolutions of switched networks, and in particular Ethernet, (see chapter “IEEE 802.1 Audio/Video Bridging and Time-Sensitive Networking” for more details on AVB and TSN). Analogously to ARINC 664 part 7, AVB traffic is available in TTEthernet as a particular flavor of rate-constraint traffic. TSN is currently standardizing a simple form of time-triggered communication (IEEE 802.1Qbv) and upcoming TTEthernet products will also support this TSN version of time-triggered communication. These industrial developments have led to Time-Triggered Ethernet in its current form, which is called TTEthernet and will be discussed in more detail in this chapter.

TTEthernet is intended as cross-industry communication infrastructure: originally designed according to aerospace standards, it is scalable in several directions. As different industrial areas define and use different variants of real-time Ethernet already, the nature of the TTEthernet technology is one of a set of services added to existing standards rather than their replacement. The TTEthernet services have been standardized by the SAE and the SAE AS6802 standard has been published by the SAE in November 2011.

A TTEthernet network consists of end systems and switches and bidirectional communication links to connect these devices to each other. Furthermore, an end system and a switch may be integrated into a single device. Figure 42.1 depicts an example TTEthernet network consisting of eight end systems (1.8) and two redundant communication channels. Channels 1 and 2 consist of the three switches each (channel 1: B,C,E; channel 2: A,D,F). Current TTEthernet implementations allow up to three channels and channels are not required to have the same number of switches each.

**FIGURE 42.1** Example TTEthernet network consisting of two channels each consisting of three switches and eight end systems.

## 42.2 TTEthernet Traffic Classes and Traffic Integration

TTEthernet is fully compliant with the Ethernet frame format as standardized in IEEE 802.3. An overview of the fields in an Ethernet frame is given in Figure 42.2: the first row lists the number of bytes for a given field, the second row the field's name.

An Ethernet frame starts with a preamble of seven octets followed by a start of frame delimiter (SOF) of one octet. For addressing of the frame, Ethernet specifies the destination address and the source address, each six octets long. Following the address fields, Ethernet IEEE 802.3 specifies two octets that are either used as a type (EtherType) or as a length field. By convention, a value from 64 to 1522 (decimal) of this field indicates its usage as length field, a value of 1536 (decimal) and higher means that the field is used to reflect an EtherType. An example EtherType is 0x0800, which defines the Ethernet frame to carry an Internet Protocol (IPv4) packet. The address fields together with the EtherType/Length field are commonly referred to as the MAC Header. The actual payload of an Ethernet frame has a size of 46–1500 octets. Ethernet specifies a 32-bit CRC called the frame check sequence (FCS), which follows the payload field. The minimum interframe gap (IFG) is 12 octets. As a result, the overall length of an Ethernet frame, as a sum of the fields discussed earlier, is between 84 and 1538 octets.

TTEthernet defines the term *traffic class* to differentiate communication modes. The prime communication mode of TTEthernet is, of course, the time-triggered traffic class (TT). Besides this mandatory traffic class, TTEthernet also supports the optional rate-constrained traffic class (RC) and the optional best-effort traffic class (BE). TTEthernet is an integrative communication protocol capable of communicating frames of these three traffic classes on the same physical network. In the following, we describe the traffic classes in more detail and use Figure 42.3 as running example, in which end systems 1 and 2

7B	1B	6B	6B	4B	2B	42B–1500B	4B	12B

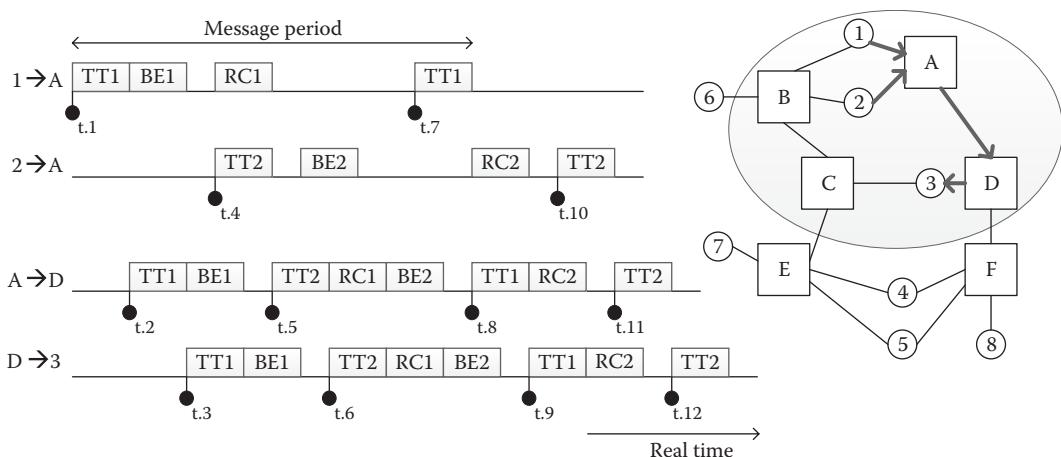

FIGURE 42.3 Example communication scenario in a TTEthernet network using all three traffic classes.

send TT, RC, and BE frames to end system 3 using switches A and D. The TT and RC traffic class also support multicast communication (not depicted).

### 42.2.1 Description of the Traffic Classes

A TTEthernet end system implements services to synchronize its local clock with the local clocks of other end systems and switches in the system. The end system can then send messages at off-line planned (or online assigned) points in this synchronized global time. These messages are said to be time-triggered. In the example of Figure 42.3, end systems 1 and 2 send TT messages. The points in time of the transmission and forwarding of the TT frames from end systems 1 and 2 to the switch A, from switch A to switch D, and from switch D to end system 3 are depicted by black circles labeled from t.1 to t.12. These points in time are the output of a configuration tool, the (off-line or online) scheduler, which will take care of arranging the TT frames in such a way that they will never be ready for transmission on the same outgoing port of a switch or end system at the same point in time. In this example, end system 1 and end system 2 send one TT message each (TT1 and TT2) with the same message period. However, other than in previous time-triggered communication protocols this is not a requirement in TTEthernet: indeed different TT messages may have different transmission periods.

Time-triggered (TT) messages are used when tight latency, jitter, and determinism are required. All TT messages are sent at predefined times. In cases where an end system decides not to use one of its assigned timed slots, for example, if there are no new data to be sent, the switch recognizes the inactivity of the sender and frees the bandwidth for the other traffic classes. TT messages are optimally suited for communication in distributed real-time systems with regular communication pattern.

Rate-constrained (RC) messages realize a communication paradigm that aims at establishing well-shaped dataflows: successive messages belonging to the same rate-constrained dataflow are guaranteed to be offset by a minimum duration as configured. RC messages are used when determinism and real-time requirements are less strict than provided by time-triggered communication. For RC messages, sufficient bandwidth must be allocated such that delays and temporal deviations have defined limits. In contrast to TT messages, RC messages are not sent with respect to a system-wide synchronized time base. Hence, different communication controllers may send RC messages at the same point in time to the same receiver. Consequently, the RC messages may queue up in the network switches, leading to increased transmission jitter and requiring increased buffer space. As the transmission rate of the RC messages is bound a priori and controlled in the network switches, an upper bound on the transmission latency can be calculated off-line and message loss is avoided. The rate-constrained communication paradigm is used in ARINC 664 part 7 and in similar form in IEEE 802.1 AVB. In the example of Figure 42.3, end systems 1 and 2 send an RC message each (RC1 and RC2). The end systems and switches will transmit and, respectively, forward the RC messages when no TT messages need to be communicated.

Best-Effort (BE) messages implement the classic switched Ethernet approach. There is no guarantee whether or when these messages can be transmitted, what delays occur, and if BE messages arrive at the recipient at all. BE messages use the remaining bandwidth of the network and have lower priority than TT and RC messages. However, BE traffic may be attractive, for example, during maintenance and configuration phases: as during such phases no critical traffic in form of TT or RC may be present, the whole network bandwidth is available for BE traffic without explicitly changing the network mode: RC messages will not be sent and bandwidth reserved for TT messages is automatically reclaimed by the switches. In the example of Figure 42.3, end systems 1 and 2 also send a BE message each (BE1 and BE2). As BE messages have lowest priority, they are communicated once; no TT and no RC message need to be transmitted.

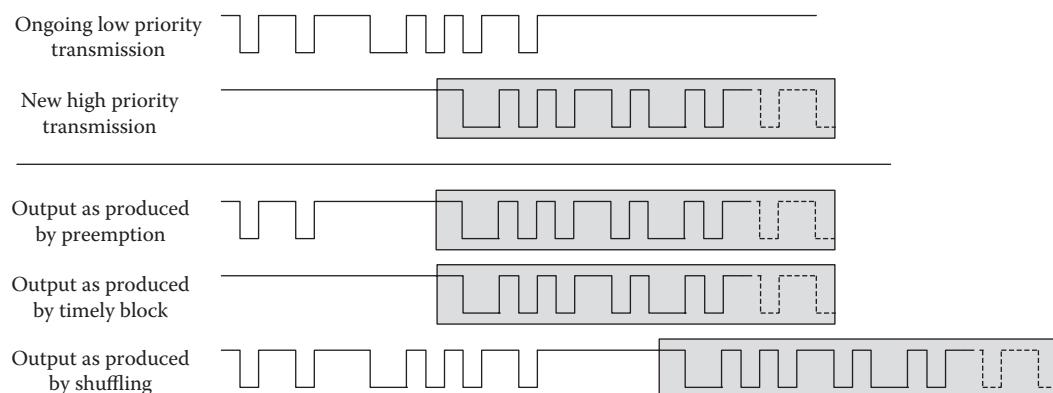

The scheduling of TT messages is often perceived as a complex problem. However, recent studies show that even general purpose tools like SMT-solvers can be used out-of-the-box to schedule a network with

about 100 frames. Furthermore, a bit more customized usage of the SMT-solver shows that networks up to 1000 messages can be configured within about half an hour [Ste10]. Other studies show that general purpose model checkers can be used to configure time-triggered systems [VSE09]. Commercial scheduling tools can schedule even bigger networks. The integration of TT messages with RC and BE messages has been studied, for example, in [Ste11, TSPS12].

## 42.2.2 Integration of the Traffic Classes

While the scheduler guarantees that TT frames are sufficiently scheduled apart from each other, such that no two TT frames will be ready for transmission on the same outgoing port of a switch (or end system), this cannot be guaranteed for mixed TT and RC/BE traffic. For example, in the communication scenario in Figure 42.3, the TT2 frame from end system 2 and the RC1 frame from end system 1 are transmitted from the end systems to switch A in a way such that the two frames become ready for relay by switch A at about the same point in time. For this case, TTEthernet, according the SAE AS6802 standard, defines a priority scheme that recommends using priorities in the following decreasing order: protocol control frames used for synchronization (see next section), TT, RC, BE. Each traffic class may define several priorities. When messages with equal priority become ready for transmit, these messages will be served in FIFO. When a high-priority message (**H**) is being served and a low-priority message (**L**) becomes ready, **L** will be queued. The third case, though, is of particular interest: there are three integration methods to resolve conflicts when a low-priority (**L**) message is already in transmission and a new high-priority (**H**) message becomes ready for transmission [SBH<sup>09</sup>]. Such a scenario can occur if end system 1 sends RC1 a tick earlier than depicted in Figure 42.3, and RC1 becomes ready for forwarding in switch A before TT2. In general, the three traffic integration methods for such scenarios are preemption, timely block, and shuffling, and are depicted in Figure 42.4.

Using the preemption method, a switch would stop the ongoing transmission of a low-priority frame and intersperse the high-priority frame. Timely block takes advantage of the planned nature of the TT frames: the switch will know by configuration when to expect TT frames and will not start the transmission of any other traffic before either the expected TT frame has been serviced or the switch can be sure that the TT frame will not arrive (in which case the bandwidth is free for other communication). The last method is called shuffling and simply means that high-priority frames will be in queue and transmitted only after the ongoing transmission of the lower-priority frame has concluded. Current TTEthernet implementations support the timely block and the shuffling integration method, while the early academic TT-Ethernet versions have implemented preemption. Preemption has not been implemented in current TTEthernet implementations for several reasons, for example, preemption systematically generates incorrect Ethernet frames, which makes system health diagnosis difficult.

**FIGURE 42.4** Integration methods for high-priority and low-priority traffic.

## 42.3 TTEthernet Synchronization Protocols

---

TTEthernet specifies and standardizes in SAE AS6802 several synchronization protocols that ensure close synchronization of the local clocks in the end systems and switches during all modes of operation of the network. These protocols have been designed to tolerate the failure of end systems and/or switches in the network. In particular, end systems are allowed to fail either arbitrarily (i.e., faulty end systems may generate sequences of arbitrary messages) or according to an inconsistent-omission failure mode (i.e., may drop messages and/or fail to transmit messages). Switches are always considered to fail according to an inconsistent-omission failure mode. If necessary, the inconsistent-omission failure mode can be guaranteed by dedicated structural design measures such as a self-checking pair design. We give an overview of these protocols in this section.

For all synchronization protocols, the TTEthernet protocol defines three different roles for synchronization: the *Synchronization Master* (SM), the *Synchronization Client* (SC), and the *Compression Master* (CM). The SM role is typically assigned to end systems, while switches act as CMs. As a minimum, one switch per channel is configured as CM. Both, switches and end systems, can be configured as SCs. In the example network in Figure 42.1, the end systems 1, 2, 3, and 4 are configured to be SM, while switches A and E act as CM, and all other devices operate as SC.

Synchronization demands the exchange of information between the devices. In the case of TTEthernet, this information is transported in standard Ethernet frames that are called protocol control frames (PCFs).

### 42.3.1 Start-Up and Integration

After initial power-on of the network, the start-up protocol ensures that the end systems and switches will synchronize their local clocks within a bounded duration. More precisely, during start-up typically two protocols are executed, the coldstart protocol and the integration protocol.

Coldstart is the actual protocol that establishes synchronized time. However, typically a newly powered-on end system or switch will not know initially, if the system as a whole is currently in start-up mode or already synchronized, and consequently will assume that a subsystem of the system is already synchronized. The component will, thus, aim to synchronize toward these subsystems. Hence, it will try to integrate into an operational synchronized time base. Only if this integration is not successful, then the component will assume that there does not exist an already synchronized subsystem and will undergo the coldstart protocol.

The TTEthernet start-up protocol is only executed between the SMs and the CMs. SCs will synchronize only after a synchronized time base has been established. The start-up protocol involves the exchange of a sequence of PCFs, in particular coldstart and coldstart acknowledgment messages.

Although the start-up protocol is rather small, its real-time behavior, the nature of distributed algorithms, and the behavior of faulty switches and/or end systems make the analysis of protocols like these rather complex. Therefore, model-checking techniques similar to [SRSP04] have been used during the development of the TTEthernet start-up protocol [Ste09].

### 42.3.2 Clock Synchronization

Once the start-up protocol has initially established the synchronized time base, the clock synchronization protocol is periodically executed to resynchronize the local clocks in the end systems and switches.

The TTEthernet clock synchronization algorithm operates in two steps. In the first step, all SMs concurrently send PCFs to all CMs at their same local time. As the local times of the SMs will be slightly different, for example, due to the drift of the local oscillators, the CMs will receive the PCFs also at slightly different points in time. The CMs will record these deviations and use them to calculate a new point in time at which the CMs will send a PCF (called the *compressed PCF*) back to the SMs and CMs.

The calculation follows a fault-tolerant midpoint selection, which guarantees that the impact of messages from faulty SMs will have only limited impact on the point in time when the CMs send their compressed PCFs. In the second step, all the SMs and SCs use the reception times of the compressed PCFs from the CMs to derive a new reference point in time for synchronization.

Note that in the preceding discussion, we ignored the transmission jitter that may occur at the network, in particular as synchronized messages are integrated with unsynchronized messages. TTEthernet uses the *permanence function* that allows us to do so. The permanence function is a simple means to translate transmission jitter almost entirely into latency. Hence, for the clock synchronization protocol and the TTEthernet synchronization protocols in general we can assume that the communication of PCFs between SMs, SCs, and CMs will be almost constant with known small jitter.

Again, formal methods have been used during the design of the clock synchronization protocol [SD11] as well as to demonstrate the correctness of the permanence function [SD10].

### 42.3.3 Clique Detection and Restart

The synchronized time base is essential to communicate the TT messages in TTEthernet, while the network is always able to communicate RC and BE messages, whether the components are synchronized or not. However, as the TT messages are likely to be critical messages in a given system TTEthernet incorporates synchronization protocols also for extremely unlikely situations such as system-wide communication blackouts and recovery when one or many components have lost synchronization.

The protocols that detect failures in the synchronization are commonly referred to as clique detection algorithms. TTEthernet implements three clique detection algorithms: the synchronous clique detection algorithm, the asynchronous clique detection algorithm, and the relative clique detection algorithm. Using the synchronous algorithm, a component will continually check as to how many SMs are currently synchronized and will report a clique if this number falls below a configured threshold. Analogously, using the asynchronous algorithm, a component will continually check if there are components in the system it is not synchronized to and will count how many such components there are. When the number of these components grows beyond a given threshold, then, again, a clique will be reported. The relative algorithm uses the information gathered in both, the synchronous and the asynchronous algorithms, and reports a clique if the number of SMs the component is synchronized to falls below the asynchronous components it monitored.

When a component detects a clique, it will restart or reintegrate. The interplay of the clique detection algorithms with the start-up, restart, and reintegration has been studied with model-checking techniques [Ste09].

## 42.4 TTEthernet Example Configurations and Implementations

---

TTEthernet has been designed as cross-industry communication infrastructure supporting the implementation of low-cost fieldbus-like networks up to ultrahighly dependable systems. In this section, we discuss two particular configurations of TTEthernet representing the extremes of the possible configuration space: a master-based configuration and a dual-fault-tolerant configuration. Furthermore, we present a system-of-systems configuration.

Current TTEthernet implementations are available in FPGA and in software. We will summarize their key characteristics in this chapter. ASIC implementations of TTEthernet will be developed as well.

### 42.4.1 Configurations

TTEthernet network configurations may differ with respect to the number of end systems and the number of switches, as well as their connecting topology. In particular for the synchronization algorithms, configurations are determined by the assignment of synchronization roles to TTEthernet devices. As a reminder, we have introduced three roles in the synchronization algorithms of TTEthernet: the synchronization master (SM), the compression master (CM), and the synchronization client (SC). We will discuss

different configurations with regard to these aspects. More general characteristics of time-triggered networks include the quality of oscillators used in the TTEthernet devices, the wire speed and associated physical layer, the communication interface, and the activated fault-containment measures.

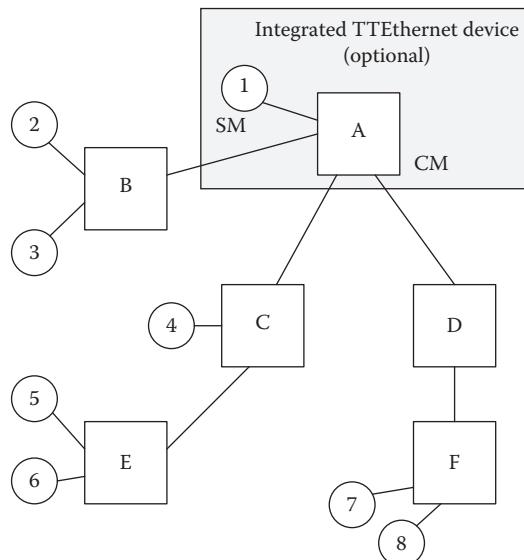

#### 42.4.1.1 Master-Based Configuration

The most basic TTEthernet configuration consists of an SM and a CM, where both synchronization roles may be integrated into a single device. From this configuration, classic single-master multiple-slave networks as depicted in Figure 42.5 can be built. This example network consists of one SM, one switch configured as CM and six SCs (two switches and four end systems). End systems and switches are connected in a tree topology and there is no redundant channel present.

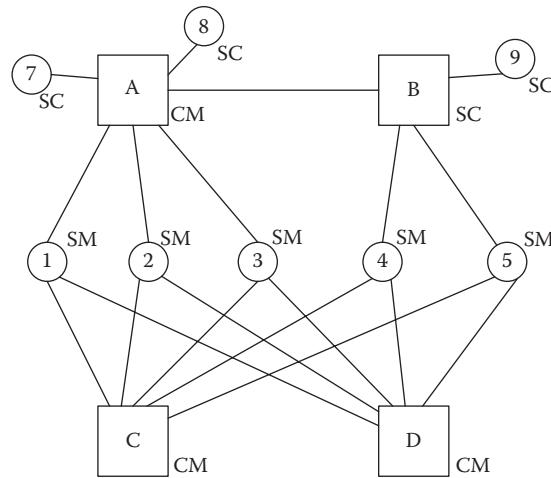

End system 1 acts as SM and sources PCFs that are relayed by switch A, which acts as CM. As there is only one SM, a compressed PCF generated by switch A will essentially carry the same information as the frame before compression. Hence, a simplified device (integrating SM and CM) that sources PCFs with a fixed period of the integration cycle is sufficient as steady synchronization source for the SCs in the network.

This single-master configuration is attractive for low-cost applications with a requirement of quality-of-service such as real-time performance. This configuration can be enhanced by safety mechanisms like the activation of the central guardian function in the switches or by the high-integrity design of key devices. Hence, given that the appropriate fault-isolation measures are in place, even this basic configuration is appropriate for fail-safe applications (applications that can enter a safe state upon failure in which no protocol operation is required).

Availability, on the other hand, is limited: the failure of an arbitrary number of SCs will not affect the services as provided by TTEthernet. However, as in all single-master-based systems, the loss of the SM or CM means a loss of the synchronization source and so of the TTEthernet protocol services. Availability requires the implementation of a sufficient degree of redundancy. The RC and BE traffic classes are not affected by the failure of the SM and/or CM as they do not require a synchronized time

**FIGURE 42.5** Master-based configuration with three switches connected in multihop topology.

**FIGURE 42.6** Dual-fault-tolerant configuration with three redundant channels and five synchronization masters.

base to be operational. Hence, RC and BE traffic can always be communicated as long as there exists a nonfaulty communication path between sender and receiver(s). We discuss a highly dependable and highly available configuration next.

#### 42.4.1.2 Dual-Fault-Tolerant Configuration

Highly dependable systems such as civil airplanes or manned space crafts are fail-operational systems. These systems have to remain operational even in the presence of failures. Figure 42.6 shows a redundant TTEthernet network that tolerates two faulty devices without degradation of the TTEthernet services. The network consists of three redundant channels and nine end systems. Two channels are formed by a single switch configured as CM and a third channel is formed by two switches, one of which acts as CM. End systems 1–5 operate as SMs. Furthermore, the SMs and CMs have to be high-integrity devices supporting an inconsistent-omission failure mode. In this configuration, the failure of any two devices is masked by the TTEthernet services without quality degradation.

#### 42.4.1.3 System-of-Systems Configuration

TTEthernet also provides a priority-based mechanism to realize system-of-systems architectures.

Figure 42.7 shows a network architecture consisting of two TTEthernet subnetworks, a high-priority subnetwork and a low-priority subnetwork. The priority of the respective network is stored in the configuration data of each TTEthernet device as well as in the Sync\_Priority field in the PCFs. A TTEthernet end system can be configured to automatically synchronize to the highest priority PCF it receives. Alternatively, the change of a TTEthernet current priority to a higher priority can demand host interaction.

This priority mechanism supports the full operation of parts of the network, for example, to realize power-down modes. In the example in Figure 42.7, either one of the subnetworks can be shut down. Once it is powered on again, both subnetworks synchronize either automatically or upon host acknowledgment.

#### 42.4.2 Implementations

TTEthernet specifies a set of services that can be implemented on top of standard Ethernet. End systems realize these services either in the form of a software stack on top of commercial-off-the-shelf (COTS) controllers or in the form of dedicated FPGA solutions. Currently, TTEthernet switches are implemented in FPGA. Furthermore, ASICs for TTEthernet end systems and TTEthernet switches are being developed at the time of this writing.

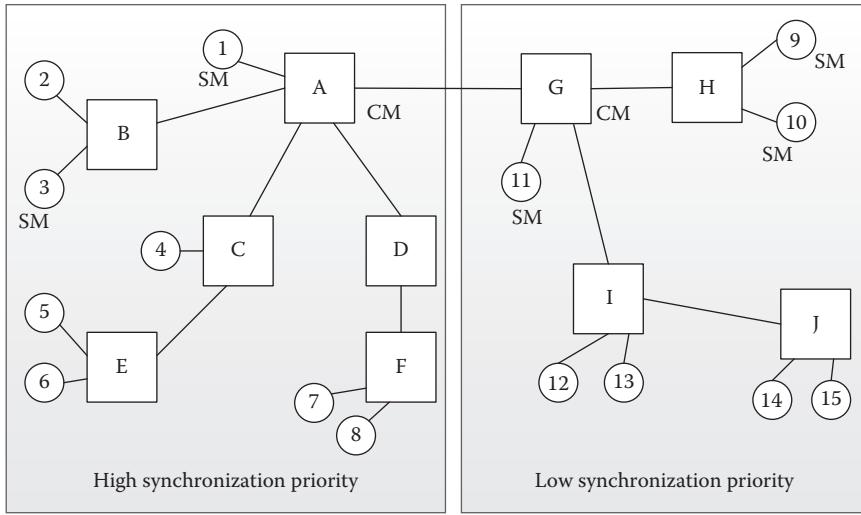

FIGURE 42.7 TTEthernet systems-of-systems configuration consisting of two subnetworks.

The FPGA-based solutions of TTEthernet mainly differ with respect to the communication speed they support. The 100 Mb/s FPGA-based version of the TTEthernet switch is specified as follows:

- Eight 100 Mb/s and one 1 Gb/s uplink port.
- Guaranteed real-time delivery and clock synchronization in the microseconds range.
- Legacy Ethernet devices can synchronize to network time base without knowing about TTEthernet
- Support for legacy and best-effort traffic.
- Standard TCP/IP protocols and applications can be used.
- Flexibility for customer-specific extensions (ALTERA Cyclone III FPGA).
- Digital I/O for triggering measurements.
- Dimensions:  $170 \times 121 \times 55$  mm; weight: 800 g; operating temperature: 0°C–70°C; storage: –40°C to +85°C.
- Robust housing.

The 1 Gb/s version of TTEthernet switch has the following characteristics:

- Four 1 Gb/s copper/fiber ports
- Message schedules and routing information stored in internal ROM (loaded by TTE-Load download tool)
- Hardware-based on Altera COTS board and PHY daughter board
- 8 Gb/s full-duplex bandwidth
- Multihop capable
- Single synchronization domain

Also, 12-port and 24-port TTEthernet switches are available. Some TTEthernet switch variants are depicted in Figure 42.8. The TTEthernet switches allow communication of all traffic classes at line-rate communication speeds.

TTEthernet end systems have been realized in FPGA and as a software stack. The FPGA solutions come in different form factors and are depicted in Figure 42.9.

The software stack realizing the TTEthernet services is depicted in Figure 42.10. This stack is designed for a 100 Mb/s software-based TTEthernet end system running a single TTEthernet channel. COTS Ethernet Controllers can be used. In an example setup on an Intel ATOM running at 1.6 GHz with 1 GB of RAM and 0.5 MB cache, the stack was implemented on Standard Linux.

FIGURE 42.8 TTEthernet switches.

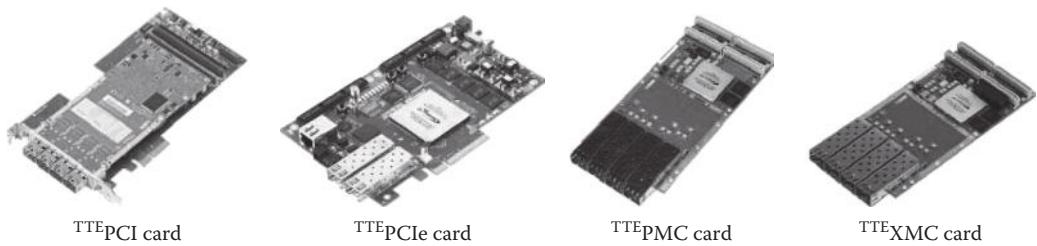

FIGURE 42.9 TTEthernet FPGA-based end systems in different form factors.

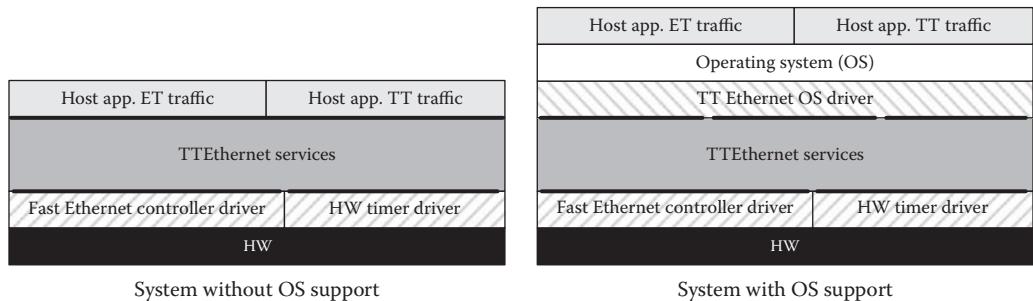

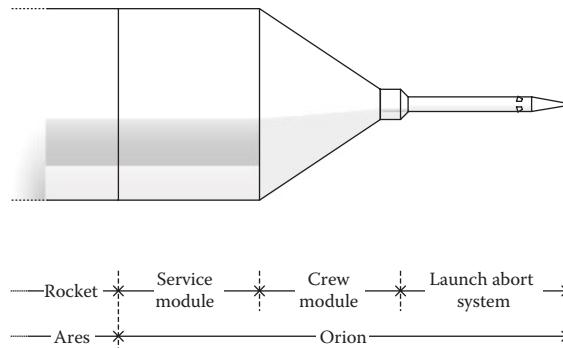

FIGURE 42.10 TTEthernet software stack with and without operating system support.

Using a cluster cycle of 3 ms and communicating 10 time-triggered messages (1500 bytes each), a total network load of 40 Mb/s has been generated. In this configuration, the software stack used about 3% of the ATOM CPU.

Given the cross-industry applicability of TTEthernet, it is currently used from space to new energy applications and is also evaluated for a broad range of use cases including automotive applications. One particular use case is the use of TTEthernet in the Orion space system, which is discussed in the next section.

## 42.5 TTEthernet in Orion

In the United States under President G.W. Bush, Orion has been planned and started to be developed under the leadership of NASA as the next-generation Crew Exploration Vehicle (CEV) replacing the Space Shuttle. Orion is part of the NASA Constellation program, which comprises several projects, among others the Ares programs, which are the rockets for lifting Orion and other space vehicles into

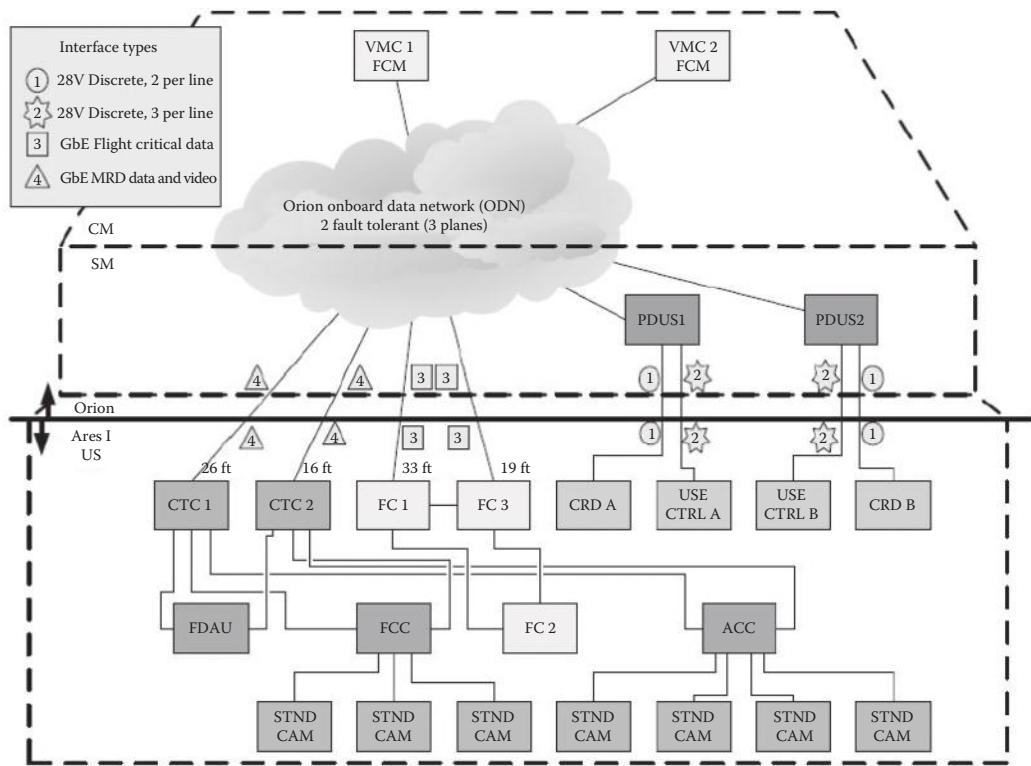

**FIGURE 42.11** Sketch of Orion (not to scale).

low earth orbit to go, for example, to the international space station, to our moon, and to Mars—at least this has been the plan. The Orion vehicle consists of two parts, the crew module (CM) and the service module (SM). The crew module provides all the facilities for housing up to six astronauts for about 2 weeks to lower earth orbit in initial configurations and up to 6 months for going to the moon. The crew module is also used for reentry into earth atmosphere to bring the crew back to earth. The service module provides the necessary supplementary equipment for the crew to live in space and is jettisoned before reentry. The concept of operation of the constellation program for space exploration is very similar to the Apollo program. Figure 42.11 sketches the structure of the Orion and Ares I as docked vehicles for the reader to get an idea of the configuration. At the time of writing this text, the future of the Constellation program is slightly rearranged and its development has been slightly changed by the US administration under President Barack Obama. As part of this, Orion is now referred to as Orion Multipurpose Crew Vehicle. However, the basic technical architecture of Orion with TTEthernet remains the same.

Both Ares I and Orion comprise separate avionics architectures due to operational constraints and control aspects. Orion deploys an integrated modular avionics (IMA) architecture approach as this allows an open architecture, a key characteristic to NASA. With an open architecture, the system is easier to integrate and maintain. For example, the central processing unit is standardized, allowing the use of COTS hardware without any single supplier constraint and, hence, reduction of nonrecurring cost for components within the system. Similarly, the use of COTS will decrease the upgrade cost since competition drives supplier upgrades to low or no cost to the project. Additionally, maintenance costs are reduced, since the COTS producers can leverage the development and maintenance tools already available. NASA's systems, such as the human-rated Orion, tend to be deployed for long durations. The space shuttle, for example, has been operational for about 30 years. An IMA architecture used in such systems benefits in more easily supporting midlife upgrades to the system, hence incorporating midlife technology upgrades into the system. Furthermore, with varying mission durations, it is also important that the avionics architecture allows for different safety and criticality protections. IMA architectures support this flexibility [MBV09]. Figure 42.12 shows the Orion/Ares interface and some avionics architecture aspects of Orion and Ares.

Orion has very specific mission requirements. It has to meet a mission requirement of up to 5000 h (about 200 days) of continuous operation at a time. It must be a flexible vehicle that will interface to several other space elements (the International Space Station, the Altair Lunar Lander, Ground Systems, and the Space Network, in addition to the Ares I interface) over the next several decades. Additionally, Orion has strict weight and power restrictions that make it desirable for its avionics system to maintain full protection against erroneous behavior even when operated in a low-power partial system mode, which is a mode when part of the avionics system is shut off to conserve power [MBV09].

**FIGURE 42.12** Orion and Ares I interface. (From McCabe, M. et al., Avionics architecture interface considerations between constellation vehicles, *Proceedings of the 28th Digital Avionics Systems Conference (DASC)*, IEEE/AIAA, pp. 1.E.2-1–1.E.2-10, October 2009.)

Early trade studies that have been conducted favored an IMA approach due to the Orion's requirements [MBV09]:

- The Orion CEV shall meet an ascent reliability allocation of 0.9999.
- The Orion CEV shall meet an overall mission reliability allocation of 0.999.
- The Orion CEV shall be one-fault-tolerant for safe return of the crew with exceptions for design for minimum risk.
- The Orion CEV shall safely recover and return the crew in case of loss of output and erroneous output from the vehicle flight computers due to software common-cause failure.
- The Orion CEV shall allow the crew to manually control, inhibit, and/or override autonomous or ground-controlled critical functions.
- The Orion CEV shall be one-fault-tolerant for mission completion with exceptions for design for minimum risk.

In order to meet requirements like full error detection in low-power partial system mode, a simple high-integrity, self-checking computing approach has been designed building on implementations and knowledge from avionics programs of aircraft like the Boeing 787, Boeing 777, and Boeing 777RS. Figure 42.13 provides a detailed block diagram of a typical self-checking pair computer design, which in a similar manner is deployed on Orion. Orion actually does deploy an IBM PowerPC 750 processor as indicated in Figure 42.13, with self-checking support logic such as an interface to the bus and external memory (BIPM) and backend interfaces. Yet, the actual main interface is a variant of TTEthernet,

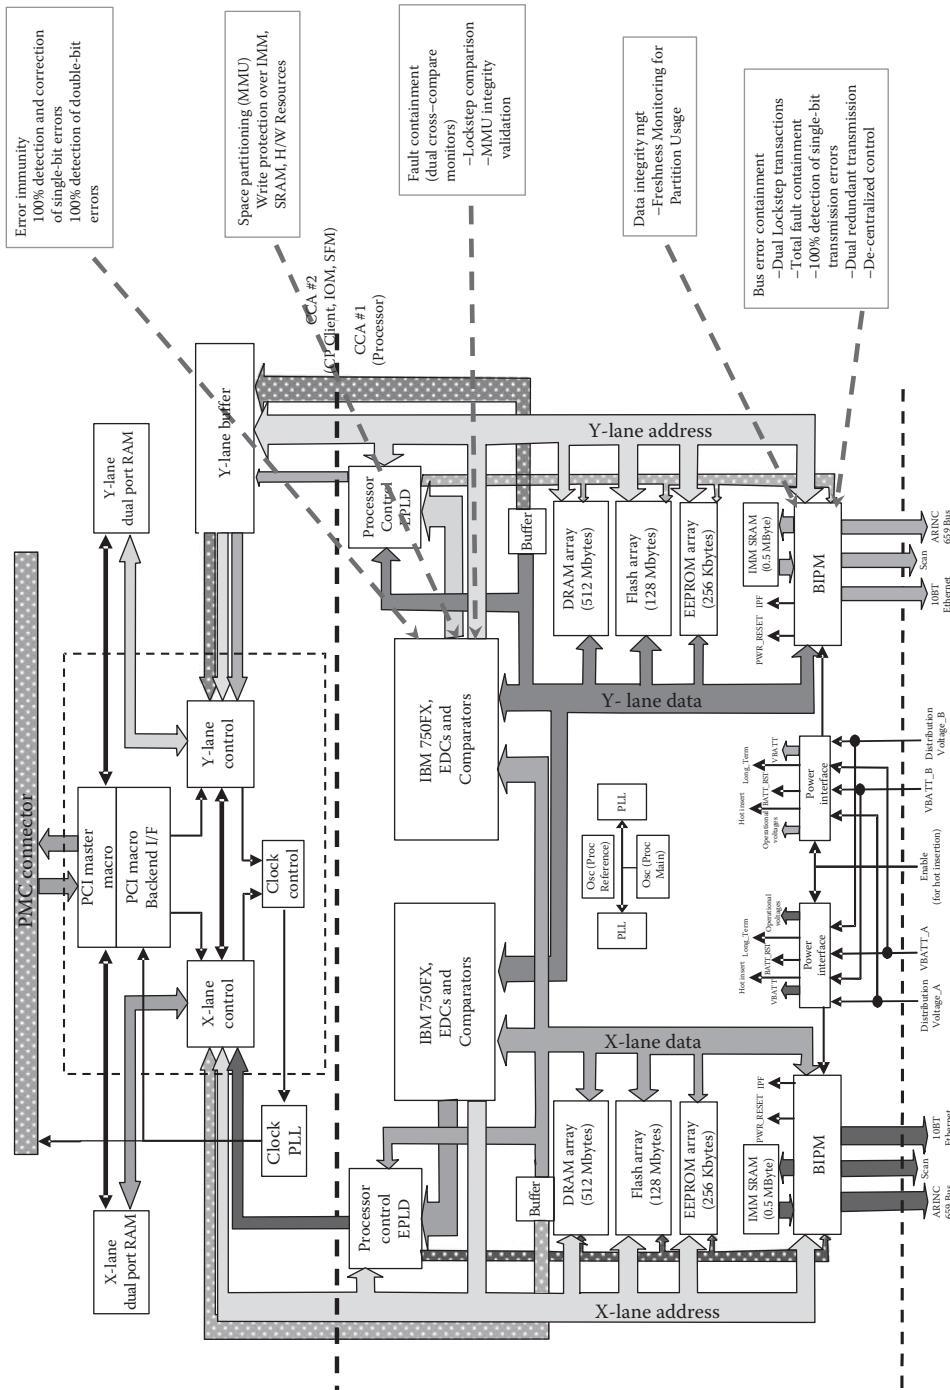

FIGURE 42.13 Self-checking pair computer. (From Fletcher, M., Progression of an open architecture: From Orion to Altair and I.S.S, Companion to report (Presentation) S65-50000-20-0, Honeywell, *FaultTolerant Spaceborne Computing Employing New Technologies 2009 Conference*, May 2009; Courtesy of Honeywell, Morristown, NJ.)

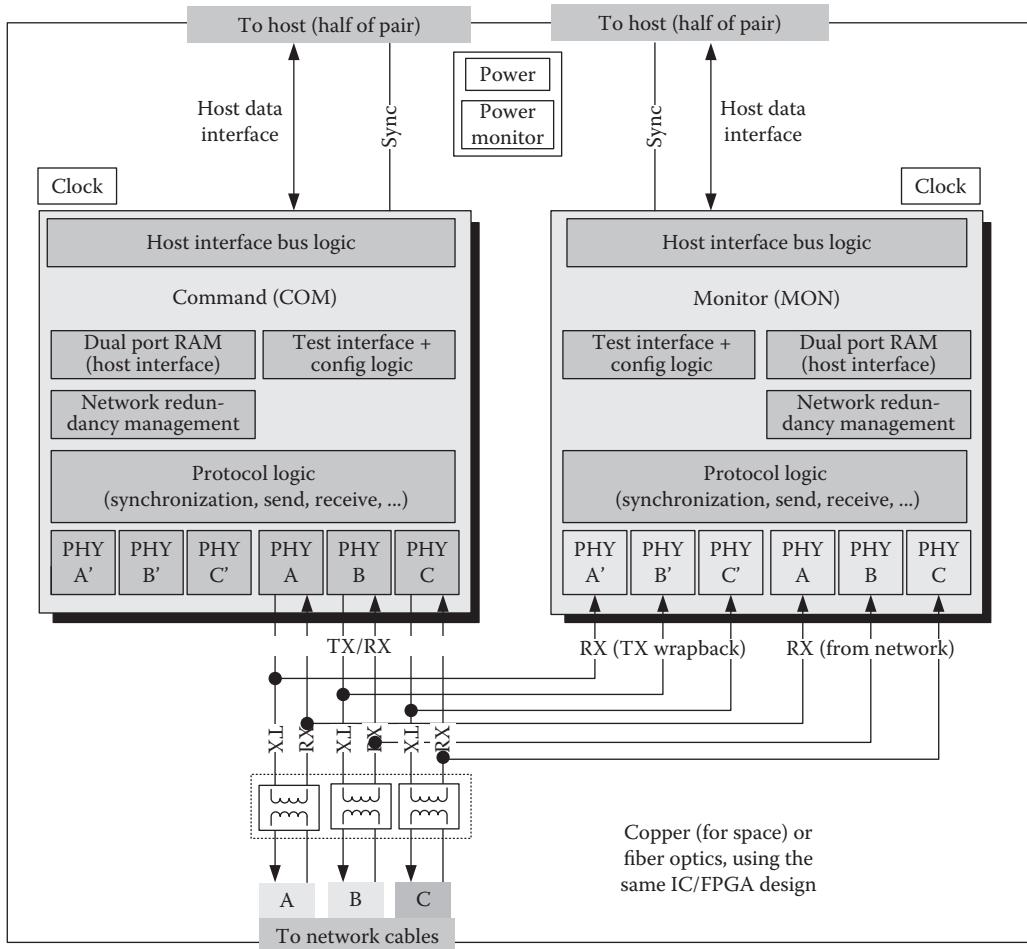

named TT-GbE, and not ARINC 659 as indicated in Figure 42.13. It shall also be noted that it is typical to perform local power and clock monitoring for a pair of processors. The presented and deployed architecture has the following advantages:

- Good error detection for bit flips in processors as well as in associated memories. In all cases, *no* inadvertent action is performed due to single event upsets with a very high probability (or in other words, the probability of undetected failures is smaller than  $10^{-9}$ ).
- No inadvertent violation of space partitioning (memory and I/O) due to features like memory management units (MMUs).

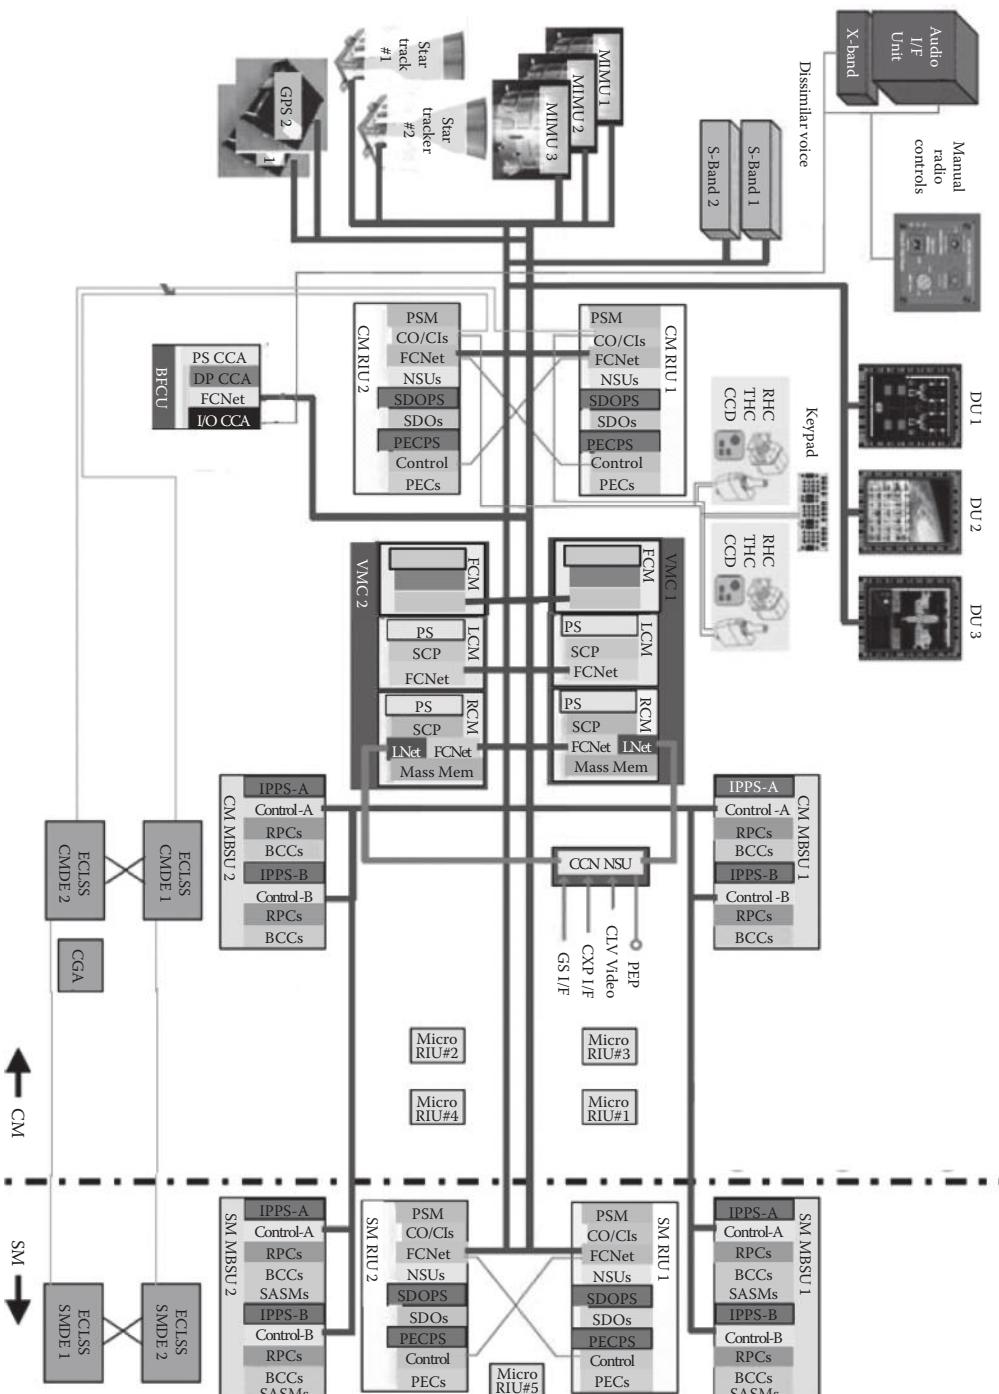

Cross-compare monitors perform constant comparison of computing outputs and validate MMU integrity.

- Data integrity management (freshness monitoring for partition usage).
- Support of bus error containment (more Orion details later).

The system network is an implementation variant of TTEthernet described. The Orion TTEthernet deployment is called *Time-Triggered Gigabit Ethernet* (or *TT-GbE*). As the name implies, it leverages a

**FIGURE 42.14** TTEthernet self-checking pair end system. (From Hall, B. and Driscoll, K., A new aerospace network family, *Presentation to INCOSE*, Honeywell, October 2009; Courtesy of Honeywell, Morristown, NJ.)

**FIGURE 42.15** Orion avionics overview. (From Fletcher, M., Progression of an open architecture: From Orion to Altair and LSS, Companion to report (Presentation) S65-5000-20-0, Honeywell, *FaultTolerant Spaceborne Computing Employing New Technologies 2009 Conference*, May 2009; Courtesy of Honeywell, Morristown, NJ.)

standard Gigabit Ethernet physical layer and the standard TTEthernet IP core including all features and support up to ISO/OSI layer 2 (i.e., not including layer 3 according to ISO/OSI). Given the harsh natural radiation environment in space, the TTEthernet IP is embedded in a space-hardened technology together with a special space-hardened SERDES (serializer/deserializer) physical layer technology, compatible with Ethernet, and other interfaces like PCI. TT-GbE supports normal and high-integrity end systems and high-integrity switches. The high-integrity variant is based on a command/monitor configuration. Figure 42.14 shows the command/monitor configuration for the TTEthernet network for an end system. It is deployed for the switches and some end systems (such as the ones interfacing to the self-checking computers) [HD09,Fle09,MBV09]. Such command/monitor component configurations ensure a validated fail-silence model in that all output of a component is checked bit-for-bit against independent monitor copy and any violation forces a consistently detectable fault output. The command/monitor end system and switch and self-checking compute components enable a reduction of end-to-end integrity augmentation normally deployed in high-integrity end systems. It also helps leaving the high dependability implementation aspects out of the application and at the electronic platform system level, which simplifies platform development.

Figure 42.15 presents a very high-level overview of the Orion avionics architecture at one time during the development. The platform was under development at the time publications [Fle09,MBV09] were written and has slightly changed in the meantime. Orion in general had to adapt to weight requirements due to Ares I rocket design. Adaptation of architectures to a certain extent is a typical system design refinement. On the left side of the dotted line of the diagram labeled CM is the equipment in the crew module. On the right side is the equipment in the SM of Orion. The crew module contains the majority of the different electronic units. The component-connecting lines in Figure 42.15 (in blue in the original publication) show the major onboard data network, which is implemented using TT-GbE and labeled by the FCNet interface cards. The architecture contains—in this instance—two major computer-related cabinets called VMCs (Vehicle Management Computers). VMCs contain three different computer modules (CMs labeled FCM, LCM, and RCM) with associated network cards and power supply modules. Remote Interface Units (RIUs) are cabinets with input/output interfacing cards. Orion has three display units (DUs) implementing modern glass cockpits, interface devices (keypad, RHC, THC, CCD), (external) communication means (e.g., audio I/F Unit, S-Band), absolute and relative navigation units (inertial measurement units (IMUs), star trackers, GPS), environmental control units (ECLSS), and multiple vehicle power management units (MBSUs) among others.

### 43.1 Introduction

---

MIL-STD-1553 is a standard that defines the electrical and protocol characteristics for a data bus. AS-15531 is the Society of Automotive Engineers (SAE) commercial equivalent to the military standard. A data bus is similar to what the personal computer and office automation industry have dubbed a *local area network* (LAN). In avionics, a data bus is used to provide a medium for the exchange of data and information among various systems and subsystems. MIL-STD-1553 has been deployed on fixed- and rotary-wing aircraft, unmanned aircraft, surface and subsurface ships, ground vehicles, spacecraft and satellites, and the International Space Station. It is undoubtedly the most successful military standard developed.

#### 43.1.1 Background

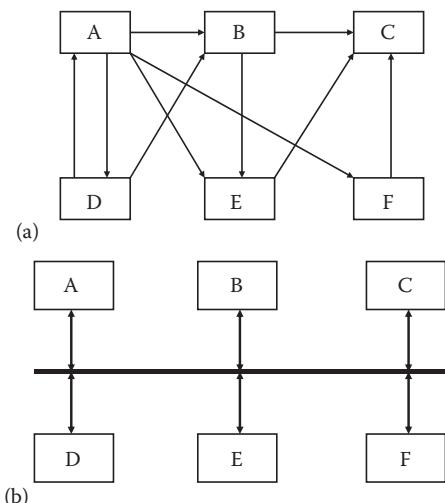

In the 1950s and 1960s, avionics were simple stand-alone systems. Navigation, communications, flight controls, and displays were analog systems. Often, these systems were composed of multiple boxes interconnected to form a single system. The interconnections between the various boxes were accomplished with point-to-point wiring. The signals mainly consisted of analog voltages, synchro-resolver signals, and relay/switch contacts. The location of these boxes within the aircraft was a function of operator need,

available space, and the aircraft weight and balance constraints. As more and more systems were added, the cockpits became crowded due to the number of controls and displays, and the overall weight of the aircraft increased.

By the late 1960s and early 1970s, it was necessary to share information between various systems to reduce the number of black boxes required by each system. A single sensor providing heading and rate information could provide those data to the navigation system, the weapons system, the flight control system, and pilot's display system (see Figure 43.1a). However, the avionics technology was still basically an analog, and while sharing sensors did produce a reduction in the overall number of black boxes, the interconnecting signals became a *rat's nest* of wires and connectors. Moreover, functions or systems that were added later became an integration nightmare as additional connections of a particular signal could have potential system impacts, plus since the system used point-to-point wiring, the system that was the source of the signal typically had to be modified to provide the additional hardware needed to output to the newly added subsystem. As such, intersystem connections were kept to the bare minimums.

By the late 1970s, with the advent of digital technology, digital computers had made their way into avionics systems and subsystems. They offered increased computational capability and easy growth, compared to their analog predecessors. However, the data signals—the inputs and outputs from the sending and receiving systems—were still mainly analog in nature, which led to the configuration of a small number of centralized computers being interfaced to the other systems and subsystems via complex and expensive analog-to-digital and digital-to-analog converters.

As time and technology progressed, the avionics systems became more digital. And with the advent of the microprocessor, things really took off. A benefit of this digital application was the reduction in the number of analog signals, and hence the need for their conversion. Greater sharing of information could be provided by transferring data between users in digital form. An additional side benefit was that digital data could be transferred bidirectionally, whereas analog data were transferred unidirectionally. Serial rather than parallel transmission of the data was used to reduce the number of interconnections within the aircraft and the receiver/driver circuitry required with the black boxes. But this alone was not enough. A data transmission medium that would allow all systems and subsystems to share a single and common set of wires was needed (see Figure 43.1b). By sharing the use of this interconnect, the various subsystems could send data among themselves and to other systems and subsystems, one at a time, and in a defined sequence using a methodology called *time-division multiplexing* (TDM). Enter the 1553 data bus.

**FIGURE 43.1** Systems configurations.

### 43.1.2 History and Applications

MIL-STD-1553 (USAF) was released in August of 1973. The first user of the standard was the F-16. Further changes and improvements were made and a tri-service version, MIL-STD-1553A, was released in 1975. The first user of the “A” version of the standard was again the Air Force’s F-16 and the Army’s new attack helicopter, the AH-64A Apache. With some *real-world* experience, it was soon realized that further definitions and additional capabilities were needed. The latest version of the standard, 1553B, was released in 1978.

Today, the 1553 standard is still at the “B” level; however, changes have still been made. In 1980, the Air Force introduced Notice 1. Intended only for Air Force applications, Notice 1 restricted the use of many of the options within the standard. While the Air Force felt this was needed to obtain a common set of avionics systems, many in industry felt that Notice 1 was too restrictive and limited the capabilities in the application of the standard. Released in 1986, the tri-service Notice 2 (which supersedes Notice 1) places tighter definitions upon the options within the standard. And while not restricting an option’s use, it tightly defines how an option will be used if implemented. Notice 2, in an effort to obtain a common set of operational characteristics, also places a minimum set of requirements upon the design of the black box. The military standard was converted to its commercial equivalent as SAE AS 15531, as part of the government’s effort to increase the use of commercial products.

Other notices have since been released. Notice 3 released in 1993 simply states that the standard has been reviewed and is still valid for use. Notice 4 released in 1996 changed the name of the document from a *military standard* to an *interface standard*. Notice 5 released in 2006 and Notice 6 released in 2007 were an effort by the Air Force to increase the data from 1 megabit per second (Mbps) up to 200 Mbps. This was to be accomplished to providing an additional orthogonal frequency division multiplex signal *on top of* the existing 1553 signal while utilizing the same cables and couplers. These notices and the addition of the higher rate signaling were not immediately accepted by the industry and the Air Force received lots of comments regarding the operation, use, and testing of this addition. Notice 7, released in 2008, cancelled Notices 5 and 6. So the last *meaningful* notice to 1553B is Notice 2. In addition, MIL-STD-1553B has been incorporated into other standards such as MIL-STD-1760 and STANAG 3910.

Since its inception, MIL-STD-1553 has found numerous applications. Notice 2 even removed all references to *aircraft* or *airborne* so as not to limit its applications. The standard has also been accepted and implemented by North Atlantic Treaty Organization (NATO) and many foreign governments. The United Kingdom has issued Def Stan 00-18 (Part 2) and NATO has published STANAG 3838 AVS, both of which are versions of MIL-STD-1553B.

## 43.2 The Standard

---

MIL-STD-1553B defines the term TDM as “the transmission of information from several signal sources through one communications system with different signal samples staggered in time to form a composite pulse train.” For our example in Figure 43.1b, this means that data can be transferred between multiple avionics units over a single transmission media, with the communications among the different avionics boxes taking place at different moments in time, hence time division. Table 43.1 is a summary of the 1553 data bus characteristics. However, before defining how the data are transferred, it is necessary to understand the data bus hardware.

### 43.2.1 Hardware Elements

The 1553 standard defines certain aspects regarding the design of the data bus system and the black boxes to which the data bus is connected. The standard defines four hardware elements: transmission media, remote terminals, bus controllers, and bus monitors, each of which is detailed as follows.

**TABLE 43.1** Summary of the 1553 Data Bus Characteristics

Data Rate	1 MHz
Word length	20 bits
Data bits per word	16 bits
Message length	Maximum of 32 DWs
Transmission technique	Half-duplex
Operation	Asynchronous
Encoding	Manchester II biphase
Protocol	Command response
Bus control	Single or multiple
Message formats	BC-RT RT-BC RT-RT Broadcast System control
Number of remote terminals	Maximum of 31
Terminal types	Remote terminal (RT) Bus controller (BC) Bus monitor (BM)
Transmission media	Twisted shielded pair cable
Coupling	Transformer or direct

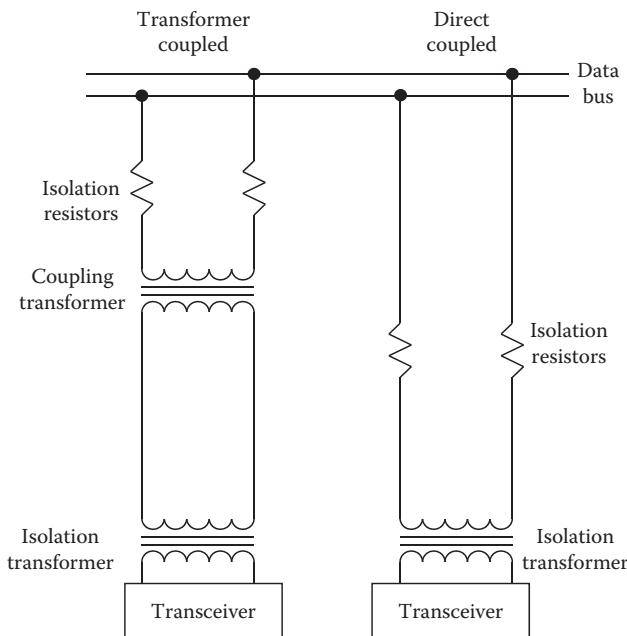

### 43.2.1.1 Transmission Media

The transmission media, or data bus, is defined as a twisted shielded pair transmission line consisting of the main bus and a number of stubs. There is one stub for each terminal (system) connected to the bus. The main data bus is terminated at each end with a resistance equal to the cable's characteristic impedance. This termination makes the data bus behave electrically like an infinite transmission line. Stubs, which are added to the main bus to connect the terminals, provide *local* loads and produce an impedance mismatch where added. This mismatch, if not properly controlled, produces electrical reflections and degrades the performance of the main bus. Therefore, the characteristics of both the main bus and the stubs are specified within the standard. Table 43.2 is a summary of the transmission media characteristics.

The standard specifies two stub methods: direct and transformer coupled. This refers to the method in which a terminal is connected to the main bus. Figure 43.2 shows the two methods, the primary difference between the two being that the transformer-coupled method utilizes an isolation transformer for connecting the stub cable to the main bus cable. In both methods, two isolation resistors are placed in series with the bus. In the direct-coupled method, the resistors are typically located within the

**TABLE 43.2** Summary of Transmission Media Characteristics

Cable Type	Twisted Shielded Pair
Capacitance	30.0 pF/ft max—wire to wire
Characteristic impedance	70.0–85.0 Ω at 1 MHz
Cable attenuation	1.5 dBm/100 ft at 1 MHz
Cable twists	4 twists per foot maximum
Shield coverage	90% minimum
Cable termination	Cable impedance (62%)
Direct-coupled stub length	Maximum of 1 ft
Transformer-coupled stub length	Maximum of 20 ft

**FIGURE 43.2** Terminal connection methods.

terminal, whereas in the transformer-coupled method, the resistors are typically located with the coupling transformer in boxes called data bus couplers. A variety of couplers are available, providing single or multiple stub connections. Bus couplers are available as either boxes using connectors or as *in-line* couplers wherein the stubs are spliced into the main bus cable.

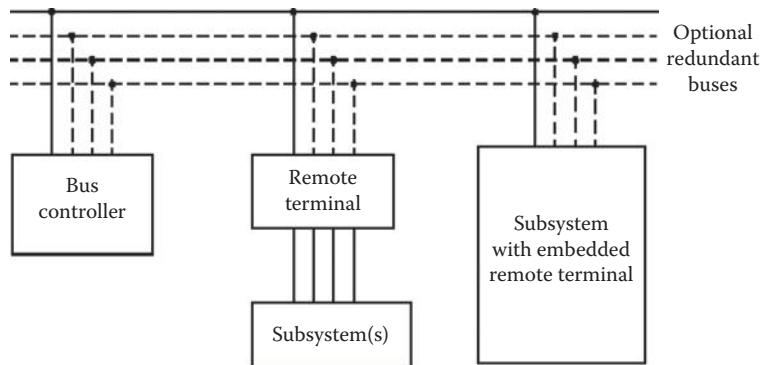

Another difference between the two coupling methods is the length of the stub. For the direct-coupled method, the stub length is limited to a maximum of 1 ft. For the transformer-coupled method, the stub can be up to a maximum length of 20 ft. Therefore, for direct-coupled systems, the data bus must be routed in close proximity to each of the terminals, whereas for a transformer-coupled system, the data bus may be up to 20 ft away from each terminal.

#### 43.2.1.2 Remote Terminal

A remote terminal is defined within the standard as “All terminals not operating as the bus controller or as a bus monitor.” Therefore if it is not a controller, monitor, or the main bus or stub, it must be a remote terminal—sort of a *catch all* clause. Basically, the remote terminal is the electronics necessary to transfer data between the data bus and the subsystem. So what is a subsystem? For 1553 applications, the subsystem is the sender or user of the data being transferred.

In the earlier days of 1553, remote terminals were used mainly to convert analog and discrete data to/from a data format compatible with the data bus. The subsystems were still the sensor that provided the data and computer that used the data. As more and more digital avionics became available, the trend became to embed the remote terminal into the sensor and computer. Today, it is common for the subsystem to contain an embedded remote terminal. Figure 43.3 shows the different levels of remote terminals possible.

A remote terminal typically consists of a transceiver, an encoder/decoder, a protocol controller, a buffer or memory, and a subsystem interface. In a modern black box containing a computer or processor, the subsystem interface may consist of the buffers and logic necessary to interface to the computer’s address, data, and control buses. For dual redundant systems, two transceivers and two encoders/decoders would be required to meet the requirements of the standard.

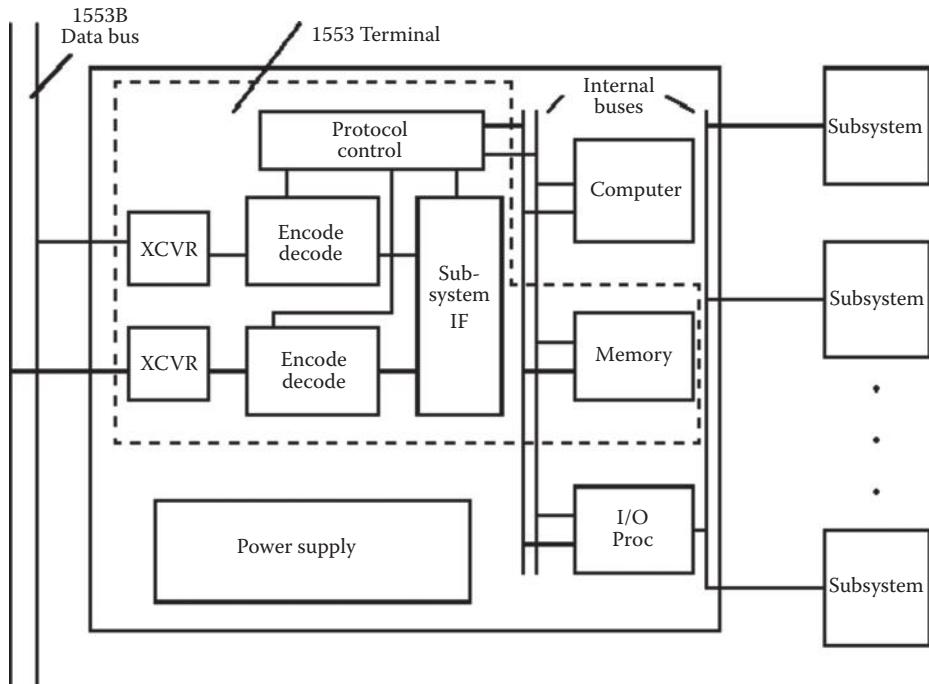

**FIGURE 43.3** Simple multiplex architecture.

Figure 43.4 is a block diagram of a remote terminal and its connection to a subsystem. In short, the remote terminal consists of all the electronics necessary to transfer data between the data bus and the user or originator of the data being transferred.

But a remote terminal is more than just a data formatter. It must be capable of receiving and decoding commands from the bus controller and respond accordingly. It must also be capable of buffering a message worth of data, detecting transmission errors and performing validation tests upon the data, and reporting the status of the message transfer. A remote terminal must be capable of performing a few of the bus management commands (referred to as mode commands [MCs]), and for dual redundant applications, it must be capable of listening to and decoding commands on both buses at the same time.

A remote terminal must strictly follow the protocol as defined by the standard. It can only respond to commands received from the bus controller (i.e., it only speaks when spoken to). When it receives a valid

**FIGURE 43.4** Terminal definition.

command, it must respond within a defined amount of time. If a message does not meet the validity requirements defined, then the remote terminal must invalidate the entire message and discard the data (not allow the data to be used by the subsystem). In addition to reporting status to the bus controller, most remote terminals today are also capable of providing some level of status information to the subsystem regarding the data received.

#### 43.2.1.3 Bus Controller

The bus controller is responsible for directing the flow of data on the bus. While several terminals may be capable of performing as the bus controller, only one bus controller is allowed to be active at any one time. The bus controller is the only device allowed to issue commands onto the data bus. The commands may be for the transfer of data or the control and management of the bus (referred to as MCs).

Typically, the bus controller is a function that is contained within some other computer, such as a mission computer, a display processor, or a fire control computer. The complexity of the electronics associated with the bus controller is a function of the subsystem interface (the interface to the computer), the amount of error management and processing to be performed, and the architecture of the bus controller. There are three types of bus controller architectures: a word controller, a message controller, and a frame controller.

A *word controller* is the oldest and simplest type. Few word controllers are built today and they are only mentioned herein for completeness. For a word controller, the terminal electronics transfers one word at a time to the subsystem. Message buffering and validation must be performed by the subsystem.

*Message controllers* output a single message at a time, interfacing with the computer only at the end of the message or perhaps when an error occurs. Some message controllers are capable of performing minor error processing, such as retransmitting once on the alternate data bus, before interrupting the computer. The computer will inform the interface electronics of where the message exists in memory and provide a control word. For each message, the control word typically informs the bus controller electronics of the message type (e.g., a remote terminal to bus controller [RT-BC] or remote terminal to remote terminal [RT-RT] command), which bus to use to transfer the message, where to read or write the data words (DWs) in memory, and what to do if an error occurs. The control words are a function of the hardware design of the electronics and are not standardized among bus controllers.

A *frame controller* is the latest concept in bus controllers. A frame controller is capable of processing multiple messages in a sequence defined by the computer. The frame controller is typically capable of error processing as defined by the message control word. Frame controllers are used to *off-load* the computer as much as possible, interrupting only at the end of a series of messages or when an error it cannot handle is detected.

There is no requirement within the standard as to the internal workings of a bus controller, only that it issue commands onto the bus.

#### 43.2.1.4 Bus Monitor

A bus monitor is just that: a terminal that listens to (monitors) the exchange of information on the data bus. The standard strictly defines what bus monitors may be used for, stating that the information obtained by a bus monitor be used “for offline applications (e.g., flight test recording, maintenance recording, or mission analysis) or to provide a backup bus controller sufficient information to take over as the bus controller.” Monitors may collect all the data from the bus or may collect selected data.

The reason for restricting its use is that while a monitor may collect data, it deviates from the command-response protocol of the standard in that a monitor is a passive device that does not transmit a status word (SW), and therefore cannot report on the status of the information transferred. Therefore, bus monitors fall into two categories: a recorder for testing or as a terminal functioning as a backup bus controller.

**TABLE 43.3** Terminal Electrical Characteristics

Requirement	Transformer Coupled	Direct Coupled	Condition
<i>Input characteristics</i>			
Input level	0.86–14.0 V	1.2–20.0 V	p-p, l-l
No response	0.0–0.2 V	0.0–0.28 V	p-p, l-l
Zero crossing stability	±150.0 ns	±150.0 ns	
Rise/fall times	0 ns	0 ns	Sine wave
Noise rejection	140.0 mV WGN <sup>a</sup>	200.0 mV WGN	BER <sup>b</sup> 1 per $10^7$
Common mode rejection	±10.0 V peak	±10.0 V peak	line-gnd, DC-2.0 MHz
Input impedance	1000 Ω	2000 Ω	75 kHz–1 MHz
<i>Output characteristics</i>			
Output level	18.0–27.0 V	6.0–9.0 V	p-p, l-l
Zero crossing stability	25.0 ns	25.0 ns	
Rise/fall times	100–300 ns	100–300 ns	10%–90%
Maximum distortion	±900.0 mV	±300.0 mV	peak, l-l
Maximum output noise	14.0 mV	5.0 mV	rms, l-l
Maximum residual voltage	±250.0 mV	±90.0 mV	peak, l-l

<sup>a</sup> WGN, White Gaussian noise.

<sup>b</sup> BER, Bit error rate.

In collecting data, a monitor must perform the same message validation functions as the remote terminal and, if an error is detected, inform the subsystem of the error (the subsystem may still record the data, but the error should be noted). For monitors that function as recorders for testing, the subsystem is typically a recording device or a telemetry transmitter. For monitors that function as backup bus controllers, the subsystem is the computer.

Today, it is common that bus monitors also contain a remote terminal. When the monitor receives a command addressed to its terminal address (TA), it responds as a remote terminal. For all other commands, it functions as a monitor. The remote terminal portion could be used to provide feedback to the bus controller of the monitor's status, such as the amount of memory or time left, or to reprogram a selective monitor as to what messages to capture.

#### 43.2.1.5 Terminal Hardware

The electronic hardware among a remote terminal, bus controller, and bus monitor does not differ much. Both the remote terminal and bus controller (and bus monitor if it is also a remote terminal) must have the transmitters/receivers and encoders/decoders to format and transfer data. The requirements on the transceivers and the encoders/decoders do not vary between the hardware elements. Table 43.3 lists the electrical characteristics of the terminals.

All three elements have some level of subsystem interface and data buffering. The primary difference lies in the protocol control logic and often this is just a different series of microcoded instructions. For this reason, it is common to find 1553 hardware circuitry that is capable of functioning as all three devices.

There is an abundance of *off-the-shelf* components available today from which to design a terminal. These vary from discrete transceivers, encoders/decoders, and protocol logic devices to a single dual redundant hybrid containing everything but the transformers to design code that can be embedded into gate arrays.

### 43.3 Protocol

The rules under which the transfers occur are referred to as *protocol*. The control, data flow, status reporting, and management of the bus are provided by three word types.

### 43.3.1 Word Types

Three distinct word types are defined by the standard. These are command words (CWs), DWs, and SWs. Each word type has a unique format yet all three maintain a common structure. Each word is 20 bits in length. The first three bits are used as a synchronization field, thereby allowing the decode clock to resync at the beginning of each new word. The following 16 bits are the information field and differ among the three word types. The last bit is the parity bit. Parity is based on odd parity for the single word. The three word types are shown in Figure 43.5.

Bit encoding for all words is based on biphase Manchester II format. The Manchester II format provides a self-clocking waveform in which the bit sequence is independent. The positive and negative voltage levels of the Manchester waveform are direct current (DC) balanced (same amount of positive signal as there is negative signal) and as such are well suited for transformer coupling. A transition of the signal occurs at the center of the bit time. A logic “0” is a signal that transitions from a negative level to a positive level. A logic “1” is a signal that transitions from a positive level to a negative level.

The terminal's hardware is responsible for the Manchester encoding and decoding of the word types. The interface that the subsystem sees is the 16-bit information field of all words. The sync and parity fields are not provided directly. However, for received messages, the decoder hardware provides a signal to the protocol logic as to the sync type the word was and as to whether parity was valid or not. For transmitted messages, there is an input to the encoder as to what sync type to place at the beginning of the word, and parity is automatically calculated by the encoder.

#### 43.3.1.1 Sync Fields

The first three bit times of all word types is called the sync field. The sync waveform is in itself an invalid Manchester waveform as the transition only occurs at the middle of the second bit time. The use of this distinct pattern allows the decoder to resync at the beginning of each word received and maintain the overall stability of the transmissions.

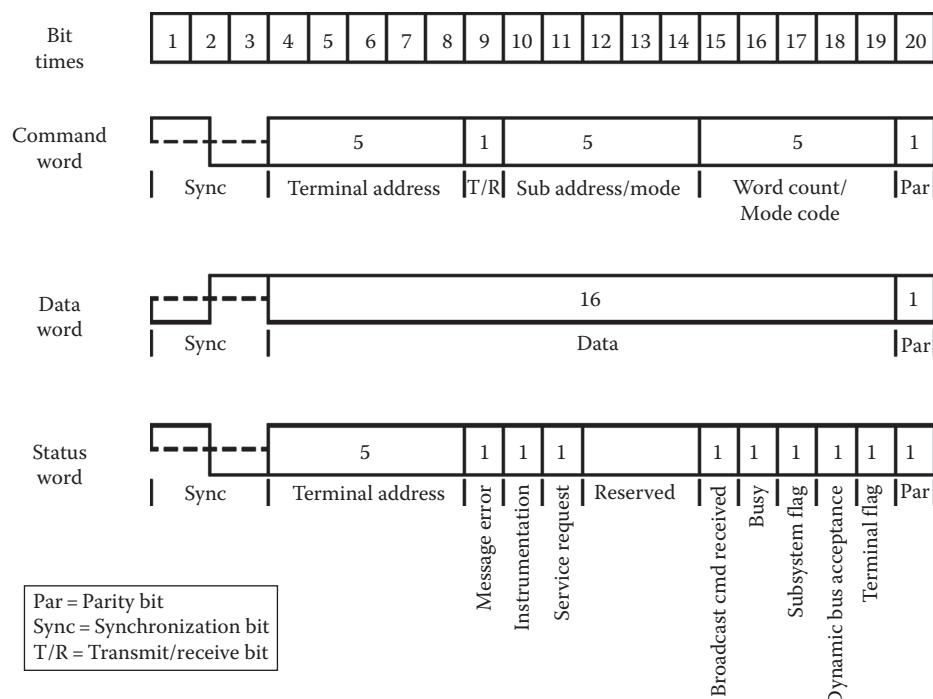

FIGURE 43.5 Word formats.

Two distinct sync patterns are used: the command/status sync and the data sync. The command/status sync has a positive voltage level for the first one and a half bit times, then transitions to a negative voltage level for the second one and a half bit times. The data sync is the opposite—a negative voltage level for the first one and a half bit times, then transitions to a positive voltage level for the second one and a half bit times. The sync patterns are shown in Figure 43.5. As the sync field is the same for both the CW and the SW, the user merely needs to follow the protocol to determine which is which—only a bus controller issues a command sync and only a remote terminal issues status sync.

#### 43.3.1.2 Command Word

The CW specifies the function that a remote terminal(s) is to perform. This word is only transmitted by the active bus controller. The word begins with a command sync in the first three bit times. The following 16-bit information field is as defined in Figure 43.5.

The five-bit TA field (bit times 4–8) states to which unique remote terminal the command is intended (no two terminals may have the same address). Note that an address of 00000 is a valid address and that an address of 11111 is reserved for use as the broadcast address. Also note that there is no requirement that the bus controller be assigned an address; therefore, the maximum number of terminals the data bus can support is 31. Notice 2 to the standard requires that the TA be wire programmable externally to the black box (i.e., an external connector) and that the remote terminal electronics perform a parity test upon the wired TA. The notice basically states that an open circuit on an address line is detected as a logic “1,” that connecting an address line to ground is detected as a logic “0,” and that odd parity will be used in testing the parity of the wired address field.

The next bit (bit time 9) is the transmit/receive (T/R) bit. This defines the direction of information flow and is always from the point of view of the remote terminal. A transmit command (logic 1) indicates that the remote terminal is to transmit data, while a receive command (logic 0) indicates that the remote terminal is going to receive data. The only exceptions to this rule are associated with MCs.

The following five bits (bit times 10–14) are the subaddress (SA)/MC bits. A logic 00000 or 11111 within this field shall be decoded to indicate that the command is a mode code command. All other logic combinations of this field are used to direct the data to different functions within the subsystem. An example might be that 00001 is position data, 00010 is rate data, 10010 is altitude information, and 10011 is self-test data. The use of the SAs is left to the designer; however, Notice 2 suggests the use of SA 30 for data wraparound.

The next five-bit positions (bit times 15–19) define the word count (WC) or mode code to be performed. If the SA/mode code field was 00000 or 11111, then this field defines the mode code to be performed. If not a mode code, then this field defines the number of DWs either to be received or transmitted depending on the T/R bit. A WC field of 00000 is decoded as 32 DWs.

The last bit (bit time 20) is the word parity bit. Only odd parity shall be used.

The best analogy of the CW would be to compare it to a post office. The TA is the address of the post office itself. The SA is the post-office (PO) box within the post office (directing information to different users/functions) and the WC is the number of letters to be input to or removed from the PO box depending on the T/R bit.

#### 43.3.1.3 Data Word

The DW contains the actual information that is being transferred within a message. DWs can be transmitted by either a remote terminal (transmit command) or a bus controller (receive command). The first three bit times contain a data sync. This sync pattern is the opposite of that used for command and SWs and therefore is unique to the DW type.

The following 16 bits of information are left to the designer to define. The only standard requirements are that the most significant bit (MSB) of the data be transmitted first and that unused bits be set to a logic 0. While the standard provides no guidance as to their use, Section 80 of MIL-HDBK-1553A and SAE AS-15532 provides guidance and lists the formats (i.e., bit patterns, resolutions) of the most commonly used DWs.

The last bit (bit time 20) is the word parity bit. Only odd parity shall be used.

### 43.3.1.4 Status Word

The SW is only transmitted by a remote terminal in response to a valid message. The SW is used to convey to the bus controller whether a message was properly received or the state of the remote terminal (i.e., service request, busy). The SW is defined in Figure 43.5. Since the SW conveys information to the bus controller, there are two views as to the meaning of each bit—what the setting of the bit means to a remote terminal and what the setting of the bit means to a bus controller. Each field of the SW, and its potential meanings, is examined in the following.

#### 43.3.1.4.1 Resetting the Status Word

The SW, with the exception of the remote TA, is cleared after receipt of a valid CW. The two exceptions to this rule are if the CW received is a transmit SW mode code or a transmit last CW mode code. Conditions that set the individual bits of the word may occur at any time. If after clearing the SW, the conditions for setting the bits still exist, then the bits shall be set again.

Upon detection of an error in the data being received, the message error (ME) bit is set and the transmission of the SW is suppressed. The transmission of the SW is also suppressed upon receipt of a broadcast message. For an illegal message (i.e., an illegal CW), the ME bit is set and the SW is transmitted.

#### 43.3.1.4.2 Status Word Bits

*Terminal address:* The first five bits (bit times 4–8) of the information field are the TA. These five bits should match the corresponding field within the CW that the terminal received. The remote terminal sets these bits to the address to which it has been programmed. The bus controller should examine these bits to ensure that the terminal responding with its SW was indeed the terminal to which the CW was addressed. In the case of a RT-RT message, the receiving terminal should compare the address of the second CW with that of the received SW. While not required by the standard, it is good design practice to ensure that the data received are from a valid source.

*Message error:* The next bit (bit time 9) is the ME bit. This bit is set to a logic “1” by the remote terminal upon detection of an error in the message or upon detection of an invalid message (i.e., illegal command) to the terminal. The error may occur in any of the DWs within the message. When the terminal detects an error and sets this bit, none of the data received within the message shall be used. If an error is detected within a message and the ME bit is set, the remote terminal must suppress the transmission of the SW (see Resetting of the Status Word). If the terminal detected an illegal command, the ME bit is set and the SW is transmitted. All remote terminals must implement the ME bit in the SW.

*Instrumentation:* The instrumentation bit (bit time 10) is provided to differentiate between a CW and an SW (remember, they both have the same sync pattern). The instrumentation bit in the SW is always set to logic “0.” If used, the corresponding bit in the CW is set to a logic “1.” This bit in the CW is the MSB of the SA field and therefore would limit the SAs used to 10000–11110, hence reducing the number of SAs available from 30 to 15. The instrumentation bit is also the reason why there are two mode code identifiers (00000 and 11111), the latter required when the instrumentation bit is used.

*Service request:* The service request bit (bit time 11) is such that the remote terminal can inform the bus controller that it needs to be serviced. This bit is set to a logic “1” by the subsystem to indicate that servicing is needed. This bit is typically used when the bus controller is *polling* terminals to determine if they require processing. The bus controller upon receiving this bit set to a logic “1” typically does one of the following. It can take a predetermined action such as issuing a series of messages, or it can request further data from the remote terminal as to its needs. The latter can be accomplished by requesting the terminal to transmit data from a defined SA or by using the transmit vector word mode code.

*Reserved:* Bit times 12–14 are reserved for future growth of the standard and must be set to a logic “0.” The bus controller should declare a message in error if the remote terminal responds with any of these bits set in its SW.

*Broadcast command received:* The broadcast command received bit (bit time 15) indicates that the remote terminal received a valid broadcast command (e.g., a CW with the TA set to 11111). Upon receipt of a valid broadcast command, the remote terminal sets this bit to logic “1” and suppresses the transmission of its SWs. The bus controller may issue a transmit SW or transmit last CW mode code to determine if the terminal received the message properly.

*Busy:* The busy bit (bit time 16) is provided as a feedback to the bus controller when the remote terminal is unable to move data between the remote terminal electronics and the subsystem in compliance to a command from the bus controller.

In the earlier days of 1553, the busy bit was required because many of the subsystem interfaces (analogs, synchros, etc.) were much slower compared to the speed of the multiplex data bus. Some terminals were not able to move the data fast enough. So instead of potentially losing data, a terminal was able to set the busy bit, indicating to the bus controller it could not handle new data at that time and for the bus controller to try again later. As new systems have been developed, the need for the use of busy has been reduced. However, there are systems that still need and have a valid use for the busy bit. Examples of these are radios, where the bus controller issues a command to the radio to tune to a certain frequency. It may take the radio several milliseconds to accomplish this, and while it is tuning, it may set the busy bit to inform the bus controller that it is doing as it was told.

When a terminal is busy, it does not need to respond to commands in the *normal* way. For receive commands, the terminal collects the data, but does not have to pass the data to the subsystem. For transmit commands, the terminal transmits its SW only. Therefore, while a terminal is busy, the data it supplies to the rest of the system are not available. This can have an overall effect upon the flow of data within the system and may increase the data latency within time-critical systems (e.g., flight controls).

Some terminals used the busy bit to overcome design problems, setting the busy bit whenever needed. Notice 2 to the standard *strongly discourages* the use of the busy bit. However, as shown in the example earlier, there are valid needs for its use. Therefore, if used, Notice 2 now requires that the busy bit may only be set as the result of a particular command received from the bus controller and not due to an internal periodic or processing function. By following this requirement, the bus controller, with prior knowledge of the remote terminal’s characteristics, can determine what will cause a terminal to go busy and minimize the effects on data latency throughout the system.

*Subsystem flag:* The subsystem flag bit (bit time 17) is used to provide *health* data regarding the subsystems to which the remote terminal is connected. Multiple subsystems may logically OR their bits together to form a composite health indicator. This single bit is only to serve as an indicator to the bus controller and user of the data that a fault or failure exists. Further information regarding the nature of the failure must be obtained in some other fashion. Typically, an SA is reserved for built-in-test (BIT) information, with one or two words devoted to subsystem status data.

*Dynamic bus control acceptance:* The dynamic bus control acceptance bit (bit time 18) is used to inform the bus controller that the remote terminal has received the dynamic bus control mode code and has accepted control of the bus. For the remote terminal, the setting of this bit is controlled by the subsystem and is based upon passing some level of BIT (i.e., a processor passing its power-up and continuous background tests).

The remote terminal upon transmitting its SW becomes the bus controller. The bus controller, upon receipt of the SW from the remote terminal with this bit set, ceases to function as the bus controller and may become a remote terminal or bus monitor.

*Terminal flag:* The terminal flag bit (bit time 19) is used to inform the bus controller of a fault or failure within the remote terminal circuitry (only the remote terminal). A logic “1” shall indicate a fault condition. This bit is used solely to inform the bus controller of a fault or failure. Further information

regarding the nature of the failure must be obtained in some other fashion. Typically, an SA is reserved for BIT information, or the bus controller may issue a transmit BIT word mode code.

*Parity:* The last bit (bit time 20) is the word parity bit. Only odd parity shall be used.

### 43.3.2 Message Formats, Validation, and Timing

The primary purpose of the data bus is to provide a common medium for the exchange of data between systems. The exchange of data is based upon message transmissions. The standard defines 10 types of message transmission formats. All of these formats are based upon the three word types just defined. The 10 message formats are shown in Figures 43.6 and 43.7. The message formats have been divided into two groups. These are referred to within the standard as the *information transfer formats* (Figure 43.6) and the *broadcast information transfer formats* (Figure 43.7).

The information transfer formats are based upon the command/response philosophy that all error-free transmissions received by a remote terminal be followed by the transmission of an SW from the terminal to the bus controller. This handshaking principle validates the receipt of the message by the remote terminal.

Broadcast messages are transmitted to multiple remote terminals at the same time. As such, the terminals suppress the transmission of their SWs (not doing so would have multiple boxes trying to talk at the same time and thereby *jam* the bus). In order for the bus controller to determine if a terminal received the message, a polling sequence to each terminal must be initiated to collect the SWs.

Each of the message formats is summarized in the following sections.

#### 43.3.2.1 Bus Controller to Remote Terminal

The bus controller to remote terminal (BC-RT) message is referred to as the receive command since the remote terminal is going to receive data. The bus controller outputs a CW to the terminal defining the SA of the data and the number of DWs it is sending. Immediately (without any gap in the transmission), the number of DWs specified in the CW is sent.

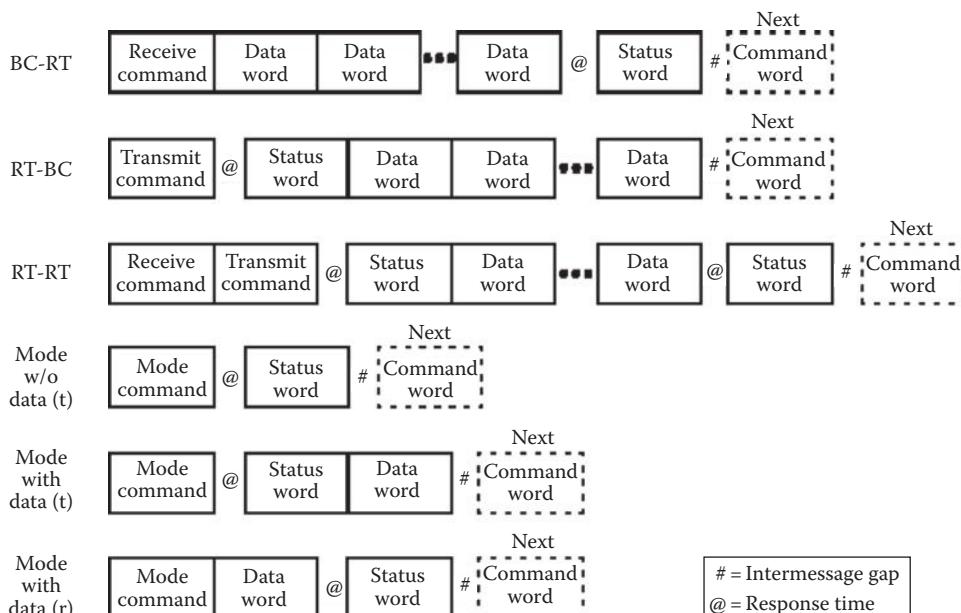

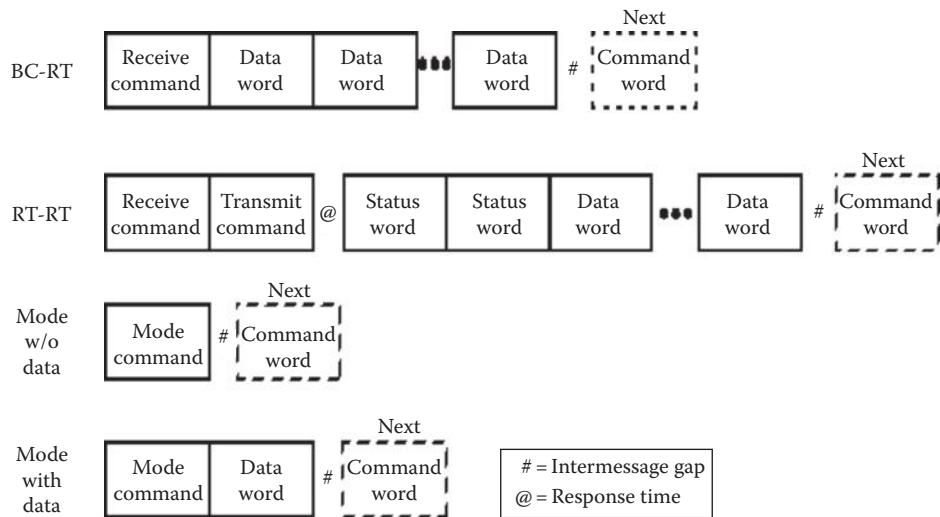

FIGURE 43.6 Information transfer formats.

**FIGURE 43.7** Broadcast information transfer formats.

The remote terminal upon validating the CW and all of the DWs will issue its SW within the response time requirements (maximum of 12  $\mu$ s).

The remote terminal must be capable of processing the next command that the bus controller issues. Therefore, the remote terminal has approximately 56  $\mu$ s (SW response time 12  $\mu$ s, plus SW transmit time 20  $\mu$ s, plus intermessage gap minimum 4  $\mu$ s, plus CW transmit time 20  $\mu$ s) to either pass the data to the subsystem or buffer the data.

#### 43.3.2.2 Remote Terminal to Bus Controller

The RT-BC message is referred to as a transmit command. The bus controller issues only a transmit CW to the remote terminal. The terminal, upon validation of the CW, will first transmit its SW followed by the number of DWs requested by the CW.

Since the remote terminal does not know the sequence of commands to be sent and does not normally operate upon a command until the CW has been validated, it must be capable of fetching from the subsystem the data required within approximately 28  $\mu$ s (the SW response time 12  $\mu$ s, plus the SW transmission time 20  $\mu$ s, minus some amount of time for message validation and transmission delays through the encoder and transceiver).

#### 43.3.2.3 Remote Terminal to Remote Terminal

The RT-RT command is provided to allow a terminal (the data source) to transfer data directly to another terminal (the data sink) without going through the bus controller. The bus controller may, however, collect and use the data.

The bus controller first issues a CW to the receiving terminal immediately followed by a CW to the transmitting terminal. The receiving terminal is expecting data, but instead of data after the CW, it sees a command sync (the second CW). The receiving terminal ignores this word and waits for a word with a data sync.

The transmitting terminal ignored the first CW (it did not contain its TA). The second word was addressed to it, so it will process the command as an RT-BC command as described earlier by transmitting its SW and the required DWs.

The receiving terminal, having ignored the second CW, again sees a command (status) sync on the next word and waits further. The next word (the first DW sent) now has a data sync and the receiving remote terminal starts collecting data. After receipt of all of the DWs (and validating), the terminal transmits its SW.

#### 43.3.2.3.1 RT-RT Validation

There are several things that the receiving remote terminal of an RT-RT message should do. First, Notice 2 requires that the terminal time is out in 54–60 µs after receipt of the CW. This is required since if the transmitting remote terminal did not validate its CW (and no transmission occurred), then the receiving terminal will not collect data from some new message. This could occur if the next message is either a transmit or receive message, where the terminal ignores all words with a command/status sync and would start collecting DWs beginning with the first data sync. If the same number of DWs were being transferred in the follow-on message and the terminal did not test the command/SW contents, then the potential exists for the terminal to collect erroneous data.

The other function that the receiving terminal should do, but is not required by the standard, is to capture the second CW and the first transmitted DW. The terminal could compare the TA fields of both words to ensure that the terminal doing the transmitting was the one commanded to transmit. This would allow the terminal to provide a level of protection for its data and subsystem.

#### 43.3.2.4 Mode Command Formats

Three MC formats are provided for. This allows for MCs with no DWs and for the MCs with one DW (either transmitted or received). The status/data sequencing is as described for the BC-RT or RT-BC messages except that the data WC is either one or zero. Mode codes and their use are described later.

#### 43.3.2.5 Broadcast Information Transfer Formats

The broadcast information transfer formats, as shown in Figure 43.7, are identical to the nonbroadcast formats described previously with the following two exceptions. First, the bus controller issues commands to TA 31 (1111), which is reserved for this function. And secondly, the remote terminals receiving the messages (those that implement the broadcast option) suppress the transmission of their SW.

The broadcast option can be used with the message formats in which the remote terminal receives data. Obviously, multiple terminals cannot transmit data at the same time, so the RT-BC transfer format and the transmit mode code with data format cannot be used. The broadcast RT-RT allows the bus controller to instruct all remote terminals to receive and then instruct one terminal to transmit, thereby allowing a single subsystem to transfer its data directly to multiple users.

Notice 2 allows the bus controller to only use broadcast commands with mode codes (see Broadcast Mode Codes). Remote terminals are allowed to implement this option for all broadcast message formats. The notice further states that the terminal must differentiate the SAs between broadcast and nonbroadcast messages (see Section 43.4.1).

#### 43.3.2.6 Command and Message Validation

The remote terminal must validate the CW and all DWs received as part of the message. The criteria for a valid CW are that the word begins with a valid command sync and valid TA (matches the assigned address of the terminal or the broadcast address if implemented), all bits are in a valid Manchester code, there are 16 information field bits, and there is a valid parity bit (odd). The criteria for a DW are the same except a valid data sync is required and the TA field is not tested. If a CW fails to meet the criteria, the command is ignored. After the command has been validated, and a DW fails to meet the criteria, then the terminal shall set the ME bit in the SW and suppress the transmission of the SW. Any single error within a message shall invalidate the entire message and the data shall not be used.

#### 43.3.2.7 Illegal Commands

The standard allows remote terminals the option of monitoring for illegal commands. An illegal command is one that meets the valid criteria for a CW but is a command (message) that is not implemented by the terminal. An example is if a terminal is designed to only output 04 DWs to SA 01 and

a CW was received by the terminal that requested it to transmit 06 DWs from SA 01, then this command, while still a valid command, could be considered by the terminal as illegal. The standard only states that the bus controller shall not issue illegal or invalid commands.

The standard provides the terminal designer with two options. First, the terminal can respond to all commands as usual (this is referred to as *responding in form*). The data received are typically placed in a series of memory locations that are not accessible by the subsystem or applications programs. This is typically referred to as the *bit bucket*. All invalid commands are placed into the same bit bucket. For invalid transmit commands, the data transmitted are read from the bit bucket. Remember, the bus controller is not supposed to send these invalid commands.

The second option is for the terminal to monitor for illegal commands. For most terminal designs, this is as simple as a lookup table with the T/R bit, SA, and WC fields supplying the address and the output being a single bit that indicates if the command is valid or not. If a terminal implements illegal command detection and an illegal command is received, the terminal sets the ME bit in the SW and responds with the SW.

#### 43.3.2.8 Terminal Response Time

The standard states that a remote terminal, upon validation of a transmit CW or a receive message (CW and all DWs), shall transmit its SW to the bus controller. The response time is the amount of time the terminal has to transmit its SW. To allow for accurate measurements, the time frame is measured from the midcrossing of the parity bit of the CW to the midcrossing of the sync field of the SW. The minimum time is 4.0  $\mu$ s; the maximum time is 12.0  $\mu$ s. However, the actual amount of *dead time* on the bus is 2–10  $\mu$ s since half of the parity bit and sync waveforms are being transmitted during the measured time frame.

The standard also specifies that the bus controller must wait a minimum of 14.0  $\mu$ s for a SW response before determining that a terminal has failed to respond. In applications where long data buses are used or where other special conditions exist, it may be necessary to extend this time to 20.0  $\mu$ s or greater.

#### 43.3.2.9 Intermessage Gap

The bus controller must provide for a minimum of 4.0  $\mu$ s between messages. Again, this time frame is measured from the midcrossing of the parity bit of the last DW or the SW and the midcrossing of the sync field of the next CW. The actual amount of *dead time* on the bus is 2  $\mu$ s since half of the parity bit and sync waveforms are being transmitted during the measured time frame.

The amount of time required by the bus controller to issue the next command is a function of the controller type (e.g., word, message, or frame). The gap typically associated with word controllers is between 40 and 100  $\mu$ s. Message controllers typically can issue commands with a gap of 10–30  $\mu$ s. But frame controllers are capable of issuing commands at the 4  $\mu$ s rate and often must require a time delay to slow them down.

#### 43.3.2.10 Superseding Commands

A remote terminal must always be capable of receiving a new command. This may occur while operating on a command on bus A and after the minimum intermessage gap, a new command appears or if operating on bus A and a new command appears on bus B. This is referred to as a superseding command. A second valid command (the new command) shall cause the terminal to stop operating on the first command and start on the second. For dual redundant applications, this requirement implies that all terminals must, as a minimum, have two receivers, two decoders, and two sets of CW validation logic.

### 43.3.3 Mode Codes

Mode codes are defined by the standard to provide the bus controller with data bus management and error handling/recovery capability. The mode codes are divided into two groups: with and without DWs. The DWs that are associated with the mode codes (and only one word per mode code is allowed) contain information pertinent to the control of the bus and do not generally contain information required by

**TABLE 43.4** Mode Code

T/R	Mode Code	Function	Data Word	Broadcast
1	00000	Dynamic bus control	No	No
1	00001	Synchronize	No	Yes
1	00010	Transmit SW	No	No
1	00011	Initiate self-test	No	Yes
1	00100	Transmitter shutdown	No	Yes
1	00101	Override transmitter shutdown	No	Yes
1	00110	Inhibit terminal flag bit	No	Yes
1	00111	Override inhibit terminal flag bit	No	Yes
1	01000	Reset	No	Yes
1	01001	Reserved	No	TBD
1	•	•	No	•
1	•	•	No	•
1	01111	Reserved	No	TBD
1	10000	Transmit vector word	Yes	No
0	10001	Synchronize	Yes	Yes
1	10010	Transmit last CW	Yes	No
1	10011	Transmit BIT word	Yes	No
0	10100	Selected transmitter shutdown	Yes	Yes
0	10101	Override selected transmitter shutdown	Yes	Yes
1/0	10110	Reserved	Yes	TBD
•	•	•	Yes	•
•	•	•	Yes	•
1/0	11111	Reserved	Yes	TBD

the subsystem (the exception may be the synchronize with DW mode code). The mode codes are defined by bit times 15–19 of the CW. The MSB (bit 15) can be used to differentiate between the two mode code groups. When a DW is associated with the mode code, the T/R bit determines if the DW is transmitted or received by the remote terminal. The mode codes are listed in Table 43.4.

#### 43.3.3.1 Mode Code Identifier

The mode code identifier is contained in bits 10–14 of the CW. When this field is either 00000 or 11111, then the contents of bits 15–19 of the CW are to be decoded as a mode code. Two mode code identifiers are provided such that the system can utilize the instrumentation bit if desired. The two mode code identifiers shall not convey different information.

#### 43.3.3.2 Mode Code Functions

The following defines the functionality of each of the mode codes.

*Dynamic bus control:* The dynamic bus control mode code is used to provide for the passing of the control of the data bus between terminals, thus providing a *round-robin* type of control. Using this methodology, each terminal is responsible for collecting the data it needs from all the other terminals. When it is done collecting, it passes control to the next terminal in line (based on some predefined sequence). This allows the applications program (the end user of the data) to collect the data when it needs it, always ensuring that the data collected are from the latest source sample and have not been sitting around in a buffer waiting to be used.

Notices 1 and 2 to the standard forbid the use of dynamic bus control for Air Force applications. This is due to the problems and concerns of what may occur when a terminal, which has been passed by the control, is unable to perform or does not properly forward the control to the next terminal, thereby

forcing the condition of no terminal being in control and having to reestablish control by some terminal. The potential amount of time required to reestablish control could have disastrous effects upon the system (i.e., especially a flight control system).

A remote terminal that is capable of performing as the bus control should be capable of setting the dynamic bus control acceptance bit in the terminal's SW to logic "1" when it receives the mode code command. Typically, the logic associated with the setting of this bit is based on the subsystem's (e.g., computer's) ability to pass some level of confidence test. If the confidence test passes, then the bit is set and the SW is transmitted when the terminal receives the MC, thereby saying that it will assume the role of bus controller.

The bus controller can only issue the dynamic bus control MC to one remote terminal at a time. The command obviously is only issued to terminals that are capable of performing as a bus controller. Upon transmitting the command, the bus controller must check the terminal's SW to determine if the dynamic bus control acceptance bit is set. If set, the bus controller ceases to function as the controller and becomes either a remote terminal or a bus monitor. If the bit in the SW is not set, the remote terminal that was issued the command is not capable of becoming the bus controller; the current controller must either remain the bus controller or attempt to pass the control to some other terminals.

*Synchronize:* The synchronize mode code is used to establish some form of timing between two or more terminals. This mode code does not use a DW; therefore, the receipt of this command by a terminal must cause some predefined event to occur. Some examples of this event may be the clearing, incrementing, or presetting of a counter; the toggling of an output signal; or the calling of some software routine. Typically, this command is used to time correlate a function such as the sampling of navigation data (i.e., present position, rates) for flight controls or targeting/fire control systems. Other uses have been for the bus controller to *sync* the backup controllers (or monitors) to the beginning of a major/minor frame processing.

When a remote terminal receives the synchronize MC, it should perform its predefined function. For a bus controller, the issuance of the command is all that is needed. The terminal's SW only indicates that the message was received, not that the *sync* function was performed.

*Transmit status word:* This is one of the two commands that does not cause the remote terminal to reset or clear its SW. Upon receipt of this command, the remote terminal transmits the SW that was associated with the previous message, not the SW of the mode code message.

The bus controller uses this command for control and error management of the data bus. If the remote terminal had detected an error in the message and suppressed its SW, then the bus controller can issue this command to the remote terminal to determine if indeed the nonresponse was due to an error. As this command does not clear the SW from the previous message, a detected error by the remote terminal in a previous message would be indicated by having the ME bit set in the SW.

The bus controller also uses this command when *polling*. If a terminal does not have periodic messages, the RT can indicate when it needs communications by setting the service request bit in the SW. The bus controller, by requesting the terminal to transmit only its SW, can determine if the terminal is in need of servicing and can subsequently issue the necessary commands. This *polling* methodology has the potential of reducing the amount of bus traffic by eliminating the transmission of unnecessary words.

Another use of this command is when broadcast message formats are used. As all of the remote terminals will suppress their SWs, *polling* each terminal for its SW would reveal whether the terminal received the message by having its broadcast command received bit set.

*Initiate self-test:* This command, when received by the remote terminal, shall cause the remote terminal to enter into its self-test. This command is normally used as a ground-based maintenance function, as part of the system power-on tests, or, in flight, as part of a fault recovery routine. Note that this test is only for the remote terminal, not the subsystem.

In earlier applications, some remote terminals, upon receipt of this command, would enter self-test and go *offline* for long periods of time. Notice 2, in an effort to control the amount of time that a terminal could be *offline*, limited the test time to 100.0  $\mu$ s following the transmission of the SW by the remote terminal.

While a terminal is performing its self-test, it may respond to a valid command in the following ways: (1) no response on either bus (*offline*), (2) transmit only the SW with the busy bit set, or (3) normal response. The remote terminal may, upon receipt of a valid command received after this mode code, terminate its self-test. As a subsequent command could abort the self-test, the bus controller, after issuing this command, should suspend transmissions to the terminal for the specified amount of time (either a time specified for the remote terminal or the maximum time of 100.0  $\mu$ s).

*Transmitter shutdown:* This command is used by the bus controller in the management of the bus. In the event that a terminal's transmitter continuously transmits, this command provides for a mechanism to turn the transmitter off. This command is for dual redundant standby applications only.

Upon receipt of this command, the remote terminal shuts down (i.e., turns off) the transmitter associated with the opposite data bus. That is to say if a terminal's transmitter is babbling on the A bus, the bus controller would send this command to the terminal on the B bus (a command on the A bus would not be received by the terminal).

*Override transmitter shutdown:* This command is the complement of the previous one in that it provides a mechanism to turn on a transmitter that had previously been turned off. When the remote terminal receives this command, it shall set its control logic such that the transmitter associated with the opposite bus be allowed to transmit when a valid command is received on the opposite bus. The only other command that can enable the transmitter is the reset remote terminal MC.

*Inhibit terminal flag:* This command provides for the control of the terminal flag bit in a terminal's SW. The terminal flag bit indicates that there is an error within the remote terminal hardware and that the data being transmitted or the data received may be in error. However, the fault within the terminal may not have any effect upon the quality of the data, and the bus controller may elect to continue with the transmissions knowing a fault exists.

The remote terminal receiving this command shall set its terminal flag bit to logic "0" regardless of the true state of this signal. The standard does not state that the BIT that controls this bit be halted, but only that the results be negated to "0".

*Override inhibit terminal flag:* This command is the complement of the previous one in that it provides a mechanism to turn on the reporting of the terminal flag bit. When the remote terminal receives this command, it shall set its control logic such that the terminal flag bit is properly reported based upon the results of the terminal's BIT functions. The only other command that can enable the response of the terminal flag bit is the reset remote terminal MC.

*Reset remote terminal:* This command, when received by the remote terminal, shall cause the terminal electronics to reset to its power-up state. This means that if a transmitter had been disabled or the terminal flag bit inhibited, these functions would be reset as if the terminal had just powered up. Again, remember that the reset applies only to the remote terminal electronics and not to the entire box.

Notice 2 restricts the amount of time that a remote terminal can take to reset its electronics. After transmission of its SW, the remote terminal shall reset within 5.0  $\mu$ s. While a terminal is resetting, it may respond to a valid command in the following ways: (1) no response on either bus (*offline*), (2) transmit only the SW with the busy bit set, or (3) normal response. The remote terminal may, upon receipt of a valid command received after this mode code, terminate its reset function. As a subsequent command could abort the reset, the bus controller, after issuing this command, should suspend transmissions to the terminal for the specified amount of time (either a time specified for the remote terminal or the maximum time of 5.0  $\mu$ s).

*Transmit vector word:* This command shall cause the remote terminal to transmit a DW referred to as the vector word. The vector word shall identify to the bus controller service request information relating to the message needs of the remote terminal. While not required, this mode code is often tied to the service request bit in the SW. As indicated, the contents of the DW inform the bus controller of messages that need to be sent.

The bus controller also uses this command when *polling*. Though typically used in conjunction with the service request bit in the SW, wherein the bus controller requests only the SW (transmit SW mode code) and upon seeing the service request bit set would then issue the transmit vector word mode code, the bus controller can always ask for the vector word (always getting the SW anyway) and reduce the amount of time required to respond to the terminal's request.

*Synchronize with data word:* The purpose of this synchronize command is the same as the synchronize without DW, except this mode code provides a DW to provide additional information to the remote terminal. The contents of the DW are left to the imagination of the user. Examples from *real-world* applications have used this word to provide the remote terminal with a counter or clock value, to provide a backup controller with a frame identification number (minor frame or cycle number), and to provide a terminal with a new base address pointer used in extending the SA capability.

*Transmit last CW:* This is one of the two commands that does not cause the remote terminal to reset or clear its SW. Upon receipt of this command, the remote terminal transmits the SW that was associated with the previous message and the last CW (valid) that it received.

The bus controller uses this command for control and error management of the data bus. When a remote terminal is not responding properly, then the bus controller can determine the last valid command the terminal received and can reissue subsequent messages as required.

*Transmit BIT word:* This MC is used to provide detail with regard to the BIT status of the remote terminal. Its contents shall provide information regarding the remote terminal only (remember the definition) and not the subsystem.

While most applications associate this command with the initiate self-test mode code, the standard requires no such association. Typical use is to issue the initiate self-test mode code, allow the required amount of time for the terminal to complete its tests, and then issue the transmit BIT word mode code to collect the results of the test. Other applications have updated the BIT word on a periodic rate based on the results of a continuous background test (e.g., as a data wraparound test performed with every data transmission). This word can then be transmitted to the bus controller, upon request, without having to initiate the test and then wait for the test to be completed. The contents of the DW are left to the terminal designer.

*Selected transmitter shutdown:* Like the transmitter shutdown mode code, this mode code is used to turn off a babbling transmitter. The difference between the two mode codes is that this mode code has a DW associated with it. The contents of the DW specify which data bus (transmitter) to shutdown. This command is used in systems that provide more than dual redundancy.

*Override selected transmitter shutdown:* This command is the complement of the previous one in that it provides a mechanism to turn on a transmitter that had previously been turned off. When the remote terminal receives this command, the DW specifies which data bus (transmitter) shall set its control logic such that the transmitter associated with that bus be allowed to transmit when a valid command is received on that bus. The only other command that can enable the selected transmitter is the reset remote terminal MC.

*Reserved mode codes:* As can be seen from Table 43.4, there are several bit combinations that are set aside as reserved. It was the intent of the standard that these be reserved for future growth. It should also be noticed from the table that certain bit combinations are not listed. The standard allows the remote

terminal to respond to these reserved and *undefined* mode codes in the following manner: set the ME bit and respond (see Section 43.3.2.7) or respond in form. The designer of terminal hardware or a multiplex system is forbidden to use the reserved mode codes for any purpose.

#### 43.3.3.3 Required Mode Codes

Notice 2 to the standard requires that all remote terminals implement the following four mode codes: transmit SW, transmitter shutdown, override transmitter shutdown, and reset remote terminal. This requirement was levied so as to provide the multiplex system designer and the bus controller with a minimum set of commands for managing the multiplex system. Note that the aforementioned requirement was placed on the remote terminal. Notice 2 also requires that a bus controller be capable of implementing all of the mode codes; however, for Air Force applications, the dynamic bus control mode code shall never be used.

#### 43.3.3.4 Broadcast Mode Codes

Notice 2 to the standard allows the broadcast of mode codes (see Table 43.4). The use of the broadcast option can be of great assistance in the areas of terminal synchronization. Ground maintenance and troubleshooting can take advantage of broadcast reset remote terminal or initiate self, but these two commands can have disastrous effects if used while in flight. The designer must provide checks to ensure that commands such as these are not issued by the bus controller or operated upon by a remote terminal when certain conditions exists (e.g., in flight).

### 43.4 Systems-Level Issues

---

The standard provides very little guidance in how it is applied. Lessons learned from real-world applications have led to design guides, application notes, and handbooks that provide guidance. This section will attempt to answer some of the systems-level questions and identify implied requirements that, while not specifically called out in the standard, are required nonetheless.

#### 43.4.1 Subaddress Utilization

The standard provides no guidance on how to use the SAs. The assignment of SAs and their functions (the data content) is left to the user. Most designers automatically start assigning SAs with 01 and count upwards. If the instrumentation bit is going to be used, then the SAs must start at 16.

The standard also requires that normal SAs be separated from broadcast SAs. If the broadcast option is implemented, then an additional memory block is required to receive broadcast commands.

##### 43.4.1.1 Extended Subaddressing

The number of SAs that a terminal has is limited to 60 (30 transmit and 30 receive). Therefore, the number of unique DWs available to a terminal is 1920 ( $60 \times 32$ ). For earlier applications, where data being transferred were analog sensor data and switch settings, this was more than sufficient. However, in today's applications, in which digital computers are exchanging data, or for a video sensor passing digitized video data, the number of words is too limited.

Most terminal designs establish a block of memory for use by the 1553 interface circuitry. This block contains an address start pointer and then the memory is offset by the SA number and the WC number to arrive at a particular memory address.

A methodology of extending the range of the SAs has been successfully utilized. This method either uses a dedicated SA and DW or makes use of the synchronize with DW mode code. The DW associated with either of these contains an address pointer that is used to reestablish the starting

address of the memory block. The changing of the blocks is controlled by the bus controller and can be done based on numerous functions. Examples are operational modes, wherein one block is used for startup messages, a different block for takeoff and landing, a different block for navigation and cruise, a different block for mission functions (i.e., attack or evade modes), and a different block for maintenance functions.

Another example is that the changing of the start address could also be associated with minor frame cycles. Minor frames could have a separate memory block for each frame. The bus controller could synchronize frames and change memory pointers at the beginning of each new minor frame.

For computers exchanging large amounts of data (e.g., GPS almanac tables) or for computers that receive program loads via the data bus at power-up, the bus controller could set the pointers at the beginning of a message block, send thirty 32-word messages, move the memory pointer to the last location in the remote terminals memory that received data, then send the next block of thirty 32-word messages, continuing this cycle until the memory is loaded. The use is left to the designer.

#### 43.4.2 Data Wraparound

Notice 2 to the standard does require that the terminal is able to perform a data wraparound and SA 30 is suggested for this function. Data wraparound provides the bus controller with a methodology of testing the data bus from its internal circuitry, through the bus media, to the terminal's internal circuitry. This is done by the bus controller sending the remote terminal a message block and then commanding the terminal to send it back. The bus controller can then compare the sent data with that received to determine the state of the data link. There are no special requirements upon the bit patterns of the data being transferred.

The only design requirements are placed upon the remote terminal. These are that the terminal, for the data wraparound function, be capable of sending the number of DWs equal to the largest number of DWs sent for any transmit command. This means that if a terminal maximum data transmission is only four DWs, it need only provide for four DWs in its data wraparound function.

The other requirement is that the remote terminal need only hold the data until the next message. The normal sequence is for the bus controller to send the data, then in the next message, it asks for it back. If another message is received by the remote terminal before the bus controller requests the data, the terminal can discard the data from the wraparound message and operate on the new command.

#### 43.4.3 Data Buffering

The standard specifies that the any error within a message shall invalidate the entire message. This implies that the remote terminal must store the data within a message buffer until the last DW has been received and validated before allowing the subsystem access to the data. To ensure that the subsystem always has the last message of valid data received to work with would require the remote terminal to, as a minimum, double buffer the received data.

There are several methods to accomplish this in hardware. One method is for the terminal electronics to contain a first-in first-out (FIFO) memory that stores the data as it is received. Upon validation of the last DW, the terminal's subsystem interface logic will move the contents of the FIFO into the memory accessible by the subsystem. If an error occurred during the message, the FIFO is reset.

A second method establishes two memory blocks for each message in common memory. The subsystem is directed to read from one block (block A), while the terminal electronics writes to the other (block B). Upon receipt of a valid message, the terminal will switch pointers, indicating that the subsystem is to read from the new memory block (block B) while the terminal will now write to block B. If an error occurs within the message, the memory blocks are not switched.

Some of the *off-the-shelf* components available provide for data buffering. Most provide for double buffering, while some provided for multilevels of buffering.

#### 43.4.4 Variable Message Blocks

Remote terminals should be able to transmit any subset of any message. This means that if a terminal has a transmit message at SA 04 of 30 DWs, it should be capable of transmitting any number of those DWs (01–30) if so commanded by the bus controller. The order in which the subset is transmitted should be the same as if the entire message is being transmitted, that being the contents of DW 01 is the same regardless of the WC.

Terminals that implement illegal command detection should not consider subsets of a message as illegal. That is to say, if in our previous example a command is received for 10 DWs, this should not be illegal. But, if a command is received for 32 DWs, this would be considered as an illegal command.

#### 43.4.5 Sample Consistency

When transmitting data, the remote terminal needs to ensure that each message transmitted is of the same sample set and contains mutually consistent data. Multiple words used to transfer multiple precision parameters or functionally related data must of the same sampling.

If a terminal is transmitting pitch, roll, and yaw rates, and while transmitting the subsystem updates these data in memory, but this occurs after pitch and roll had been read by the terminal's electronics, then the yaw rate transmitted would be of a different sample set. Having data from different sample rates could have undesirable effects on the user of the data.

This implies that the terminal must provide some level of buffering (the reverse of what was described earlier) or some level of control logic to block the subsystem from updating data while being read by the remote terminal.

#### 43.4.6 Data Validation

The standard tightly defines the criteria for the validation of a message. All words must meet certain checks (i.e., valid sync, Manchester encoding, number of bits, odd parity) for each word and each message to be valid. But what about the contents of the DW? MIL-STD-1553 provides the checks to ensure the quality of the data transmission from terminal to terminal, sort of a *data in equals data out*, but is not responsible for the validation tests of the data itself. This is not the responsibility of the 1553 terminal electronics, but of the subsystem. If bad data are sent, then *garbage in equals garbage out*. But the standard does not prevent the user from providing additional levels of protection. The same techniques used in digital computer interfaces (i.e., disk drives, serial interfaces) can be applied to 1553. These techniques include checksums, cyclic redundancy check (CRC) words, and error detection/correction codes. Section 80 of MIL-HDBK-1553A that covers DW formats even offers some examples of these techniques.

But what about using the simple indicators embedded within the standard. Each remote terminal provides an SW—indicating not only the health of the remote terminal's electronics but also that of the subsystem. However, in most designs, the SW is kept within the terminal electronics and not passed to the subsystems. In some *off-the-shelf* components, the SW is not even available to be sent to the subsystem. But two bits from the SW should be made available to the subsystem and the user of the data for further determination as to the validity of the data. These are the subsystem flag and the terminal flag bits.

#### 43.4.7 Major and Minor Frame Timing

The standard specifies the composition of the words (command, data, and status) and the messages (information formats and broadcast formats). It provides a series of management messages (mode codes), but it does not provide any guidance on how to apply these within a system. This is left to the imagination of the user.

Remote terminals, based upon the contents of their data, will typically state how often data are collected and the fastest rate they should be outputted. For input data, the terminal will often state how often it needs certain data to either perform its job or maintain a certain level of accuracy. The rates are referred to as the transmission and update rates. It is the system designer's job to examine the data needs of all of the systems and determine when data are transferred from whom to whom. These data are subdivided into periodic messages, those that must be transferred at some fixed rate, and aperiodic messages, those that are typically either event driven (i.e., the operator pushes a button) or data driven (i.e., a value is now within range).

A major frame is defined such that all periodic messages are transferred at least once. This is therefore defined by the message with the slowest transmission rate. Typical major frame rates used in today's applications vary from 40 to 640  $\mu\text{s}$ . There are some systems that have major frame rates in the 1–5 s range, but these are the exceptions, not the norm. Minor frames are then established to meet the requirements of the higher update rate messages.

The sequence of messages within a minor frame is again left undefined. There are two methodologies that are predominately used. In the first method, the bus controller starts the frame with the transmission of all of the periodic messages (transmit and receive) to be transferred in that minor frame. At the end of the periodic messages, either the bus controller is finished (resulting in dead bus time—no transmissions) until the beginning of the next frame or the bus controller can use this time to transfer aperiodic messages, error handling messages, or transfer data to the backup bus controller(s).

In the second method (typically used in a centralized processing architecture), the bus controller issues all periodic and aperiodic transmit messages (collects the data), then processes the data (possibly using dead time during this processing), and then issues all the receive messages (outputting the results of the processing). Both methods have been used successfully.

#### 43.4.8 Error Processing

The amount and level of error processing is typically left to the systems designer but may be driven by the performance requirements of the system. Error processing is typically only afforded to critical messages, wherein the noncritical messages just await the next normal transmission cycle. If a data bus is 60% loaded and each message received an error, the error processing would exceed 100% of available time and thereby cause problems within the system.

Error processing is again a function of the level of sophistication of the bus controller. Some controllers (typically message or frame controllers) can automatically perform some degree of error processing. This usually is limited to a retransmission of the message either once on the same bus or once on the opposite bus. Should the retried message also fail, the bus controller software is informed of the problem. The message may then be retried at the end of the normal message list for the minor frame.

If the error still persists, then it may be necessary to stop communicating with the terminal, especially if the bus controller is spending a large amount of time performing error processing. Some systems will try to communicate with a terminal for a predefined number of times on each bus. After this, all messages to the terminal are removed from the minor frame lists and substituted with a single transmit SW mode code.

An analysis should be performed on the critical messages to determine the effects upon the system if they are not transmitted or the effects of data latency if they are delayed to the end of the frame.

### 43.5 Testing

---

The testing of a MIL-STD-1553 terminal or system is not a trivial task. There are a large number of options available to the designer including message formats, MCs, SW bits, and coupling methodology. In addition, history has shown that different component manufacturers and designers have made different interpretations regarding the standard, thereby introducing products that implement the same function quite differently.

**TABLE 43.5 SAE 1553 Test Plans**

AS-4111	Remote terminal validation test plan
AS-4112	Remote terminal production test plan
AS-4113	Bus controller validation test plan
AS-4114	Bus controller production test plan
AS-4115	Data bus system test plan
AS-4116	Bus monitor test plan
AS-4117	Bus components test plan

For years, the Air Force provided for the testing of MIL-STD-1553 terminals and components. Today, this testing is the responsibility of the industry. The SAE, in conjunction with the government, has developed a series of test plans for all 1553 elements. These test plans are listed in Table 43.5.

## 43.6 Further Information

---

In addition to the SAE test plans listed in Table 43.5, there are other documents that can provide a great deal of insight and assistance in designing with MIL-STD-1553:

- MIL-STD-1553B *Digital Time Division Command/Response Multiplex Data Bus*
- MIL-HDBK-1553A *Multiplex Applications Handbook*
- SAE AS-15531 *Digital Time Division Command/Response Multiplex Data Bus*
- SAE AS-15532 *Standard Data Word Formats*
- SAE AS-12 *Multiplex Systems Integration Handbook*
- SAE AS-19 MIL-STD-1553 *Protocol Reorganized*
- DDC 1553 *Designers Guide*
- UTMC 1553 *Handbook*

And lastly, there is the SAE 1553 Users Group. This is a collection of industry and military experts in 1553 who provide an open forum for information exchange and provide guidance and interpretations/clarifications with regard to the standard. This group meets twice a year as part of the SAE Avionics Systems Division conferences.

### 44.1 Protocol Overview

---

ASCB stands for *Avionics Standard Communication Bus* and is a proprietary communication protocol for the avionics domain of general, business, and regional aviation aircraft. The general aviation market comprises small multiple-seater aircraft, the business aviation market consists of turbo-engine-powered comfortable small aircraft for business clients, and regional aviation aircraft are single-aisle medium-sized aircraft flying regionally with up to about 100 passengers. Honeywell has developed ASCB for fault-tolerant periodic, real-time communication between avionic modules of its Primus Epic® avionics suit deployed in such aircraft. ASCB is the primary bus in Primus Epic. There are multiple ASCB versions available, some standardized [1], the latest being version D (abbreviated ASCB-D). Detailed information on Primus Epic is available in [2–7].

### 44.2 Protocol Services

---

ASCB-D is based on an architecture consisting of four Ethernet buses, two for each side of an airplane. Each of the network interface controllers (NICs) is assigned to one side of the airplane. The NICs on the left side are connected to the left-side primary, the right-side primary, and the left-side secondary (backup) bus. The NICs on the right side are connected to the right-side primary, the left-side primary, and the left-side secondary (backup) bus. Each NIC can listen to and transmit messages on its two buses on its side. Each NIC can also listen to but not transmit on the primary bus of the other side. For example, a left-side NIC can transmit and receive on the left-side primary and backup bus, and listen-only on the right-side primary. It is not connected to the right-side backup bus. From the viewpoint of one NIC, the NICs on the same side are called *onside* NICs; NICs of the other side are called *xside* NICs, where *xside* stands for *cross-side*. Figure 44.1 depicts the structure of the main buses and connections of NICs.

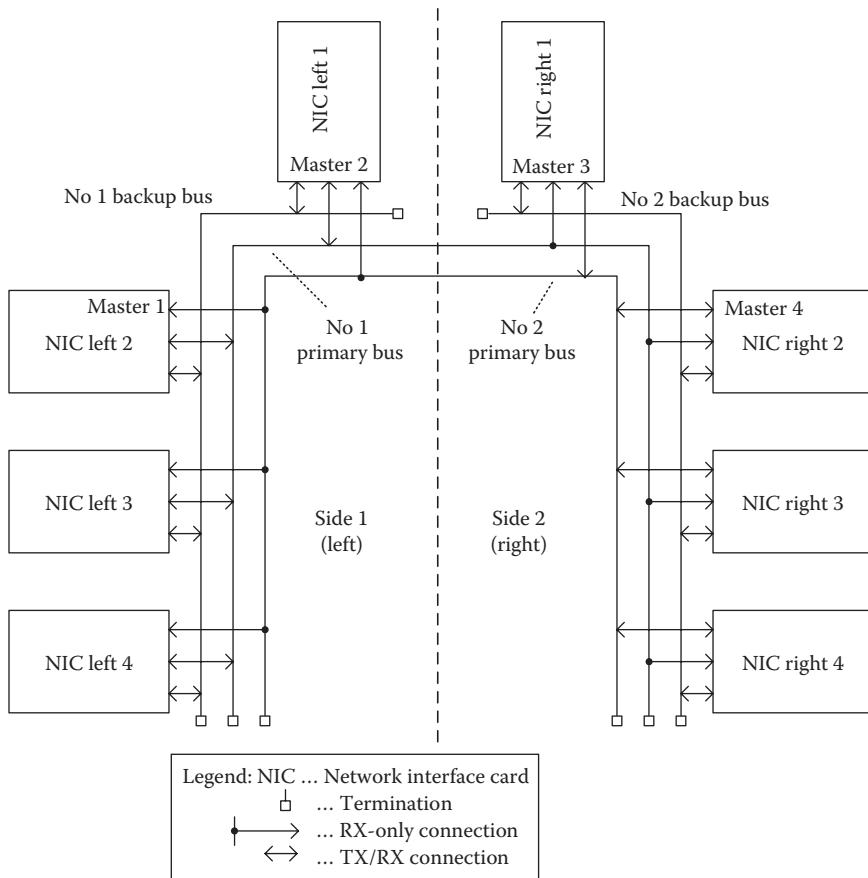

FIGURE 44.1 ASCB architecture.

#### 44.2.1 Communication Services

ASCB-D is a TDMA-based protocol where a minor frame (the fastest period) is running at 80 Hz. Figure 44.2 depicts the bus traffic of one bus. First, master NICs send synchronization pulses (sync pulse) followed by periodic traffic (Ethernet frames). The beginning of each frame is called a *frame tick*. The physical layer of the buses is based on 10 Mbit/s Ethernet using twinax cables and connectors. Figure 44.2 shows the minimum period (called *minor frame*) on the bus. Two sync pulses (special Ethernet frames with synchronization information) are the first frames on the bus. The two time servers that are connected to this bus send these sync pulses. After the sync pulse period, individual NICs (i.e., both the time

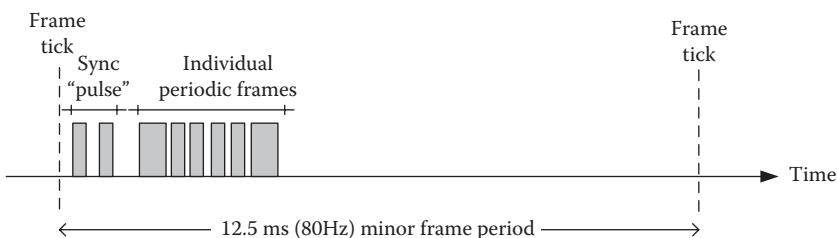

FIGURE 44.2 ASCB minor frame period.

servers and the time slaves) send relative to the frame tick according to a predefined dispatch schedule, where the frame tick is the beginning of a minor frame. The synchronized time of NICs is used for avoidance of collisions on the network. ASCB is part of the Primus Epic architecture, which does not leverage subframe timing (i.e., on actions based on time offsets within the minor period).

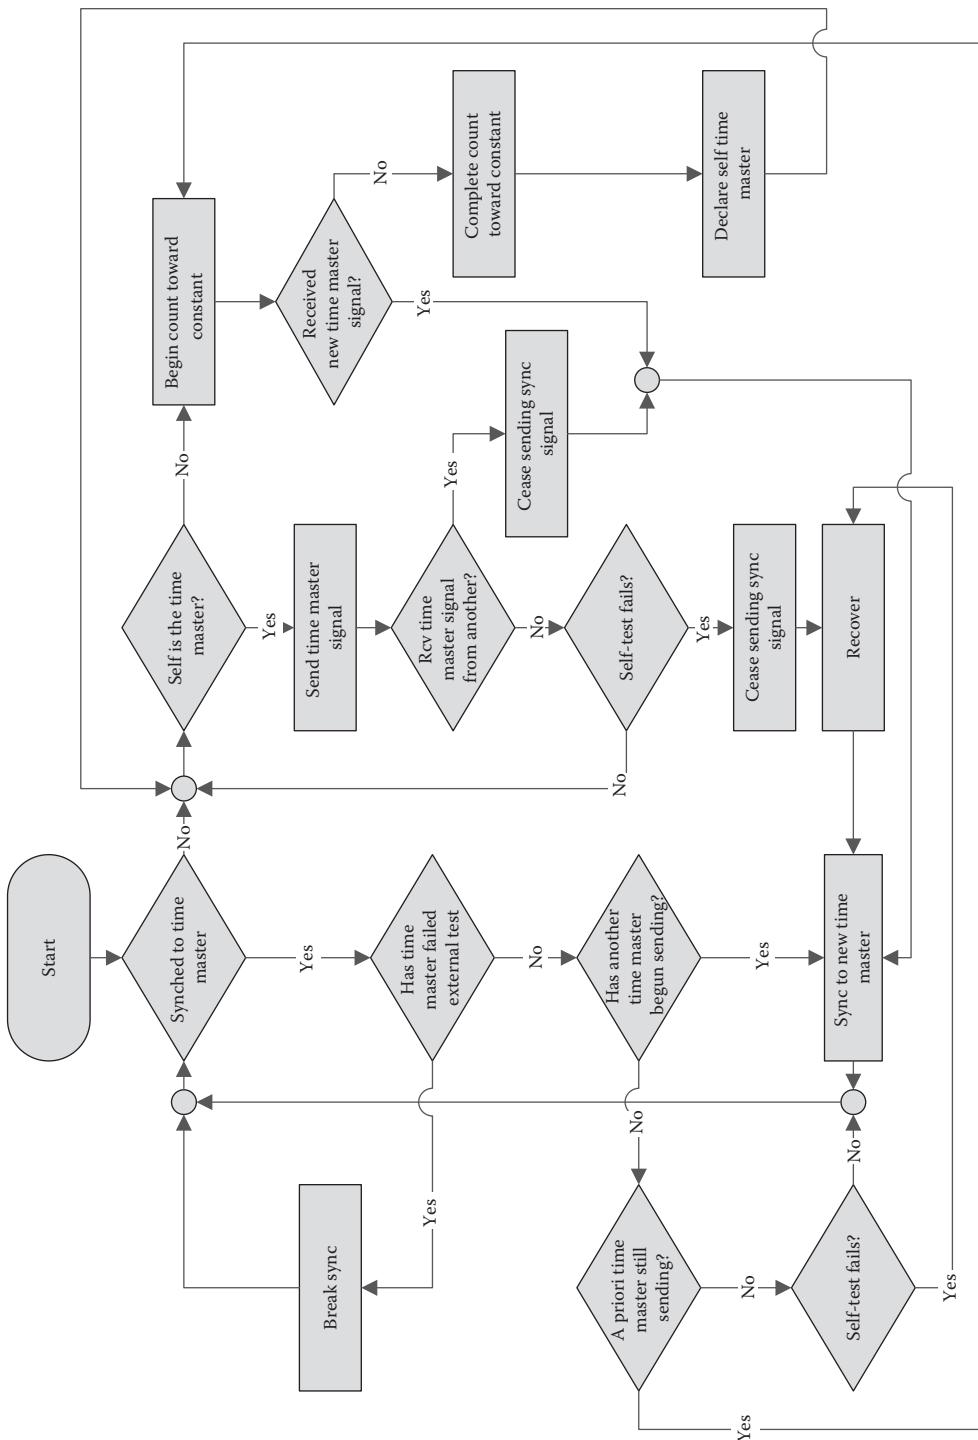

#### 44.2.2 Clock Synchronization, Restart, Reintegration, and Integration

Clock synchronization, start-up, or reintegration in Primus Epic is basically the same, as ASCB deploys a master-selection protocol between four cooperating masters called *time servers*. Each of the NICs (including time servers) needs to select one time server. The arbitration on which of the four time servers is selected by other NICs is based on a protocol of cooperating time servers leveraging strike counters and predetermined unique constants in case of conflicts between multiple time servers (multimaster conflict) or no master is active (mastership transition). The time server that first or last counts to its predetermined constant depending on the strike counter communicates its decision of being the timing master, which is then followed by other time servers. Start-up has to complete in 200 ms [4].

In more detail, each time server sends on both of its onside buses and receives the messages on the xsidex primary bus. A time master receives messages only on one of the onside buses (backup or primary). A time master sends a sync pulse at an offset from its frame tick (i.e., the start of its frame period) based on its ID. Each time server can derive the time difference between another time server's frame tick and its own by measuring the time difference between that server's sync pulse reception time and the expected reception time. Each time server can choose to synchronize to another time server's sync pulse by adjusting its local clock to account for the measured time difference with another time server's sync pulse so that their frame ticks are synchronized.

The protocol provides two strike counters at each time server, called *mastership transition* and *multimaster* strike count, with individual unique thresholds. The *time master* is the currently active time server driving the common time-base for all NICs, hence the names multimaster and mastership transition strike counters. The increment operations of the two strike counters are mutually exclusive. Each time server counts for different periods (using the mastership transition strike counter) in case no time master is detected and sends a sync pulse including indication of mastership (claiming the elected time server is the time master) on the bus in case the mastership transition count reaches the local unique threshold. Once the first one succeeds in sending this, other correct time servers back off and follow the time master. During the period of no time master, time servers run autonomously. If the situation occurs where multiple time servers claim mastership, a time server claiming mastership increases its multimaster strike count. The time server with the largest multimaster threshold wins. A time server gives up mastership and restarts when the multimaster strike count reaches the threshold and multiple time masters are still present. In case of connectivity issues, the synchronization master that does receive multiple synchronization masters does not back off and receives the mastership over other less well-connected masters. This second situation already assumes multiple errors. In case this also fails, the remaining units choose one master and follow its local master. The protocol is not guaranteed to resolve multiple failure scenarios.

The *external timing master test* is performed at certain points in time and is a test that is based upon the receiving sync pulses from other time masters and the relationship of sync pulses to each other. Examples for relationships are tests for periodicity, for temporal gap between successive synchronization signals, for errors in the order of arrival of synchronization signals, and for the absence of particular synchronization signals. The external time master test should prevent any time master from selecting a timing master with unacceptable timing integrity and detect the absence of the timing master. The *self-test* implements a self-monitor and deactivation component in the algorithm. Each time server validates its own timing integrity and deactivates itself when it does not have the required integrity. The time server performs a sync pulse wraparound monitor of the frame counter, a frame tick periodicity monitor, and a local clock integrity monitor. The *break sync action* in Figure 44.3 implies that a master

**FIGURE 44.3** Flow diagram of ASCB/D synchronization, integration, and start-up algorithms. (From Davidson, D.D. and Chiu, V.Y., Fail-operational global time reference in a redundant synchronous data bus system, Patent Application US 2005/0102586 A1, Honeywell, May 12, 2005.)

that is sure that it is the correct master—based on these locally performed tests (external and self test)—does indicate this to other time masters via sending a synchronization signal claiming mastership or indicating that it wants to take over mastership. Figure 44.3 provides a graphical overview of the ASCB start-up and clock synchronization algorithm.

Please note that the algorithm may have changed slightly due to reported incidents tracing back to synchronization [8].

#### 44.2.3 Diagnostic Services

Examples of diagnostic services are already explained earlier in the synchronization section, where time servers check their correctness based on externally stimulated events. Similarly, NICs perform built-in extensive self-tests at power-up and some continuous self-tests during operation. Heartbeats for power and microcontrollers are deployed and are based, for example, upon the frequency of data transmissions.

#### 44.2.4 Fault Isolation

Fault isolation in ASCB is implemented by the separation of data buses and listen-only connections to primary buses as a first defense. Secondary data buses, which are buses that are limited to one side only, serve as a second level of defense. Transceiver functions for different buses are separated.

#### 44.2.5 Configuration Services

Configuration of ASCB is performed via a special network, a separate local-area connection. This is used to configure local configuration tables of networks and processors. This network can also be used for the monitoring of operation.

### 44.3 Protocol Parameterization

---

The communication schedule is composed of multiple minor frames (12.5 ms) in powers of 2 up to 1 s. Exact sending patterns are designed and automatically scheduled by a tool called ESCAPE (Essential System Configuration and Architecture for Primus Epic). Data groups, so-called parameter groups, are handled as a unit, meaning that they are used only if the correctness and completeness checks of all elements of these groups are correct. A correctness check is, for example, whether the error detection codes associated with this data group are correct. A data group is a logical unit, which also implies that a group does not necessarily need to be transmitted in the same Ethernet frame.

Data elements sent on the network are scheduled at frame level (frame is used here in the sense of a frame period). That is, the location of a message (Ethernet frame) within the frame period does not matter for end-to-end latency calculations for applications. The data transmitted during a frame period are not immediately used within this frame period, but only in the next frame period. This allows deploying very simple scheduling algorithms at the expense of delay. Effectively, the frame-period-level scheduling approach decouples any dependencies between the network timing table and operating system (OS) timing tables. Consequently, the delay from one data element in an application is always larger than a minor frame period. Actually, as this principle is deployed based on the frequency of the application, the delay is always larger than the frame period of the application at which the application is run.

### 44.4 Communication Interface

---

The communication interfaces in Primus Epic are generally using ping/pong buffers. These are double buffers, where one buffer is used by the application in one period, while the other buffer is used for updates by the network in the same period. This way, network traffic does not overwrite the data that

are currently used by the application and vice versa. At a predefined point in time, namely, at the period boundaries, the role of the buffers changes, and the other buffer that has been reserved by the application is now used by the network for sending and receiving.

## 44.5 Validation and Verification Efforts

---

ASCB core algorithms, such as clock synchronization, have been verified under the covered fault assumptions and is described in [4,5]. ASCB has been developed using the common applicable aerospace standards for design including DO-178b.

## 44.6 Example Configuration and Implementation: ASCB in Primus Epic

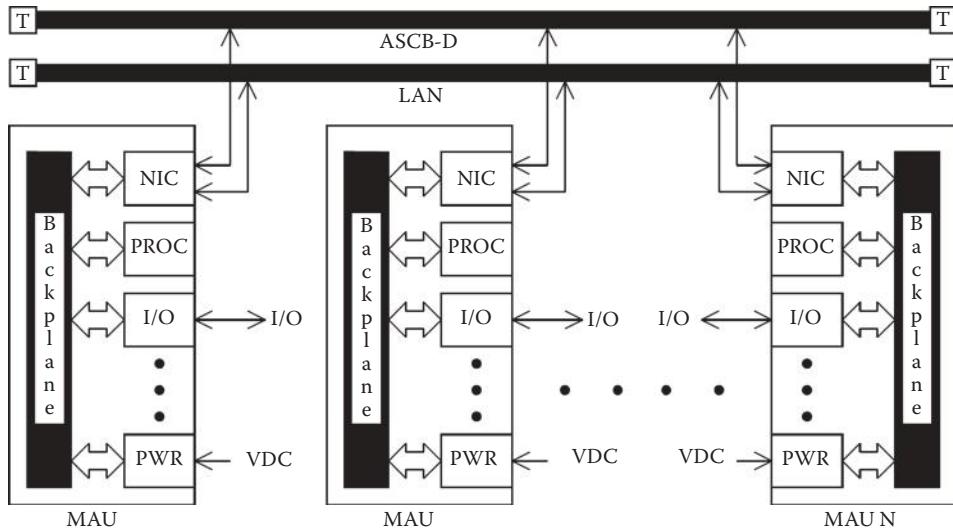

---

Primus Epic is one of Honeywell's avionics platforms for general, business, and regional aviation. The general aviation market comprises small multiple-seater aircraft, the business aviation market mainly consists of comfortable small turbo-engine-powered aircraft for business clients, and regional aviation aircraft are single-aisle medium aircraft flying regionally with up to about 100 passengers. Honeywell deploys the Primus Epic avionics suite in such aircrafts. In one instance, Primus Epic is also deployed on a helicopter. The biggest market, however, is business aviation. Specifically, Primus Epic is used on the following certified airframes: Agusta AW139 (helicopter), Cessna Citation Sovereign, Dassault Falcon 2000DX, Dassault Falcon 2000LX, Dassault Falcon 900DX, Dassault Falcon 900EX, Dassault Falcon 900LX, Dassault Falcon 7X, Gulfstream 350, Gulfstream 450, Gulfstream 500, Gulfstream 550, Gulfstream 650, Raytheon Hawker 4000, Embraer 170/175, and Embraer 190/195. Further aircraft using Primus Epic are under development.

Primus Epic is an avionics suite consisting of single or multiple racks and cabinets with integrated circuit cards/modules, which are installed in slots in the cabinets. Each module can contain one or more functions. Each cabinet's configuration can vary by the number of modules installed in each cabinet and the functions loaded into the modules. There can be multiple racks and cabinets installed on the aircraft. The software loaded into the modules determines the functionality of the system modules. The modular avionics unit (MAU) is a hardware cabinet containing field-replaceable modules that represent the *building blocks* of the Primus Epic system. The MAU incorporates input/output (I/O), processing, and database storage modules linked to ASCB and LAN aircraft-wide networks via the NIC modules. Primus Epic deploys a concept called *Virtual Backplane*, meaning that the physical location (e.g., cabinet) of a module is not important. All data generated by any one function within the system are *globally* available to any other function. This makes the MAU flexible and adaptive, allowing for more options in locating and mounting equipment on the aircraft. The integration of processing into a single processing unit (in the meaning of a card) means that it can be shared to perform multiple tasks previously requiring individual processors. This increases the integration results in improved power, weight, reliability, maintainability, and volume. The Primus Epic system redundancy can support multiple redundancy concepts, among others a dual-dual replication arrangement for system redundancy [6].

Summarizing, Honeywell claims that deployment of Primus Epic with its MAU, modular radio cabinets, and flat panel displays provides the following advantages over existing avionics suites mainly due to integration and improved technology deployment:

- Lower total acquisition costs
- Higher reliability and dispatchability
- Improved maintainability
- Lower weight and power
- Lower wire count and installation costs

**FIGURE 44.4** Primus Epic buses. (Courtesy of Honeywell.)

- Increased functionality
- Large growth capability
- Lower pilot workload and increased safety
- Open architecture by supplying development kits to third-party module suppliers

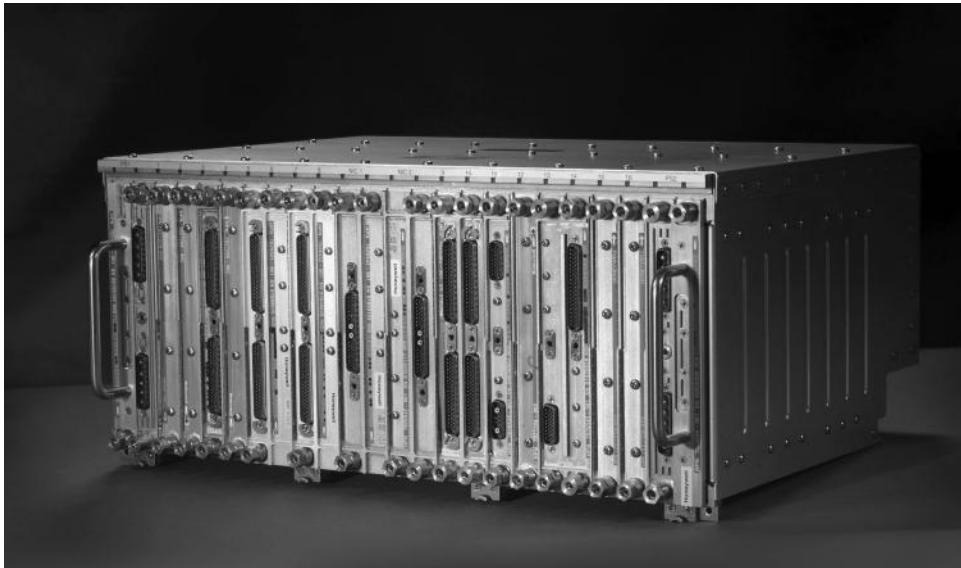

Figure 44.4 provides a high-level diagram of Primus Epic's compute and on-board communication architecture. Primus Epic in this example consists of multiple MAUs. ASCB-D is depicted as one network in Figure 44.4. The detailed four-bus diagram can be found in Figure 44.6. Furthermore, a LAN is shown, which is used for system maintenance, diagnostics, software and table loading tasks, and a printer. The LAN is an Ethernet 10Base2 network. In each MAU, one or two NICs connect the system-level data sent on ASCB with the backplane databus, a version of Compact PCI (industrial version of PCI derated to 25 MHz being 32-bit-wide). Power modules provide local power to the modules in the cabinet. I/O cards provide interfaces to sensor and actuator data as well as integrate other more federated aircraft systems into the Primus Epic architecture.

Figure 44.5 shows a picture of one Primus Epic cabinet (MAU).

Figure 44.6 depicts an example Primus Epic deployment with two MAUs in the center. Many peripheral, display, utility, sensor, and actuator systems/devices are also shown.

Primus Epic distinguishes itself from other avionics platforms in that it deploys a special OS called DEOS, which stands for *digital engine operating system*. DEOS is a DO-178B level A OS deployed in Federal Aviation Administration-certified environments. It allows multiple software applications/levels to execute on the same processor and provides time and space (memory, I/O) partitioning. Associated with DEOS is a consistent software development method throughout engineering using COTS and custom tools that help in isolating software from hardware. DEOS supports reduction of revalidation and verification efforts of software that changes.

DEOS differs from earlier ARINC 653 [9–11] systems in that it uses preemptive fixed priority (PFP) scheduling, and consequently the time partitioning model includes preemption. The most well-known PFP algorithm is rate-monotonic scheduling [12], where tasks with higher rate have higher priority. Additionally, DEOS supports dynamic thread and dynamic time partition allocation. Upgrades of DEOS slack and time partitioning lead to several improvements. For example, about a threefold increase in communication throughput between a processor and a remote file server and approximately a sevenfold

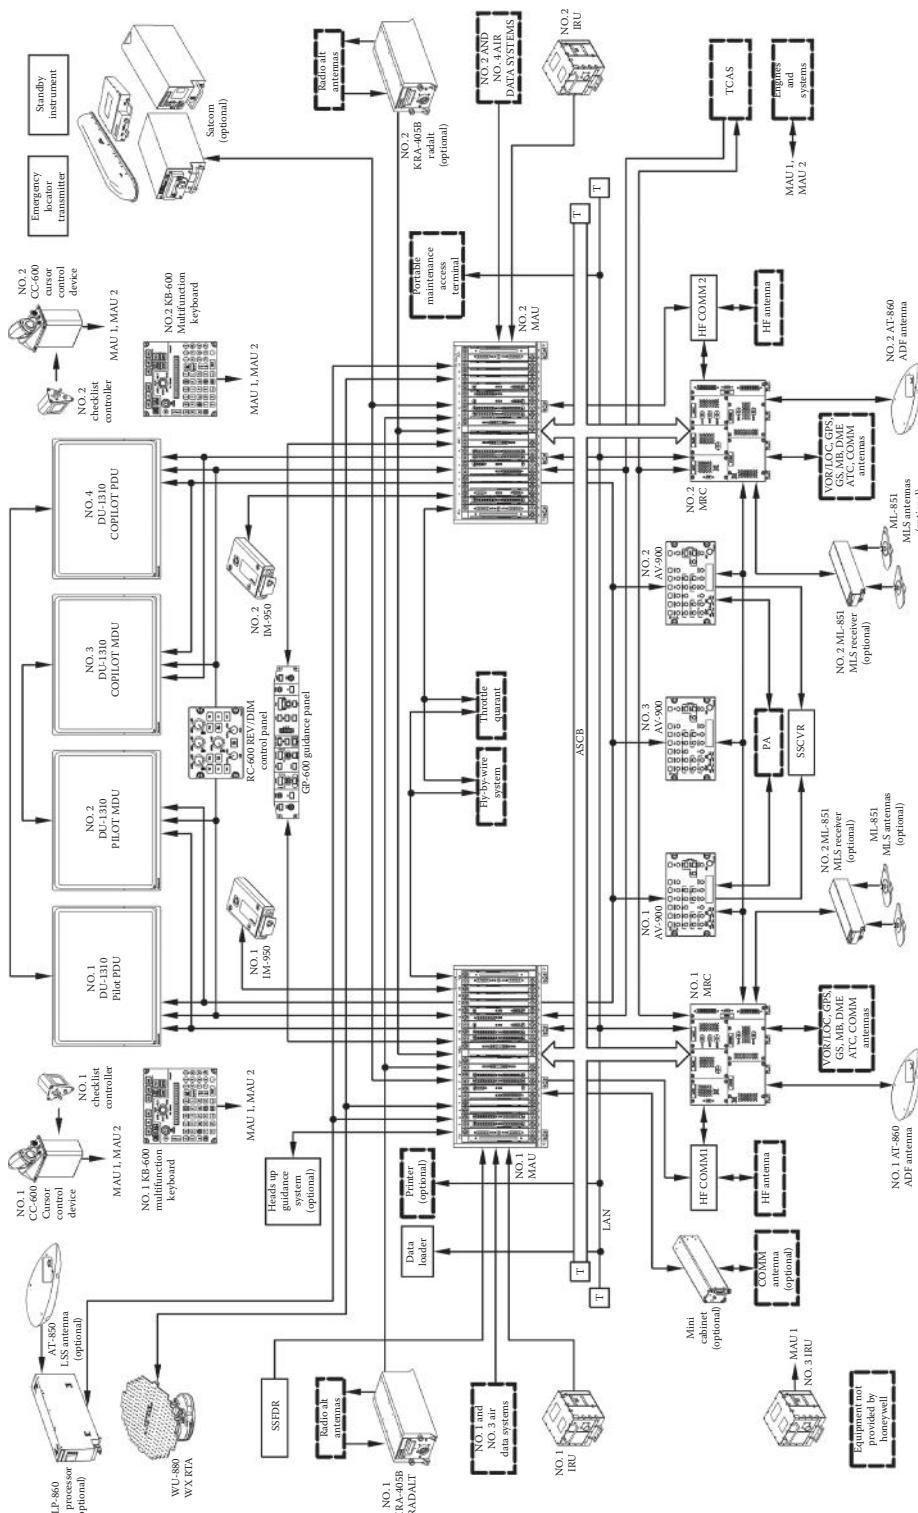

**FIGURE 44.5** Primus Epic cabinet (MAU). (Courtesy of Honeywell.)

reduction in the amount of a priori reserved execution time required for response times of noncritical applications were reported. Also, certain display tasks were able to achieve higher average refresh update rates using slack. DEOS algorithms provide robust time partitioning capabilities, enabling the safe cohosting of COTS software with safety-critical software without decreases in the COTS software performance [13].

The concept of *slack stealing* has been a unique feature in safety-critical OSs deployed in aerospace and in DEOS. It enables many improvements like higher processor utilization and quicker response times. Slack stealing is a preemptive processor scheduling algorithm that delays the execution of high-priority periodic tasks to improve response times of aperiodic tasks provided the periodic tasks will not miss any of their deadlines. When the set of periodic tasks is fixed, there is predictable slack inherent in the execution timeline, known as timeline slack, for threads scheduled using PFP scheduling. Timeline slack can be calculated offline, and table lookups can be used at runtime, in combination with other quantities, to quickly determine the amount of time a periodic task can be delayed and still meet its deadline. Slack stealing also makes available reclaimed slack or equivalently unused worst-case compute time of periodic tasks at the priority at which the compute time was initially reserved [13].

The key for the success of slack stealing in DEOS is the relatively high worst-case execution times compared to actual average execution times. Slack stealing boosts processor utilization efficiency and reduces response times significantly. As can be imagined, slack *moves* the actual execution time of tasks within a frame period. This may be a good illustration for readers to understand why Primus Epic does not deploy subframe-level scheduling. Subframe-level scheduling is a concept denoting the fact that data sent on a network are used by an application with its frame period (i.e., on actions based on time offsets within the frame period). This may tightly couple processor and network execution time. As slack requires some *freedom* of moving actual task execution times within its frame period, Primus Epic designers have chosen *not* to leverage end-to-end worst-case latency improvements obtained by deploying subframe-scheduling, but rather leverage the slack of execution time to boost performance. Each approach has its advantages, but both cannot practically be deployed at the same time.

### 45.1 Introduction

---

ARINC specifications 419, 429, and 629 and Project Paper 453 are documents prepared by the Airlines Electronic Engineering Committee (AEEC) and published by Aeronautical Radio Inc. (ARINC). These are among over 300 air transport industry avionics standards published since 1949. These documents, commonly referred to as ARINC 419, ARINC 429, ARINC 453, and ARINC 629, describe data communication systems used primarily on commercial transport airplanes, but which are also used by general aviation and military airplanes. The differences between the systems are described in detail in the subsequent sections.

## 45.2 ARINC 419

---

ARINC specification 419, “Digital Data Compendium,” provides detailed descriptions of the various interfaces used in the ARINC 500 series of avionics standards prior to 1980. ARINC 419 is often incorrectly assumed to be a stand-alone bus standard. It provides a summary of electrical interfaces, protocols, and data standards for avionics built prior to the airlines’ selection of a single standard (i.e., ARINC 429) for the distribution of digital information aboard aircraft.

## 45.3 ARINC 429

---

### 45.3.1 General

ARINC specification 429, “Digital Information Transfer System (DITS),” was first published in 1977 and has since become the ARINC standard most widely used by the airlines. The title of this airline standard was chosen so as not to describe it as a “data bus.” Although ARINC 429 is a vehicle for data transfer, it does not fit the normal definition of a data bus. A typical data bus provides multidirectional transfer of data between multiple points over a single set of wires. ARINC 429’s simplistic one-way flow of data significantly limits this capability, but the associated low cost and the integrity of the installations have provided the airlines with a system exhibiting excellent service for more than two decades. Additional information regarding avionics standards may be found at <http://www.aviation-ia.com/aec>.

### 45.3.2 History

In the early 1970s, the airlines recognized the potential advantage of implementation of digital equipment. Some digital equipment had already been implemented to a certain degree on airplanes existing at that time. However, there were three new transport airplanes on the horizon: the Airbus A-310 and the Boeing B-757 and B-767. The airlines, along with the airframe and equipment manufacturers, established a goal to create an all-new suite of avionics using digital technology.

With digital avionics came the need for an effective means of data communications among the avionics units. The airlines recognized that the military was also in the early stages of development of a data bus that could perform the data transfer functions among military avionics. A joint program to produce a data bus common to the air transport industry and the military suggested a potential for significant economical benefits.

The Society of Automotive Engineers (SAE) took on the early work to develop the military’s data bus. Participants in the SAE program came from many parts of the military and private sectors of aviation. Considerable effort went into defining all aspects of the data bus with the goal of meeting the needs of both the military and air transport users. That work culminated in the development of the early version of the data bus identified by Mil-Std 1553 (see Chapter 1).

Early in the process of the Mil-Std 1553 development, representatives from the air transport industry realized that the stringent and wide range of military requirements would cause the Mil-Std 1553 to be overly complex for the commercial user and would not exhibit the flexibility to accommodate the varying applications of transport airplanes. Difficulty in certification also was considered a potential problem. The decision was made to abandon a cooperative data bus development program with the military and pursue work on a data bus to more closely reflect commercial airplane requirements.

The numerous single transmitter and multiple receiver data transfer systems used on airplanes built in the early 1970s proved to be reliable and efficient compared to the more complex data buses of the time. These transfer systems, described in ARINC 419, were considered as candidates for the new digital aircraft.

Although none of the systems addressed in the ARINC specification could adequately perform the task, each exhibited desirable characteristics that could be applied to a new design. The result was the

release of a new data transfer system exhibiting a high level of efficiency, extremely good reliability, and ease of certification. ARINC 429 became the industry standard. Subsequent to release of the standard, solid-state component manufacturers produced numerous low-cost integrated circuits. ARINC 429 was used widely by the air transport industry and even found applications in nonaviation commercial and military applications. ARINC 429 has been used as the standard for virtually all ARINC 700-series standards for “digital avionics” used by the air transport industry.

ARINC has maintained and provided the necessary routine updates for new data word assignments and formats. There were no significant changes in the basic design until 1980, when operational experience showed that certain shorted wire conditions would allow the bus to operate in a faulty condition with much reduced noise immunity. This condition also proved to be very difficult to locate during routine maintenance. In response, the airlines suggested that the design be changed to ensure that the bus would not continue to operate when this condition occurred, and a change to the receiver voltage thresholds and impedances solved this problem.

No basic changes to the design have been made since that time. ARINC 429 has remained a reliable system and even today is used extensively in the most modern commercial airplanes.

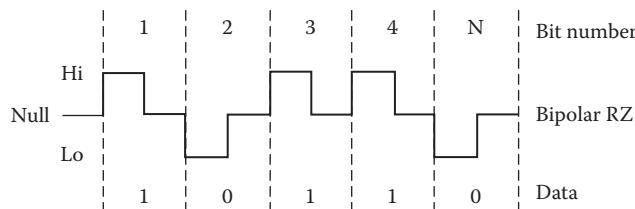

### 45.3.3 Design Fundamentals

#### 45.3.3.1 Equipment Interconnection

A single transmitter is connected with up to 20 data receivers via a single twisted and shielded pair of wires. The shields of the wires are grounded at both ends and at any breaks along the length of the cable. The shields' connections to the ground should be kept as short as possible.

#### 45.3.3.2 Modulation

Return-to-Zero (RZ) modulation is used. The voltage levels are used for this modulation scheme.

#### 45.3.3.3 Voltage Levels

The differential output voltages across the transmitter output terminal with no load is described in the following table:

	HI (V)	NUL (V)	LO (V)
Line A to line B	+10 ± 1.0	0 ± 0.5	-10 ± 1.0
Line A to ground	5 ± 0.5	0 ± 0.25	-5 ± 0.5
Line B to ground	-5 ± 0.5	0 ± 0.25	5 ± 0.5

The differential voltage seen by the receiver will depend on wire length, loads, stubs, and so on. With no noise present on the signal lines, the nominal voltages at the receiver terminals (A and B) would be the following:

- HI +7.25 V to +11 V
- NULL +0.5 V to -0.5 V
- LO -7.25 V to -11 V

In practical installations impacted by noise, and so on, the following voltage ranges will be typical across the receiver input (A and B):

- HI +6.5 V to +13 V
- NULL +2.5 V to -2.5 V
- LO -6.5 V to -13 V

Line (A or B) to ground voltages are not defined. Receivers are expected to withstand without damage steady-state voltages of 30 volts alternating current (VAC) root mean square (RMS) applied across terminals A and B, or volts direct current (VDC) applied between terminal A or B and the ground.

#### 45.3.3.4 Impedance Levels

##### 45.3.3.4.1 Transmitter Output Impedance

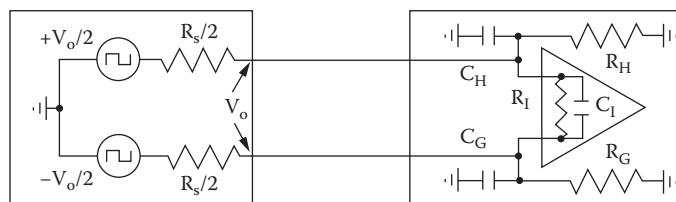

The transmitter output impedance is 70–80 (nominal 75)  $\Omega$  and is divided equally between lines A and B for all logic states and transitions between those states.

##### 45.3.3.4.2 Receiver Input Impedance

The typical receiver input characteristics are as follows:

- Differential Input Resistance  $R_I = 12,000 \Omega$  minimum
- Differential Input Capacitance  $C_I = 50 \text{ pF}$  maximum
- Resistance to Ground  $R_H$  and  $R_G \geq 12,000 \Omega$
- Capacitance to Ground  $C_H$  and  $C_G \leq 50 \text{ pF}$

The total receiver input resistance, including the effects of  $R_I$ ,  $R_H$ , and  $R_G$  in parallel, is 8000  $\Omega$  minimum (400  $\Omega$  minimum for 20 receivers). A maximum of 20 receivers is specified for any one transmitter. See below for the circuit standards.

##### 45.3.3.4.3 Cable Impedance

The wire gauges used in the interconnecting cable will typically vary between 20 and 26 depending on desired physical integrity of the cable and weight limitations. Typical characteristic impedances will be in the range of 60–80 ohms. The transmitter output impedance was chosen at 75 ohms nominal to match this range.

#### 45.3.3.5 Fault Tolerance

A generator on each engine provides the electrical power on an airplane. The airplane electrical system is designed to take into account any variation in, for example, engine speeds, phase differentials, and power bus switching. However, it is virtually impossible to ensure that the power source will be perfect at all times. Failures within a system can also cause erratic power levels, and the design of the ARINC 429 components takes power variation into account and is not generally susceptible to either damage or erratic operation when those variations occur. The ranges of those variations are provided in the following sections.

##### 45.3.3.5.1 Transmitter External Fault Voltage

Transmitter failures caused by external fault voltages will not typically cause other transmitters or other circuitry in the unit to function outside of their specification limits or to fail.

#### 45.3.3.5.2 Transmitter External Fault Load Tolerance

Transmitters should indefinitely withstand without sustaining damage a short circuit applied (a) across terminals A and B, (b) from terminal A to ground, (c) from terminal B to ground, or (d) b and c simultaneously.

#### 45.3.3.6 Fault Isolation

##### 45.3.3.6.1 Receiver Fault Isolation

Each receiver incorporates isolation provisions to ensure that the occurrence of any reasonably probable internal line replaceable unit (LRU) or bus receiver failure does not cause any input bus to operate outside its specification limits (both undervoltage and overvoltage).

##### 45.3.3.6.2 Transmitter Fault Isolation

Each transmitter incorporates isolation provisions to ensure that it does not undermine any reasonably probable equipment fault condition providing an output voltage in excess of (a) 30 VAC RMS between terminal A and B, (b) +29 VDC between A and ground, or (c) +29 VDC between B and ground.

#### 45.3.3.7 Logic-Related Elements

This section describes the digital transfer system elements considered to be principally related to the logic aspects of the signal circuit.

##### 45.3.3.7.1 Digital Language

**45.3.3.7.1.1 Numeric Data** The ARINC 429 accommodates numeric data encoded in two digital languages: BNR expressed in two's complement fractional notation and binary coded decimal (BCD) per the numerical subset of International Standards Organization (ISO) Alphabet No. 5. An information item encoded in both BCD and BNR is assigned unique labels for both BCD and BNR (see Section 45.4.3).

**45.3.3.7.1.2 Discrete Data** In addition to handling numeric data as specified above, ARINC 429 is also capable of accommodating discrete items of information either in the unused (pad) bits of data words or, when necessary, in dedicated words.

The rule in the assignment of bits in discrete numeric data words is to start with the least significant bit (LSB) of the word and to continue toward the most significant bit available in the word. There are two types of discrete words: general-purpose discrete words and dedicated discrete words. Seven labels (270 XX-276 XX) are assigned to the general-purpose discrete words. These words are assigned in ascending label order (starting with 270 XX), where XX is the equipment identifier.

32	31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1

P	SSM	Data →								← Pad								← Discretes			SDI		Label								

Generalized BCD word format

**45.3.3.7.1.3 Maintenance Data (General Purpose)** The general-purpose maintenance words are assigned labels in sequential order, as are the labels for the general-purpose discrete words. The lowest octal value label assigned to the maintenance words is used when only one maintenance word is transmitted. When more than one word is transmitted, the lowest octal value label is used first, and the other labels are used sequentially until the message has been completed. The general-purpose maintenance words may contain discrete, BCD, or BNR numeric data. They do not contain ISO Alphabet No. 5 messages. The general-purpose maintenance words are formatted according to the layouts of the corresponding BCD, BNR, and discrete data words shown in the word formats above.

## 45.4 Message and Word Formatting

---

### 45.4.1 Direction of Information Flow

The information output of a system element is transmitted from a designated port (or ports) to which the receiving ports of other system elements in need of that information are connected. In no case does information flow into a port designated for transmission. A separate data bus (twisted and shielded pair of wires) is used for each direction when data are required to flow both ways between two system elements.

### 45.4.2 Information Element

The basic information element is a digital word containing 32 bits. There are five application groups for such words: BNR data, BCD data, discrete data, general maintenance data and acknowledgment, ISO Alphabet No. 5, and maintenance (ISO Alphabet No. 5) data (AIM). The relevant data-handling rules are set forth in Section 45.4.6. When less than the full data field is needed to accommodate the information conveyed in a word in the desired manner, the unused bit positions are filled with binary zeros or, in the case of BNR and BCD numeric data, valid data bits. If valid data bits are used, the resolution may exceed the accepted standard for an application.

### 45.4.3 Information Identifier

A six-character label identifies the type of information contained in a word. The first three characters are octal characters coded in binary in the first 8 bits of the word. The 8 bits will identify the information contained within BNR and BCD numeric data words (e.g., DME distance, static air temperature, etc.) and identify the word application for discrete, maintenance, and AIM data.

The last three characters of the six-character label are hexadecimal characters used to identify ARINC 429 bus sources. Each triplet of hexadecimal characters identifies a system element with one or more DITS ports. Each three-character code (and black box) may have up to 255 8-bit labels assigned to it. The code is used administratively to retain distinction between unlike parameters having like label assignments.

Octal label 377 has been assigned for the purpose of electrically identifying the system element. The code appears in the three least significant digits of the 377 word in a BCD word format. Although data encoding is based on the BCD word format, the sign/status matrix (SSM) encoding is per the discrete word criteria to provide enhanced failure warning. The transmission of the equipment identifier word on a bus will permit receivers attached to the bus to recognize the source of the DITS information. Since the transmission of the equipment identifier word is optional, receivers should not depend on that word for correct operation.

### 45.4.4 Source/Destination Identifier

Bit numbers 9 and 10 of numeric data words are used for a data source and destination identification function. They are not available for this function in alphanumeric (ISO Alphabet No. 5) data words

**TABLE 45.1 SDI Encoding**

Bit No.		Installation
10	9	See text
0	0	—
0	1	1
1	0	2
1	1	3

*Note:* In certain specialized applications of the SDI function, the all-call capability may be forfeited so that code "00" is available as an "installation no. 4" identifier.

or when the resolution needed for numeric (BNR/BCD) data necessitates their use for valid data. The source and destination identifier function may be applied when specific words need to be directed to a specific system of a multisystem installation or when the source system of a multisystem installation needs to be recognizable from the word content. When it is used, a source equipment encodes its aircraft installation number in bits 9 and 10 as shown in Table 45.1. A sink equipment will recognize words containing its own installation number code and words containing code "00," the "all-call" code.

Equipment will fall into the categories of source only, sink only, or both source and sink. Use of the SDI bits by equipment functioning only as a source or only as a sink is described above. Both the source and sink texts above are applicable to equipment functioning as both a source and a sink. Such equipment will recognize the SDI bits on the inputs and also encode the SDI bits, as applicable, on the outputs. DME, VOR, ILS (Instrument Landing System), and other sensors are examples of source and sink equipment generally considered to be only source equipment. These are actually sinks for their own control panels. Many other types of equipment are also misconstrued as source only or sink only. If a unit has a 429 input port and a 429 output port, it is a source and sink. With the increase of equipment consolidation (e.g., centralized control panels), the correct use of the SDI bits cannot be overstressed.

When the SDI function is not used, binary zeros or valid data should be transmitted in bits 9 and 10.

#### 45.4.5 Sign/Status Matrix

This section describes the coding of the SSM field. In all cases, the SSM field uses bits 30 and 31; for BNR data words, the SSM field also includes bit 29. The SSM field is used to report hardware equipment condition (fault/normal), operational mode (functional test), or validity of data word content (verified/no computed data). The following definitions apply:

*Invalid data:* This is defined as any data generated by a source system whose fundamental characteristic is the inability to convey reliable information for the proper performance of a user system. There are two categories of invalid data: (1) no computed data and (2) failure warning.

*No computed data:* This is a particular case of data invalidity in which the source system is unable to compute reliable data for reasons other than system failure. This inability to compute reliable data is caused exclusively by a definite set of events or conditions whose boundaries are uniquely defined in the system characteristic.

*Failure warning:* This is a particular case of data invalidity in which the system monitors have detected one or more failures. These failures are uniquely characterized by boundaries defined in the system characteristic.

Displays are normally “flagged invalid” during a “failure warning” condition. When a “no computed data” condition exists, the source system indicates that its outputs are invalid by setting the SSM of the affected words to the “no computed data” code, as defined in the subsections that follow. The system indicators may or may not be flagged depending on system requirements.

While the unit is in the functional test mode, all output data words generated within the unit (i.e., pass-through words are excluded) are coded with “functional test.” Pass-through data words are those words received by the unit and retransmitted without alteration.

When the SSM code is used to transmit status and more than one reportable condition exists, the condition with the highest priority is encoded in bits number 30 and 31. The order of condition priorities is shown in the following table:

Failure warning	Priority 1
No computed data	Priority 2
Functional test	Priority 3
Normal operation	Priority 4

Each data word type has its own unique utilization of the SSM field. These various formats are described in the following sections.

#### 45.4.5.1 BCD Numeric

When a failure is detected within a system that would cause one or more of the words normally output by that system to be unreliable, the system stops transmitting the affected word or words on the data bus. Some avionics systems are capable of detecting a fault condition that results in less than normal accuracy. In these systems, when a fault of this nature (for instance, partial sensor loss which results in degraded accuracy) is detected, each unreliable BCD digit is encoded “1111” when transmitted on the data bus. For equipment having a display, the “1111” code should, when received, be recognized as representing an inaccurate digit and a dash or equivalent symbol is normally displayed in place of the inaccurate digit.

The sign (plus/minus, north/south, etc.) of BCD numeric data is encoded in bits 30 and 31 of the word as shown in Table 45.2. Bits 30 and 31 of BCD numeric data words are zero where no sign is needed.

The “no computed data” code is annunciated in the affected BCD numeric data words when a source system is unable to compute reliable data for reasons other than system failure. When the “functional test” code appears in bits 30 and 31 of an instruction input data word, it is interpreted as a command to perform a functional test.

#### 45.4.5.2 BNR Numeric Data Words

The status of the transmitter hardware is encoded in the status matrix field (bit numbers 30 and 31) of BNR numeric data words as shown in Table 45.3.

**TABLE 45.2 BCD Numeric Sign/Status Matrix**

Bit No.		Function
31	30	
0	0	Plus, north, east, right, to, above
0	1	No computed data
1	0	Functional test
1	1	Minus, south, west, left, from, below

**TABLE 45.3 Status Matrix**

Bit No.		Function
31	30	
0	0	Failure warning
0	1	No computed data
1	0	Functional test
1	1	Normal operation

A source system announces any detected failure that causes one or more of the words normally output by that system to be unreliable by setting bit numbers 30 and 31 in the affected word(s) to the “failure warning” code defined in Table 45.3. Words containing this code continue to be supplied to the data bus during the failure condition.

The “no computed data” code is announced in the affected BNR numeric data words when a source system is unable to compute reliable data for reasons other than system failure.

When the “functional test” code appears as a system output, it is interpreted as advice that the data in the word result from the execution of a functional test. A functional test produces indications of one-eighth of positive full-scale values unless indicated otherwise in an ARINC equipment characteristic.

If, during the execution of a functional test, a source system detects a failure that causes one or more of the words normally output by that system to be unreliable, it changes the states of bits 30 and 31 in the affected words such that the “functional test” annunciation is replaced with a “failure warning” annunciation.

The sign (plus, minus, north, south, etc.) of BNR numeric data words are encoded in the sign matrix field (bit 29) as shown in Table 45.4. Bit 29 is zero when no sign is needed.

Some avionics systems are capable of detecting a fault condition that results in less than normal accuracy. In these systems, when a fault of this nature (for instance, partial sensor loss, which results in degraded accuracy) is detected, the equipment will continue to report “normal” for the SSM while indicating the degraded performance by coding bit 11 as shown in Table 45.5.

This implies that degraded accuracy can be coded only in BNR words not exceeding 17 bits of data.

#### 45.4.5.3 Discrete Data Words

A source system announces any detected failure that could cause one or more of the words normally output by that system to be unreliable. Three methods are defined. The first method is to set bits 30 and 31 in the affected words to the “failure warning” code defined in Table 45.6. Words containing the “failure warning” code continue to be supplied to the data bus during the failure condition. When using the second method, the equipment may stop transmitting the affected word or words on the data bus. This method

**TABLE 45.4 Status Matrix**

Bit No. 29	Function
0	Plus, north, east, right, to, above
1	Minus, south, west, left, from, below

**TABLE 45.5 Accuracy Status**

Bit No.11	Function
0	Nominal accuracy
1	Degraded accuracy

**TABLE 45.6** Discrete Data Words

Bit No.		
31	30	Function
0	0	Verified data, normal operation
0	1	No computed data
1	0	Functional test
1	1	Failure warning

is used when the display or utilization of the discrete data by a system is undesirable. The third method applies to data words, which are defined such that they contain failure information within the data field. For these applications, the associated ARINC equipment characteristic specifies the proper SSM reporting. Designers are urged not to mix operational and built-in test equipment (BITE) data in the same word.

The “no computed data” code is annunciated in the affected discrete data words when a source system is unable to compute reliable data for reasons other than system failure. When the “functional test” code appears as a system output, it is interpreted as advice that the data in the discrete data word contents are the result of the execution of a functional test.

#### 45.4.6 Data Standards

The units, ranges, resolutions, refresh rates, number of significant bits, and pad bits for the items of information to be transferred by the Mark 33 DITS are administered by the AEEC and tabulated in ARINC characteristic 429.

ARINC characteristic 429 calls for numeric data to be encoded in BCD and binary, the latter using two's complement fractional notation. In this notation, the most significant bit of the data field represents half of the maximum value chosen for the parameter being defined. Successive bits represent the increments of a binary fraction series. Negative numbers are encoded as the two's complements of positive value and the negative sign is annunciated in the SSM.

In establishing a given parameter's binary data standards, the unit's maximum value and resolution are first determined in that order. The LSB of the word is then given a value equal to the resolution increment, and the number of significant bits is chosen such that the maximum value of the fractional binary series just exceeds the maximum value of the parameter (i.e., it equals the next whole binary number greater than the maximum parameter value less one LSB value). For example, to transfer altitude in units of feet over a range of zero to 100,000 ft with a resolution of 1 ft, the number of significant bits is 17 and the maximum value of the fractional binary series is 131,071 (i.e., 131,072 – 1).

Note that because accuracy is a quality of the measurement process and not the data transfer process, it plays no part in the selection of word characteristics. Obviously, the resolution provided in the data word should equal or exceed the accuracy not to degrade it.

For the binary representation of angular data, the ARINC 429 employs “degrees divided by” as the unit of data transfer and  $\pm 1$  (semicircle) as the range for two's complement fractional notation encoding (ignoring, for the moment, the subtraction of the LSB value). Thus, the angular range 0 through 359. XXX degrees is encoded as 0 through  $\pm 179$ .XXX degrees, the value of the most significant bit is one half semicircle, and there are no discontinuities in the code.

This may be illustrated as follows. Consider encoding the angular range 0–360 in one degree increments. Per the general encoding rules above, the positive semicircle will cover the range 0–179 (one LSB less than full range). All the bits of the code will be zeros for 0 and ones for 179, and the SSM will indicate the positive sign. The negative semicircle will cover the range 180–359. All the bits will be zeros for 180. The codes for angles between 181 and 359 will be determined by taking the two's complements of the fractional binary series for the result of subtracting each value from 360. Thus, the code for 181 is the two's complement of the code for 179. Throughout the negative semicircle, which includes 180, the SSM contains the negative sign.

## 45.5 Timing-Related Elements

---

This section describes the digital data transfer system elements considered to be principally related to the timing aspects of the signal circuit.

### 45.5.1 Bit Rate

*High-speed operation:* The bit rate for high-speed operation of the system is 100 kilobits per second (kbps)  $\pm 1\%$ .

*Low-speed operation:* The bit rate for low-speed operation of the system is within the range 12.0–14.5 kbps. The selected rate within this range is maintained within 1%.

### 45.5.2 Information Rates

The minimum and maximum transmit intervals for each item of information are specific by ARINC 429. Words with like labels but with different SDI codes are treated as unique items of information. Each and every unique item of information is transmitted once during an interval bounded in length by the specified minimum and maximum values. Stated another way, a data word having the same label and four different SDI codes will appear on the bus four times (once for each SDI code) during that time interval.

Discrete bits contained within data words are transferred at the bit rate and repeated at the update rate of the primary data. Words dedicated to discretes should be repeated continuously at specified rates.

### 45.5.3 Clocking Method

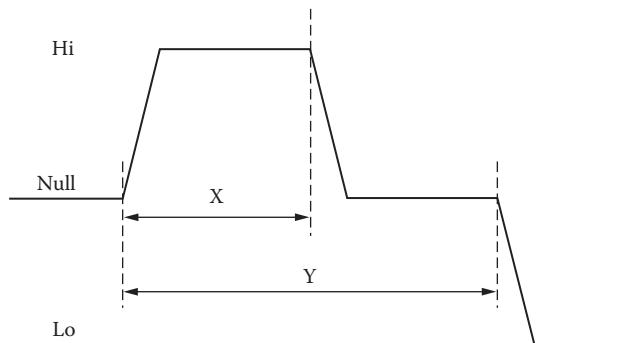

Clocking is inherent in the data transmission. The identification of the bit interval is related to the initiation of either a HI or LO state from a previous NULL state in a bipolar RZ code.

### 45.5.4 Word Synchronization

The digital word should be synchronized by reference to a gap of four bit times (minimum) between the periods of word transmissions. The beginning of the first transmitted bit following this gap signifies the beginning of the new word.

### 45.5.5 Timing Tolerances

The waveform timing tolerances are shown below. (Table 45.7)

**TABLE 45.7** Timing Tolerances

Parameter	High-Speed Operation	Low-Speed Operation
Bit rate	100 kbps $\pm$ 1%	12–14.5 kbps
Time Y	10 $\mu$ s $\pm$ 2.5%	Z <sup>a</sup> $\mu$ s $\pm$ 2.5%
Time X	5 $\mu$ s $\pm$ 5%	Y/2 $\pm$ 5%
Pulse rise time	1.5 $\pm$ 0.5 $\mu$ s	10 $\pm$ 5 $\mu$ s
Pulse fall time	1.5 $\pm$ 0.5 $\mu$ s	10 $\pm$ 5 $\mu$ s

<sup>a</sup> Z = 1/R, where R = bit rate selected from 12 to 14.5 kbps range.

**Note:** Pulse rise and fall times are measured between the 10% and 90% voltage amplitude points on the leading and trailing edges of the pulse and include time skew between the transmitter output voltages A-to-ground and B-to-ground.

## 45.6 Communications Protocols

### 45.6.1 Development of File Data Transfer

AEEC adopted ARINC 429 in July 1977. It defined a broadcast data bus with general provisions for file data transfer. In October 1989, AEEC updated a file data transfer procedure with a more comprehensive process that will support the transfer of both bit- and character-oriented data. The new protocol became known as the “Williamsburg Protocol.”

#### 45.6.1.1 File Data Transfer Techniques

This “file data transfer techniques” specification describes a system in which an LRU may generate binary extended length messages “on demand.” Data is sent in the form of link data units (LDUs) organized in 8-bit octets. System address labels (SALs) are used to identify the recipient. Two data bus speeds are supported.

#### 45.6.1.2 Data Transfer

The same principles of the physical layer implementation apply to file data transfer. Any avionics system element having information to transmit does so from a designated output port over a single twisted and shielded pair of wires to all other system elements having need of that information. Unlike the simple broadcast protocol that can deliver data to multiple recipients in a single transmission, the file transfer technique can be used only for point-to-point message delivery.

#### 45.6.1.3 Broadcast Data

The broadcast transmission technique described above can be supported concurrently with file data transfer.

#### 45.6.1.4 Transmission Order

The most significant octet of the file and LSB of each octet should be transmitted first. The label is transmitted ahead of the data in each case. It may be noted that the label field is encoded in reverse order (i.e., the LSB of the word is the most significant bit of the label). This “reversed label” characteristic is a legacy from past systems in which the octal coding of the label field was, apparently, of no significance.

#### 45.6.1.5 Bit-Oriented Protocol Determination

An LRU will require logic to determine which protocol (character- or bit-oriented) and which version to use when prior knowledge is not available.

## 45.6.2 Bit-Oriented Communications Protocol

This subsection describes Version 1 of the bit-oriented (Williamsburg) protocol and message exchange procedures for file data transfer between units desiring to exchange bit-oriented data assembled in data files. The bit-oriented protocol is designed to accommodate data transfer between sending and receiving units in a form compatible with the Open Systems Interconnect (OSI) model developed by the ISO. This document directs itself to an implementation of the link layer; however, an overview of the first four layers (physical, link, network, and transport) is provided.

Communications will permit the intermixing of bit-oriented file transfer data words (which contain system address labels [SALs]) with conventional data words (which contain label codes). If the sink should receive a conventional data word during the process of accepting a bit-oriented file transfer message, the sink should accept the conventional data word and resume processing of the incoming file transfer message.

The data file and associated protocol control information are encoded into 32-bit words and transmitted over the physical interface. At the link layer, data are transferred using a transparent bit-oriented data file transfer protocol designed to permit the units involved to send and receive information in multiple word frames. It is structured to allow the transmission of any binary data organized into a data file composed of octets.

*Physical medium:* The physical interface is described above.

*Physical layer:* The physical layer provides the functions necessary to activate, maintain, and release the physical link that will carry the bit stream of the communication. The interfacing units use the electrical interface, voltage, and timing described earlier. Data words will contain 32 bits; bits 1–8 will contain the SAL and bit 32 will be the parity (odd) bit.

*Link layer:* The link layer is responsible for transferring information from one logical network entity to another and for enunciating any errors encountered during transmission. The link layer provides a highly reliable virtual channel and some flow control mechanisms.

*Network layer:* The network layer performs a number of functions to ensure that data packets are properly routed between any two terminals. The network layer expects the link layer to supply data from correctly received frames. The network layer provides for the decoding of information up to the packet level to determine which node (unit) the message should be transferred to. To obtain interoperability, this process, though simple in this application, must be reproduced using the same set of rules throughout all the communications networks (and their subnetworks) on-board the aircraft and on the ground. The bit-oriented data link protocol was designed to operate in a bit-oriented network layer environment. Specifically, ISO 8208 would typically be selected for the subnetwork layer protocol for air and ground subnetworks. There are, however, some applications in which the bit-oriented file transfer protocol will be used under other network layer protocols.

*Transport layer:* The transport layer controls the transportation of data between a source end-system to a destination end-system. It provides “network independent” data delivery between these processing end-systems. It is the highest order function involved in moving data between systems and it relieves higher layers from any concern specifically with the transportation of information between them.

### 45.6.2.1 Link Data Units

An LDU contains binary encoded octets. The octets may be set to any possible binary value. The LDU may represent raw data, character data, bit-oriented messages, character-oriented messages, or any string of bits desired. The only restriction is that the bits must be organized into full 8-bit octets. The interpretation of those bits is not a part of the link layer protocol. The LDUs are assembled to make up a data file.

LDUs consist of a set of contiguous ARINC 429 32-bit data words, each containing the SAL (see Section 45.6.2.3) of the sink. The initial data word of each LDU is a start of transmission (SOT). The data described above are contained within the data words that follow. The LDU is concluded with an end of transmission (EOT) data word. No data file should exceed 255 LDUs.

Within the context of this document, LDUs correspond to frames and files correspond to packets.

#### 45.6.2.2 Link Data Unit Size and Word Count

The LDU may vary in size from 3 to 255 ARINC 429 words including the SOT and EOT words. When an LDU is organized for transmission, the total number of ARINC 429 words to be sent (word count) is calculated. The word count is the sum of the SOT word, the data words in the LDU, and the EOT word. In order to obtain maximum system efficiency, the data is typically encoded into the minimum number of LDUs.

The word count field is 8 bits in length. Thus, the maximum number of ARINC 429 words that can be counted in this field is 255. The word count field appears in the request to send (RTS) and clear to send (CTS) data words. The number of LDUs needed to transfer a specific data file will depend upon the method used to encode the data words.

#### 45.6.2.3 System Address Labels

LDUs are sent point-to-point, even though other systems may be connected and listening to the output of a transmitting system. In order to identify the intended recipient of a transmission, the label field (bits 1–8) is used to carry a SAL. Each on-board system is assigned a SAL. When a system sends an LDU to another system, the sending system (the source) addresses each ARINC 429 word to the receiving system (the sink) by setting the label field to the SAL of the sink. When a system receives any data containing its SAL that is not sent through the established conventions of this protocol the data are ignored.

In the data transparent protocol data files are identified by content rather than by an ARINC 429 label. Thus, the label field loses the function of parameter identification available in broadcast communications.

#### 45.6.2.4 Bit Rate and Word Timing

Data transfer may operate at either high speed or low speed. The source introduces a gap between the end of each ARINC 429 word transmitted and the beginning of the next. The gap should be 4 bit times (minimum), and the sink should be capable of receiving the LDU with the minimum word gap of 4 bit times between words. The source should not exceed a maximum average of 64 bit times between data words of an LDU.

The maximum average word gap is intended to compel the source to transmit successive data words of an LDU without excessive delay. This provision prevents a source that is transmitting a short message from using the full available LDU transfer time. The primary value of this provision is realized when assessing a maximum LDU transfer time for short fixed-length LDUs, such as for automatic dependence surveillance (ADS).

If a Williamsburg source device were to synchronously transmit long-length or full LDUs over a single ARINC 429 data bus to several sink devices, the source may not be able to transmit the data words for a given LDU at a rate fast enough to satisfy this requirement because of other bus activity. In aircraft operation, given the asynchronous burst mode nature of Williamsburg LDU transmissions, it is extremely unlikely that a Williamsburg source would synchronously begin sending a long-length or full LDU to more than two Williamsburg sink devices. A failure to meet this requirement will result in either a successful (but slower) LDU transfer or an LDU retransmission due to an LDU transfer time-out.

### 45.6.2.5 Word Type

The Word Type field occupies bits 31–29 in all bit-oriented LDU words and is used to identify the function of each ARINC 429 data word used by the bit-oriented communication protocol.

### 45.6.2.6 Protocol Words

The protocol words are identified with a Word Type field of 100 and are used to control the file transfer process.

#### 45.6.2.6.1 *Protocol Identifier*

The protocol identifier field occupies bits 28–25 of the protocol word and identifies the type of protocol word being transmitted. Protocol words with an invalid protocol identifier field are ignored.

#### 45.6.2.6.2 *Destination Code*

Some protocol words contain a Destination Code. The Destination Code field (bits 24–17) indicates the final destination of the LDU. If the LDU is intended for the use of the system receiving the message, the destination code may be set to null (hex 00). However, if the LDU is a message intended to be passed on to another on-board system, the Destination Code will indicate the system to which the message is to be passed. The Destination Codes are assigned according to the applications involved and are used in the Destination Code field to indicate the address of the final destination of the LDU.

In an OSI environment, the link layer protocol is not responsible for validating the destination code. It is the responsibility of the higher-level entities to detect invalid destination codes and to initiate error logging and recovery. Within the pre-OSI environment, the Destination Code provides network layer information. In the OSI environment, this field may contain the same information for routing purposes between OSI and non-OSI systems.

#### 45.6.2.6.3 *Word Count*

Some protocol words contain a Word Count field. The Word Count field (bits 16–9) reflects the number of ARINC 429 words to be transmitted in the subsequent LDU. The maximum word count value is 255 ARINC 429 words and the minimum is 3 ARINC 429 words. An LDU with the minimum word count value of 3 ARINC 429 words would contain a SOT word, a data word, and an EOT word. An LDU with the maximum word count value of 255 ARINC 429 words would contain a SOT word, 253 data words, and an EOT word.

## 45.7 Applications

---

### 45.7.1 Initial Implementation

ARINC 429 was first used in the early 1980s on the Airbus A-310 and Boeing B-757 and B-767 airplanes. Approximately 150 separate buses interconnecting computers, radios, displays, controls, and sensors accommodated virtually all data transfer on these airplanes. Most of these buses operate at the lower speed; the few that operate at the higher speed of 100 kbps are typically connected to critical navigation computers.

### 45.7.2 Evolution of Controls

The first applications of ARINC 429 for controlling devices were based on the federated avionics approach used on airplanes that comprised mostly analog interfaces. Controllers for tuning communications equipment used an approach defined as two-out-of-five tuning. Each digit of the desired radio frequency was encoded on each set of five wires. Multiple digits dictated the need for multiple sets of wires for each radio receiver.

The introduction of ARINC 429 proved to be a major step toward reduction of wires. A tuning unit needed only one ARINC 429 bus to tune multiple radios of the same type. An entire set of radios and navigation receivers could be tuned with a few control panels, using approximately the same number of wires previously required to tune a single radio.

As cockpit space became more critical, the need to reduce the number of control panels became critical. The industry recognized that a single control panel, properly configured, could replace most of the existing control panels. The multipurpose control/display unit (MCDU), which came from the industry effort, was derived essentially from the control and display approach used by the rather sophisticated controller for the flight management system. For all intents and purposes, the MCDU became the cockpit controller.

A special protocol had to be developed for ARINC 429 to accommodate the capability of addressing different units connected to a single ARINC 429 bus from the MCDU. The protocol employed two-way communications using two pairs of wires between the controlling unit and the controlled device. An addressing scheme provided for selective communications between the controlling unit and any one of the controlled units. Only one output bus from the controller is required to communicate addresses and commands to the receiving units. With the basic ARINC 429 design, up to 20 controlled units could be connected to the output of the controller. Each of the controlled units is addressed by an assigned SAL.

### 45.7.3 Longevity of ARINC 429

New airplane designs in the twenty-first century continue to employ the ARINC 429 bus for data transmission. The relative simplicity and integrity of the bus, as well as the ease of certification, are characteristics that contribute to the continued selection of the ARINC 429 bus when the required data bandwidth is not critical. The ARINC 629 data bus developed as the replacement for ARINC 429 is used in applications where a large amount of data must be transferred or where many sources and sinks are required on a single bus.

## 45.8 ARINC 453

---

ARINC Project Paper 453 was developed by the AEEC in response to an anticipated requirement for data transfer rates higher than achievable with ARINC 429. The original drafts of Project Paper 453 were based on techniques already employed at that time. The electrical characteristics, including the physical medium, voltage thresholds, and modulation techniques, were based on Mil-Std 1553 (see Chapter 1). The data protocols and formats were based on those used in ARINC Specification 429.

During the preparation of the drafts of Project Paper 453, Boeing petitioned AEEC to consider the use of the digital autonomous terminal access communications (DATAAC) bus developed by Boeing to accommodate higher data throughput. AEEC accepted Boeing's recommendation for the alternative. ARINC 629 was based on the original version of the Boeing DATAAC bus. The work on Project 453 was then curtailed. The latest draft of Project Paper 453 is maintained by ARINC for reference purposes only.

Michael Paulitsch  
Airbus Group Innovations

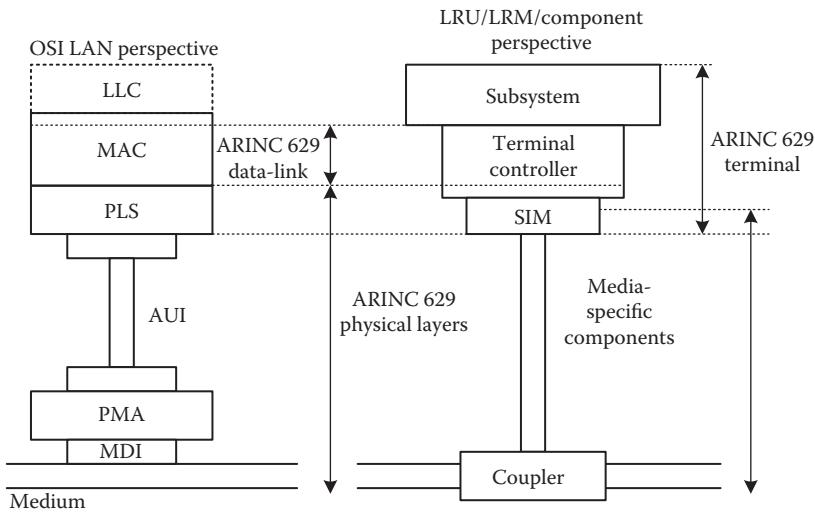

In the late 1980s, there was a push toward integration of multiple functions on a common computing and I/O platform, also referred to as integrated modular avionics (IMA). Combined with this push was a trend to reduce wiring and integrate formerly dedicated buses into system-level communication buses. The advantages are decreased size, cost, and weight; increased reliability; less-frequent maintenance; and more flexibility. The ARINC 629 communication network was the answer in aerospace to the request of integrated system-level buses. The predecessor ARINC 429 [3] had a single sender and multiple receiver topological and logical approach, and ARINC 629 extends the capabilities of the network to support a multiple-sender, multiple-receiver architecture while guaranteeing timely communication. And all this in an environment where high reliability, high availability, and high integrity are required to ensure safety of an aircraft. In addition, ARINC 629 uses current coupling for an electrical physical connection avoiding error-prone physical connections. ARINC 629 is a time division multiplex system. It includes multiple transmitters with broadcast-type, autonomous terminal access.

### 46.1 Physical Layer

---

ARINC 629 physical layer specifies the functional, electrical/optical, and mechanical characteristics of the physical layer entities. The physical layer entities and media in conjunction with the terminal controller form a complete communication path. ARINC 629 supports three different physical entity types as part of its physical layers: a current mode bus, a voltage mode bus, and a fiber-optic mode bus.

ARINC 629 deploys 2 Mbit/s serial data transmission rate specified for twisted pair conductors. The standard also supports the use of fiber optics. Within each line-replaceable unit (LRU), a single ARINC 629 terminal and the main computational component interact via shared memory. To reinforce the approach of collision avoidance adopted at the data link level, multiple timers and redundant circuitry are employed within each terminal to prevent single hardware faults causing multiple terminals

**FIGURE 46.1** Scope of ARINC 629 physical layers. LLC, link layer control; MAC, medium access control; PLS, physical layer signaling; AUI, attachment unit interface; PMA, physical medium attachment; MDI, media-dependent interface. (From Airlines Electronic Engineering Committee, Multi-transmitter data bus—Technical description—ARINC specification 629P1-5, Standard 629P1-5, Aeronautical Radio, Inc (ARINC), Annapolis, MD, March 31, 1999.)

to transmit simultaneously. At the physical layer, mechanisms and signals support higher-level data link-level protocols. The maximum number of terminals permissible on the bus is 120. Figure 46.1 illustrates the scope of the physical layer specifications and the mapping of the logical communication layers onto hardware. In the following, we describe the physical layer requirements, entities, and interface essentials for higher layers.

### 46.1.1 Requirements for Physical Layer

The ARINC 629 system requirements that pertain to the physical layer are as follows [2]:

1. The serial transmission rate should be 2.0 Mbit/s with an accuracy of  $\pm 0.01\%$ .
2. The bit error rate should not exceed 1 bit in  $10^8$  bits. This error rate includes both detected and undetected errors.
3. Each terminal should be capable of receiving the transmissions of every other terminal on the network.
4. The network should support the reliability goals for flight-critical functions, and shortening and opening of a stub at any terminal output should not cause any adverse effect on the bus. A probability of an undetected single point of failure of the terminal affecting the bus should be extremely unlikely. Any terminal should provide an isolation barrier between subsystem and bus, which means that any failure of the subsystem only affects data validity.
5. The installation should provide flexibility in a manner that physical reconfiguration of the network (addition or removal of terminals) should still satisfy the network reliability requirements.
6. The network should meet the RTCA DO-160 [7] standard pertinent to the specific application.
7. The bus medium should enable a receive portion of the transmitting terminal controller to discern simultaneous transmission by other terminal controllers for collision recovery purposes.
8. The bus medium should also enable a receive portion of the transmitting terminal controller to independently monitor the transmitted data directly from the bus for wraparound transmission monitoring.

9. The bus medium should enable detection of *bus quiet* (BQ) and *bus active* (BA) for higher protocol layers and provide signals indicating these states. BQ indicates no sending activity on the bus. BA means a signal is present.

## 46.1.2 Physical Layer Entities

ARINC 629 specifies three physical layer entity (PLE) types [2]:

*Current mode bus:* The current mode bus uses the principle of current induction to induce current pulses (so-called doublets) in the conductors of an unshielded twisted pair cable. The advantage of current induction is the nonintrusive coupling for linking terminals to the medium. That is, with current induction, neither cables have to be spliced nor tap connectors are required.

*Voltage mode bus:* The voltage mode bus implementation is characterized coupling via breaking the cable and insertion of T couplers or splicing of cable conductors for a (typically) shielded cable. Conduction is based on application of voltage.

*Fiber-optic mode bus:* The optical mode bus implementation utilizes electro-optic transceivers to inject pulses of light into an optical fiber either via use of optical coupler or tap and splicing of connectors.

Current mode and fiber-optic bus are defined in detail in the ARINC 629 specification, while a voltage mode bus is not specified.

### 46.1.2.1 Current Mode Bus

The current mode bus allows up to 120 terminals and supports a physical bus lengths of up to 100 m and stub lengths of up to 40 m.

The serial interface module (SIM) should convert Manchester biphase logic transition transmitter by the terminal controller into analog signals called doublets. These doublets are induced via the stub cable into the bus via the current mode coupler (CMC). Similarly, on the receiving side, signals on the bus are flowing from the bus via the CMC and the stub back to the terminal controller. The SIM provides power to the CMC by conditioning its supply voltage of  $\pm 15$  V. The SIM also performs fault checking (monitoring) on itself and performs built-in self-test (BIST) when commanded to do so.

Tables 46.1 and 46.2 present an overview of the stub and bus cable requirements. Figure 46.13 also shows a CMC deployed.

### 46.1.2.2 Fiber-Optic Mode Bus

The optical bus is characterized by passing optical signals through a passive fiber-optic network of either topology (star, linear, or other). Fiber optics has the advantage of immunity to lightning and electromagnetic interference. It also uses passive coupling techniques. Table 46.3 provides an overview of the fiber-optic common characteristics. Details on the transmitter, receiver, and transmission media characteristics can be found in [2].

**TABLE 46.1** Stub Cable Requirements

Description	Parameter Value
Insulation rating	600 V RMS
Attenuation	<1.8 dB (CMC to SIM/pair) ( $F = 6$ MHz)
Velocity of propagation	$>0.75 \times c$ (where $c = 2.9979 \times 10^8$ m/s)
DC resistance	<1 $\Omega$ (CMC to SIM/pair)

### 46.1.3 Physical Layer Signaling

Physical layer signaling specifies the interface between PLE and higher communication layers (or the terminal controller and the SIM when speaking of component perspectives).

The medium access control (MAC) sublayer bus access protocols (see Section 46.3) are reliant on the indication of bus activity from the physical layer for operation. The presence of a signal on the bus is called bus active, while a period of no activity is called bus quiet. Messages are communicated in serial digital pulse code modulation by means of complementary TTL compatible lines, TXO/TXN, and RXI/RXN. The data code used is Manchester II biphase, where a logic one is encoded 1/0 (a half bit time high followed by a half bit time low). A logic zero is encoded 0/1 (a half bit time low followed by a half bit time high). Transitions occur always at the midpoint of each bit time.

MAC sublayer messages are comprised of word strings. A message consists of 1–31 word strings, which are described in detail in the next section. The physical layer should ensure that no gaps are present between successive bit-level encoded words in a word string.

## 46.2 Data Link Layer

This and the next section describe the two main functions associated with the ARINC 629 data link control procedure to be performed in the medium access sublayer: the media access management and data encapsulation (framing, addressing, and error detection).

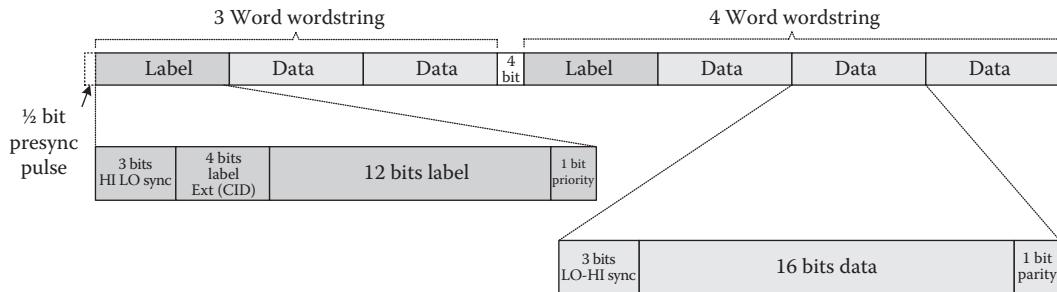

FIGURE 46.2 Example message with two word strings.

#### 46.2.1 Message Format

An ARINC 629 message has variable length up to 31 word strings separated by a 4-bit delimiter. Each word string is made up of one label and several data words. Bus time is decomposed into bus cycles. Each terminal sends one message per bus cycle.

In detail, label words start with a Hi-Lo sync waveform (3 bit times) followed by the channel identification (CID, word bits WB4–WB7), then the label, and finally the parity bit (WB20). Data words start with the Lo-Hi sync waveform (3 bit times) followed by the sign bit (WB4), then the 15-bit data field (word bits WB5–WB19) with the MSB first, and finally the parity bit (WB20).

Data messages consist of word strings with a gap of 4 bit times between word strings and a 3-bit-time sync waveform to initialize each label or data word. The first label word of a message should be preceded by a half-bit-time presync pulse. The beginning of the first transmitted sync waveform following this 4-bit-time gap signifies the beginning of the new word string as indicated in Figure 46.2.

The last bit of each label and data word is a parity bit encoded such that word parity is rendered odd.

#### 46.2.2 Open Systems Interconnection (OSI)-Compatible Format

ARINC 629 supports OSI and non-OSI-compatible formats. Figure 46.3 presents the IEEE Std 802.2 compatible logical link control MAC format. Each MAC should contain two address fields: the source

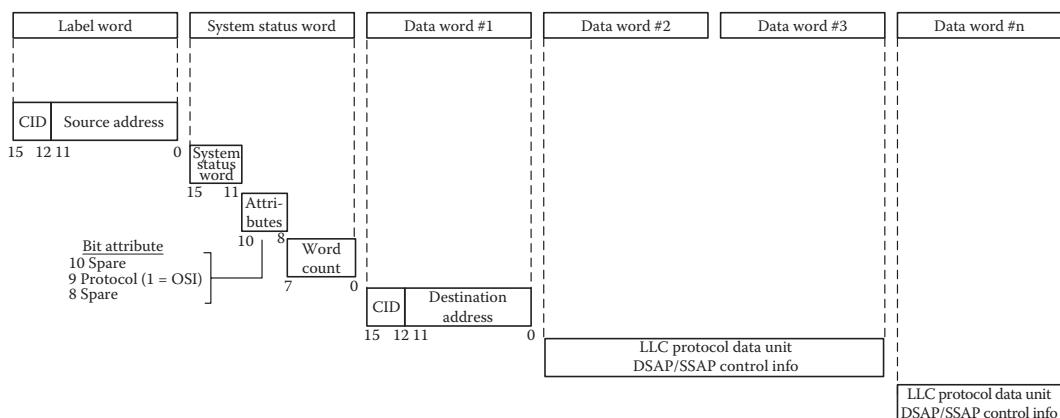

FIGURE 46.3 OSI message format. LLC, logical link control; CID, channel identification; DSAP, destination service access point; SSAP, source service access point. (From Airlines Electronic Engineering Committee, Multi-transmitter data bus—Technical description—ARINC specification 629P1-5, Standard 629P1-5, Aeronautical Radio, Inc (ARINC), Annapolis, MD, March 31, 1999.)

address field and the destination address field. The *source address* field identifies the sending terminal. The *destination address* field specifies the terminal(s) intended recipients. An address can either be an individual or a group address.

The system status word (SSW) describes the systems health and operating environment. The five high-order bits of the SSW identify a system operating with a partial malfunction or in a temporary state that causes the systems data to transmit predefined valid values (i.e., stale data).

The protocol indication field (attribute field, bit number 9) indicates whether the frame is an OSI-compatible frame. The word count field indicates the length of the message. The CRC field contains a frame check sequence based on a 16-bit cyclic redundancy check value.

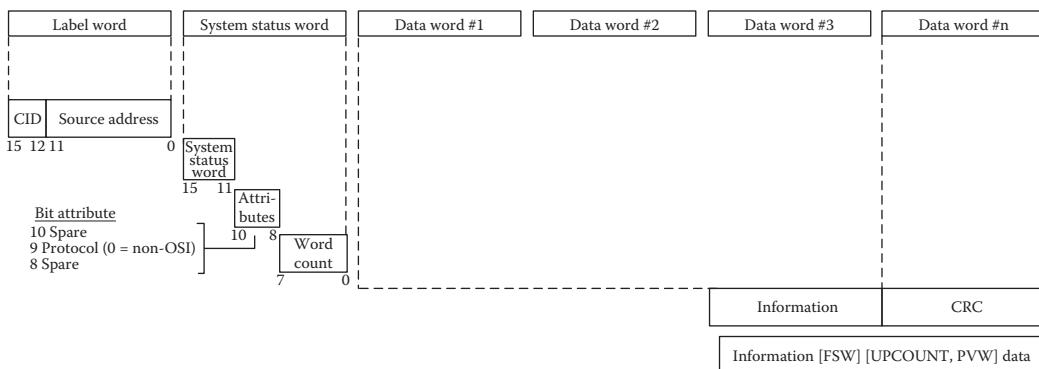

Receivers of all terminals not transmitting data monitor all labels being transmitted on the bus. For all labels of interest, the receiver uses the memory mapping information associated with that label to store data directly in the user system's memory. Details of mapping into memory and configuration formats can be found in [2].

#### 46.2.3 ARINC 629 Non-OSI Data Transfer

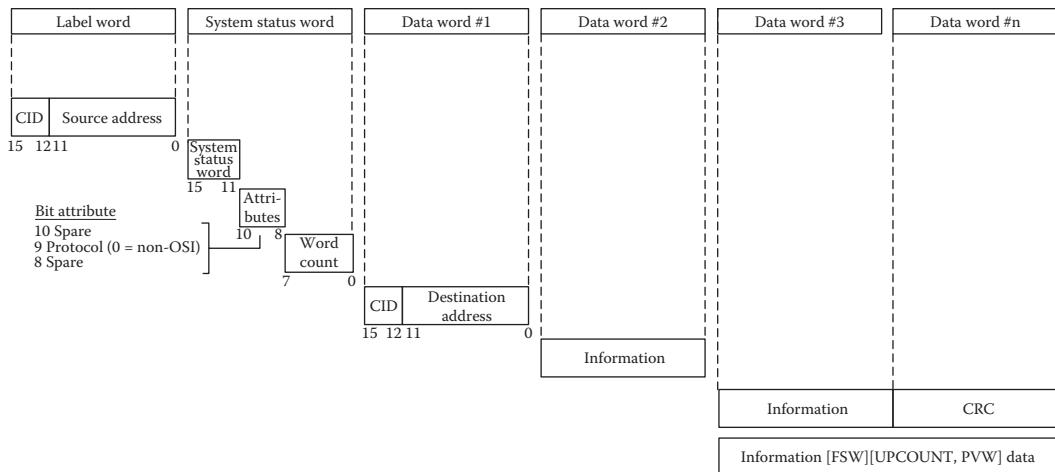

Non-OSI data transfer supports broadcast and directed data. Frames are defined at least 1 digital word containing 20 bits, but only 16 are available to the user, as described in Section 46.2.1. There are multiple predefined word formats for different applications, which are exemplary specified in [2].

Two events are important during normal operation of periodic transmissions on the bus. These are the *minor frame* and *major frame*. Minor frame is a terminal-oriented or bus-oriented event and refers to a specific period on the bus (not to a frame in the sense of a network frame that is physically send or word strings as it is called in ARINC 629). The beginning and end of terminals' minor frame are linked to the transmission of a particular terminal. A bus minor frame is identical to the minor frame of the terminal with the slowest clock for basic protocol (BP) or of the lead terminal in combined protocol (CP), the first terminal to transmit following the longest quiet time [2]. A major frame is a series of unique minor frames as is also signaled. Minor and major frames are related to aircraft-level control loops.

A non-OSI broadcast message includes the following elements: label, CID, word count (if necessary), data status, protocol indication, and information. Figure 46.4 presents the non-OSI broadcast message format.

**FIGURE 46.4** Non-OSI message broadcast format. LLC, logical link control; CID, channel identification; FSW, function status word; PVW, parameter validity word. (From Airlines Electronic Engineering Committee, Multi-transmitter data bus—Technical description—ARINC specification 629P1-5, Standard 629P1-5, Aeronautical Radio, Inc (ARINC), Annapolis, MD, March 31, 1999.)

**FIGURE 46.5** Non-OSI directed message format. LLC, logical link control; CID, channel identification; FSW, function status word; PVW, parameter validity word. (From Airlines Electronic Engineering Committee, Multi-transmitter data bus—Technical description—ARINC specification 629P1-5, Standard 629P1-5, Aeronautical Radio, Inc (ARINC), Annapolis, MD, March 31, 1999.)

Data messages are composed of word string comprising the label word in the first word followed by 16 data bits in the following words. Each position in a word string contains specific data elements that are specified for an aircraft. These are also sometimes called parameters. Figure 46.5 presents the non-OSI directed message format.

More detailed description of the syntax of non-OSI messages like labels, channel identifiers and its use, data status, word count, protocol indication, information, and frame check sequence can be found in [2].

## 46.3 Medium Access Layer

The ARINC medium access layer is a carrier-sense multiple access/collision avoidance (CSMA/CA) scheme. Bus access control is distributed among all participating terminals, each of which autonomously determines its transmission sequence. Each terminal achieves access by the use of bus access timers combined status information about the state of the medium. There are two implementations of ARINC 629, which essentially differ at the MAC layer:

1. Basic mode protocol (BP)
2. Combined mode protocol (CP)

The two protocols differ in how stations access the physical medium and especially in the way they handle aperiodic data.

### 46.3.1 Basic Protocol

The BP is a dual-mode protocol in which the bus can operate in either the periodic mode or the aperiodic mode. The bus system design, that is, factors like the loading factor of the bus, determines which of two modes that the bus will operate in. Buses designed to operate in the periodic mode will automatically transition to the aperiodic mode when they are overloaded. The description in this section is a summary of [2]. It is also slightly more detailed than the description of the CP as it explains also more details about the background and rationale of timers.

#### 46.3.1.1 Timers for Operation

The three timers that are used to access the physical medium are (1) the transmit interval (TI), (2) the synchronization gap (SG), and (3) the terminal gap (TG). In more detail,

1. The TI is identical for all terminals on the same bus. It is the longest time of the three timers and can range from 0.5 to 64.0 ms. It starts every time the terminal starts transmitting. Once a terminal has transmitted, it should wait the length of time specified by the TI before it can transmit again. Hence, it is equal to the minimum possible bus cycle time.

For a normally periodic bus, the selected value should be such that data are available on the bus at a minimum update rate required of the user system. Hence, TI is a transmission deferral mechanism in periodic mode.

Lower TI decreases efficiency of the bus due to increasing bus protocol overhead. For aperiodic mode operation, TI should be relatively short, that is, as short as to ensure all users have the opportunity to transmit as often as possible.

2. The SG is also identical for all terminals on the same bus. SG is the second longest timer. The value of SG is selected from the TG-relative binary values (BVs) of 16, 32, 64, and 127 (corresponding to 17.7, 33.7, 65.7, and 127.7  $\mu$ s for the bit rate of 2 MHz [2,4]). The SG time is effectively dead time on the bus and should be selected to be as small as possible. However, the selection of SG should allow for the use of additional terminals on the bus.

SG ensures that all terminals are given access and are chosen to be greater than the maximum TG. It starts every time BQ is sensed and may be reset before it has expired if bus activity is sensed. It is restarted the next time the terminal starts to transmit. Allegorically speaking, SG is used to implement a waiting room protocol in aperiodic mode [6]. All stations enter a waiting room by waiting the time of length SG before being serviced in the order of a station's TG with lower TG values first. Hence, for aperiodic mode, SG provides the deferral mechanism for sending.

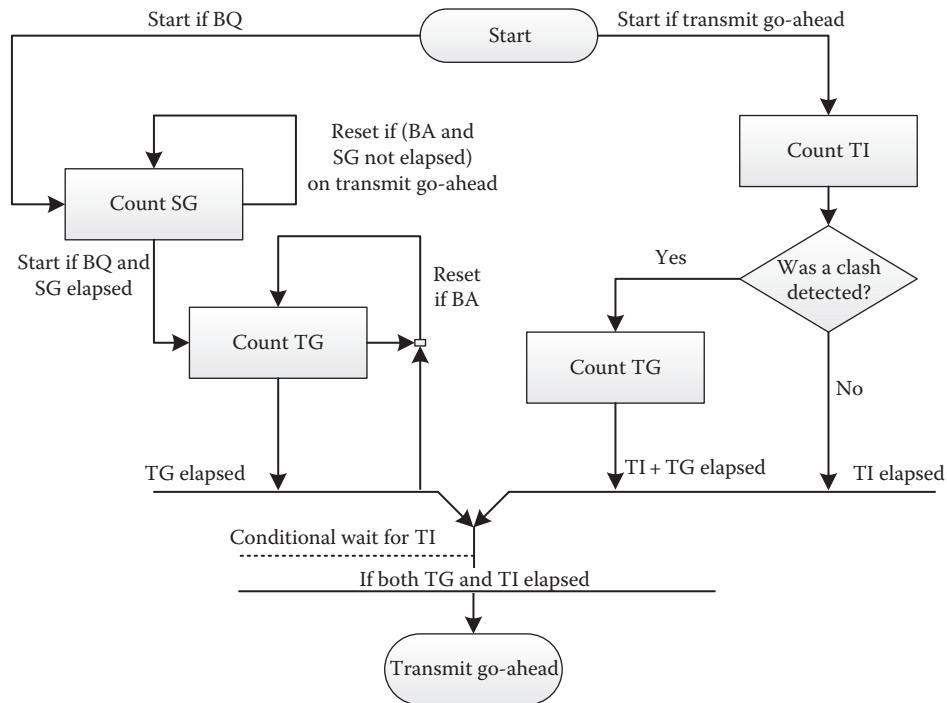

3. The TG is unique for each terminal on the same bus. It is necessary for each terminal on the bus to have a unique number ( $N$ ) from 1 to 125 starting at the lowest value. The terminal BV is set to the binary equivalent of the terminal number plus one (i.e.,  $BV_{10} = N + 1$  [2]). The specific TG values for the bit rate of 2 MHz are between 3.7 and 127.7  $\mu$ s. The TG timer is reset by the presence of a carrier. TG starts only after SG has expired and the bus is quiet. Unlike the SG, TG is reset if bus activity is sensed. As a consequence, TG and SG should not overlap in time but run consecutively. Also, the value of  $111111_2$  or  $127_{10}$  is not used in order that SG be greater than TG.

Figure 46.6 shows the media access flow chart of aperiodic and periodic transmission.

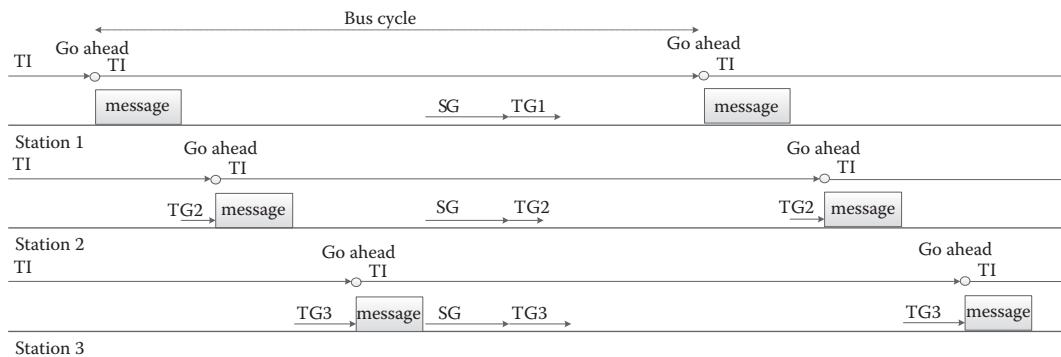

A typical timing diagram for a very simple bus with three terminals operating in periodic mode is shown in Figure 46.7 (attention: diagram is not to scale). The figure shows the terminals in a steady state (some time after start-up and initialization).

The order in which terminals achieve bus access is the same for all bus cycles and is determined by the initialization sequence (if there was no aperiodic mode in between). It does not necessarily (but can) equate to the relative durations of the terminals' TG timers. If the sum of all the TGs, transmission times, and SG is less than TI, then the bus cycle time remains fixed and equal to TI.

If the sum of all the TGs, transmission times, and SG is greater than TI, then the system switches to operation in aperiodic mode as shown in Figure 46.8. For every bus cycle, the terminals transmit in the order of their increasing TG durations. Here,  $TG2 < TG1 < TG3$ . Each bus cycle consists of a sequence of transmissions separated by the various TG delays followed by an SG delay that provides synchronization. Referring to the explanation of the aforementioned waiting room protocol, Figure 46.8 shows that SG opens the waiting room door and then each terminal is served in the order of increasing TG values.

**FIGURE 46.6** BP—media access flow chart (not indicating monitoring). BA, bus active; BQ, bus quiet. (From Airlines Electronic Engineering Committee, Multi-transmitter data bus—Technical description—ARINC specification 629P1-5, Standard 629P1-5, Aeronautical Radio, Inc (ARINC), Annapolis, MD, March 31, 1999.)

**FIGURE 46.7** BP—periodic mode.

#### 46.3.1.2 Bus Cycle Start and Initialization

The initialization phase of bus operation may be relatively uncontrolled depending on the sequence in which local clocks are initialized across multiple terminals. However, as a result of synchronization mechanisms, bus operation will normally settle down to some steady state after a very short time.

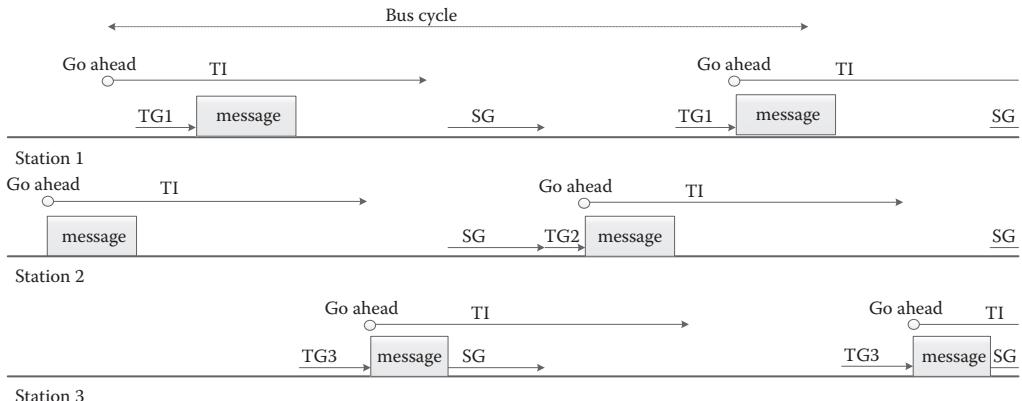

FIGURE 46.8 BP—aperiodic mode.

### 46.3.2 Combined Protocol

The CP allows sending of periodic and multiple different quality levels of aperiodic messages. The operations of the CP are quite complex. It uses five timers in each station. The combination of the five timers and associated state machines build the kernel of the system network behavior. In the following, we base our description of the ARINC 629 CP closely on an excellent description from Gallon and others provided in [5].

#### 46.3.2.1 Bus Cycle

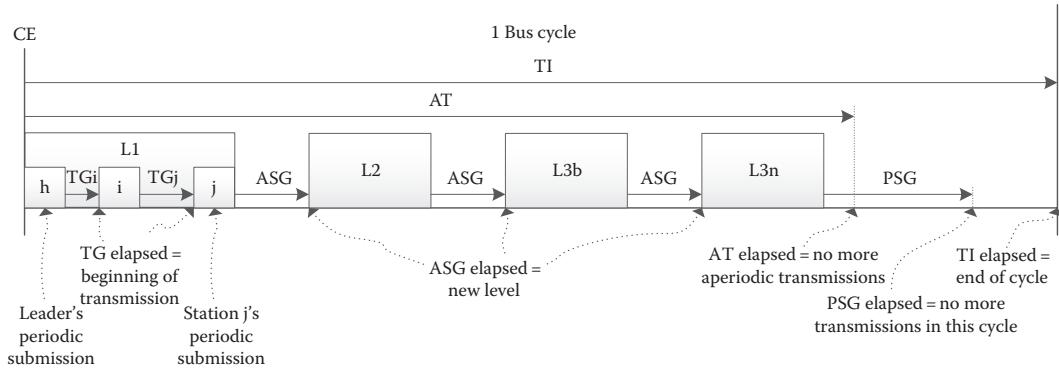

Media access to the bus is cyclic. A bus cycle is started by one of the ARINC 629 stations—also called the leader in the following. Each bus cycle is divided into four durations also called areas or levels. The first three levels are for periodic traffic (level 1), urgent aperiodic traffic (level 2), and nonurgent aperiodic traffic (level 3). Level 3 can be divided into two further sublevels: *level 3 backlog*, for nonurgent aperiodic traffic, which could not be sent in the previous bus cycle, and *level 3 new* for new nonurgent aperiodic traffic. Level 1 traffic has priority and its bus load contribution is evaluated first. Worst-case estimates can be obtained by summing the maximum bus loads. Level 1 traffic does not change significantly between different flight phases. Level 2 and level 3 traffics depend on flight phases. Level 2 traffic is of low periodicity or aperiodic in nature. Level 3 traffic is predominantly aperiodic in nature with some very low-rate periodic data (long messages). Worst-case assessment is not straightforward.

Each station can transmit at most one message per level. Sending of a message is mandatory at level 1, but optional at all other levels. The leader station starts the cycle by sending its first periodic message (i.e., beginning of level 1). The beginning of this first periodic message is the signal for other (nonleading) stations of the beginning of the new bus cycle (this signal is called concatenation event). The fourth area of the bus cycle allows the synchronization of the stations at the end of a cycle in order to define a leader for the new bus cycle (the definition is made by election on local information).

#### 46.3.2.2 Timers for Operation

In the CP, there are two types of timers:

- Type 1 timers—Involving three timers—allow the stations to deal with the bus cycle. The behavior of these timers is bound to the transmission activity on the bus as the information BA and BQ are fundamental for the operation of the bus:
  - The timer TG controls the access to the bus at levels 1, 2, and 3. Each station has a different value for TG; we have the following relation:  $\forall i, j, \text{TG}_j > \text{TG}_i + 2\tau$ , with  $\tau$  being the

**FIGURE 46.9** Role of different timers in CP. (From Gallon, L. et al., Modelling and analysis of the ARINC specification 629 CP MAC layer protocol, in *Proceedings of IEEE International Workshop on Factory Communication Systems*, pp. 91–100, Barcelona, Spain, 1997.)

maximum propagation time on the bus. TG allows specifying a static priority scheme and then implementing a collision avoidance mechanism. As soon as we have the signal BA (beginning of a bus activity), the timer TG is reset, and as soon as we have the signal BQ (end of a bus activity), the timer TG is running. The timer TG is also reset when the station enters a new level of a bus cycle (i.e., when aperiodic synchronization gap [ASG] becomes elapsed). When the timer TG expires, the station can send a message on the bus (if it has not already sent a message at this level).

- The timer ASG controls the level changes. Each station has the same value for ASG and  $ASG > TG_{max}$ . As for the timer TG, as soon as a station gets the signal BA (BQ), the timer ASG is reset (running). At the time when the ASG becomes elapsed, the station changes level.
- The timer periodic synchronization gap (PSG) allows all the stations to synchronize themselves at the end of the bus cycle. Each station has the same value for PSG ( $PSG = 5 ASG$ ). As for the timers TG and ASG, as soon as a station gets the signal BA (BQ), the timer PSG is reset (running). When PSG becomes elapsed, there will be no more transmission in this bus cycle and a station enters a new bus cycle.
- Type 2 timers concern two timers that have the same value in all the stations and which specify the bounds of the bus cycle (i.e., constraints imposed by the stations to the different traffics):
  - Timer TI defines the periodicity of the cycle. It is started at the beginning of the periodic transmission and elapses either by a normal runoff or by a CE interruption (beginning of a new bus cycle). In a permanent normal behavior, the TI of the leader goes to its normal end and then is restarted immediately (new bus cycle). It is then the leader that imposes the periodicity of the cycle (TI).
  - Timer AT (aperiodic access time-out) defines the last instant in a bus cycle for an aperiodic transmission start (i.e.,  $AT = TI - (PSG + ASG + MAL)$ , which MAL being the maximum allowed length for a message).

Figure 46.9 summarizes the definition and the use of the timers.

#### 46.3.2.3 Bus Cycle Start and Initialization

The station that is the leader in one bus cycle normally (i.e., no bus overload, bus initialization, or transient disturbance) stays the leader for the next cycle. This is because the following three local conditions hold at a leader, which are the same the conditions a station satisfies to assert itself as a leader: (1) PSG elapsed (there will be no more transmission in the bus cycle in progress), (2) TI elapsed (the period has finished), and (3) TG elapsed (the station has the right to access to the bus). Normally, the first station powered up

will become the leader (considering differences between power-up of stations are greater than differences in TG), but details on the leader election during initialization as described in the next paragraph.

During initialization, which is a transient behavior from the station being switched on to the introduction of the station in a bus cycle (i.e., emitting the first periodic message [at level 1]), a station starts off with PSG and wants to get the information that the message transmission of the stations already running is ended in the cycle in progress (PSG elapsed). Next, the station starts TI and tries to introduce itself on the bus as nonleader (waiting for a cycle end [CE] and, then, if CE is received, it will start introducing itself into level 1). In the case of an empty bus, there will not be a CE and then TI will elapse. When TI elapses, TG is restarted and at the end of TG (TG elapsed), the station becomes the leader and starts TI and its periodic transmission in level 1. Using TG when TI becomes elapsed allows to control the phenomenon of collision, which can occur at the initialization if several stations want to join regular bus operation simultaneously (remember the stations have different TG). But we cannot avoid all the collisions with this mechanism (which depend on the dephasing between the stations at the switch on, which can compensate the difference between the TGs of the stations). This protocol avoids collisions in the permanent state, but stations can exhibit collisions in transient phases like the initialization. Whenever a collision occurs, there is a signal Bus Clash (BC), which comes from the physical layer, sent to the MAC entity. The station cannot transmit any more message in this bus cycle, and a reinitialization procedure at the end of the bus cycle (i.e., after the condition PSG elapsed) is started.

### 46.3.3 Exceptions

Exceptions can be caused in bus overload situations (the duration of level 1 is greater than TI because of two long messages), timer drifts, ghost transmissions (e.g., the lightning-induced noise signals), and failure of a station, which participate to the bus cycle (deaf station and/or dumb station). ARINC 629 implementations deploy significant monitoring mechanisms, but no monitoring is perfect.

#### 46.3.3.1 Architecture of Link Layer

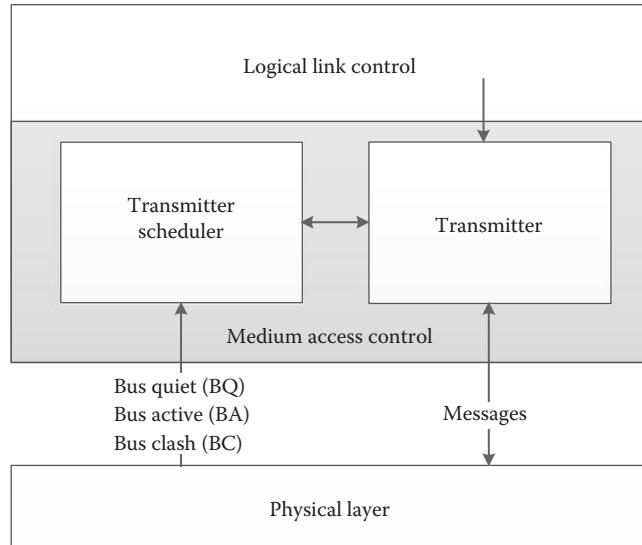

Reference [5] also provides a good overview of the architecture of the link entity, which is represented in Figure 46.10. The MAC is composed of two main modules: (1) the transmitter scheduler and (2) the transmitter. The transmitter scheduler is the core of the implementation of the CSMA/CA mechanism and the cycle bus concept. The signals BA, BQ, and BC are basic signals. The transmitter scheduler implements the mechanisms for the following bus states:

- Initialization of a station on the bus (start-up and reinitialization of the station on the bus after power-up)
- Determining of the leader or nonleader of a station
- Commanding the transmitter to emit messages in levels 1, 2, and 3 of the bus cycle (these messages contain the data from the logical link control)

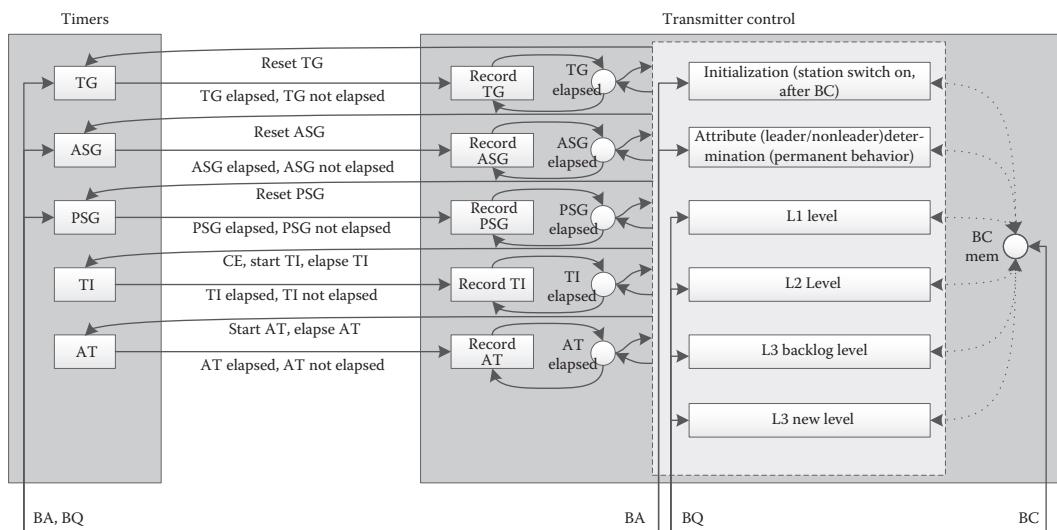

The architecture of the transmitter scheduler is shown in Figure 46.11, which depicts the transmitter scheduler architecture, states, and dependencies with its two main modules: the *timer module* and the *transmitter control module*. The timer module comprises the timers TG, ASG, PSG, TI, and AT. The transmitter control module includes the submodules' initialization; attribute (leader/nonleader) determination, levels 1, 2, and 3, and a submodule that memorizes the conditions (elapsed, not elapsed) of the timers; and the BC occurrences. Figure 46.11 also shows essential interactions for the behavior of the transmitter scheduler (signals from the physical layer, signals between the timers and the transmitter control).

#### 46.3.3.2 Example Scenario

Figure 46.12 sketches a stable bus cycle with only three stations i, j, and k. Station i is the leader but it does not have the smallest TG. Station j has the smallest TG. Station i transmits in levels 1 and 2; station j

**FIGURE 46.10** MAC architecture of CP. (From Gallon, L. et al., Modelling and analysis of the ARINC specification 629 CP MAC layer protocol, in *Proceedings of IEEE International Workshop on Factory Communication Systems*, pp. 91–100, Barcelona, Spain, 1997.)

**FIGURE 46.11** CP transmitter scheduler architecture. (From Gallon, L. et al., Modelling and analysis of the ARINC specification 629 CP MAC layer protocol, in *Proceedings of IEEE International Workshop on Factory Communication Systems*, pp. 91–100, Barcelona, Spain, 1997.)

transmits in levels 1, 2, and 3 backlog (which means that it had a message to send in level 3 new during the previous bus cycle that could not be sent); station k transmits in levels 1 and 2; the three stations have nothing to send in level 3 new. Figure 46.12 neglects the time propagation  $\tau$ . In Figure 46.12, circles indicate the actions that are undertaken in the leader and nonleader role. A horizontal piece of line represents a timer. When a line ends with an arrow, it means that the timer expired; otherwise, there is a reset. We can observe the following interesting scenario in line with the aforementioned rules and explanations. Station i starts this bus cycle and the next bus cycle. At level 2, station j sends the first (because it has the smallest TG).

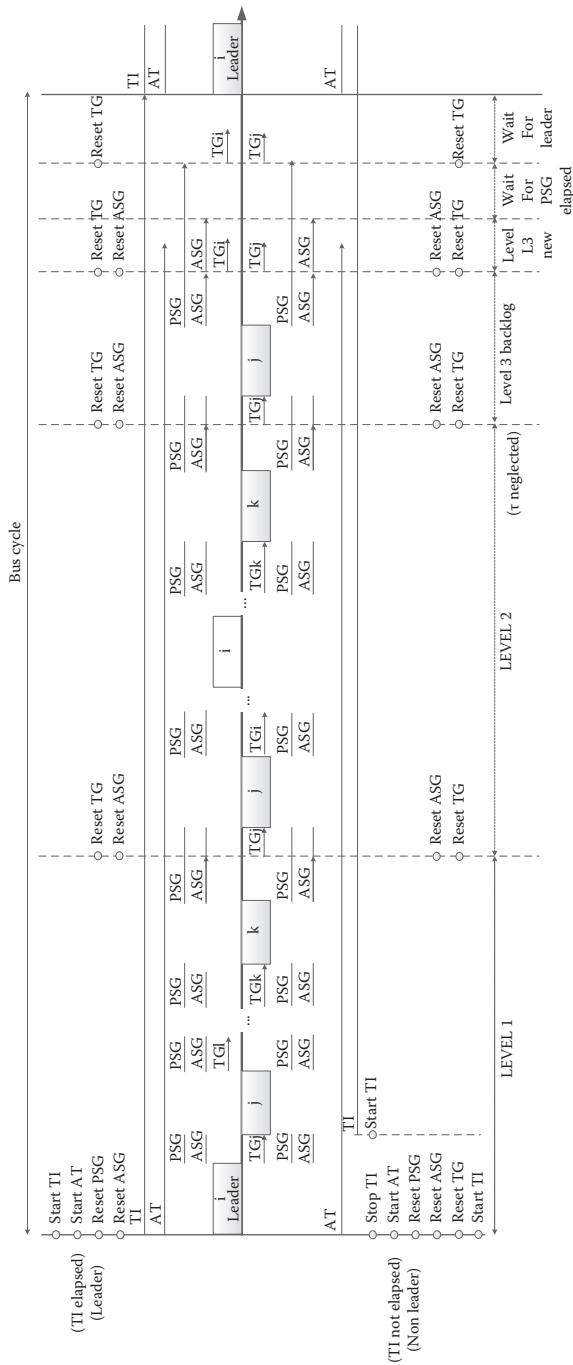

FIGURE 46.12 CP—normal operation.

**TABLE 46.4** Main Features of BP and CP

	BP	CP
Operations	Periodic or aperiodic, or aperiodic messages sent in periodic mode No segregation between periodic and aperiodic messages	Period and aperiodic (optimization of bandwidth) Segregation between periodic and aperiodic messages
File transfer	Padding in XPP even if no request; label sent on the bus	Aperiodic word strings sent on request by the host, burst of word strings possible
Determinism for periodic messages	Guaranteed by TI/SIG timers	Guaranteed by TI, PSG, and AT timers
Scheduling modes	Block, independent, sync, alternate	Block, independent, sync

*Source:* Airlines Electronic Engineering Committee, Multi-transmitter data bus—Part 2 applications guide—ARINC specification 629P2-2, Standard 629P2-2, Aeronautical Radio, Inc (ARINC), Annapolis, MD, February 26, 1999.

#### 46.3.4 Comparison and Summary

Table 46.4 presents an overview of main features of the BP and CP.

### 46.4 Robustness and Fault Tolerance Features

Next to parity for each word string and robustness checks of the physical layer (like amplitude and coding correctness checks), ARINC 629 requires other robustness and fault tolerance features like three types of terminal monitoring: (1) receive data monitoring, (2) transmission monitoring, and (3) protocol check.

#### 46.4.1 Receive Data Monitoring

Receive data monitoring ensures that any received data word that does not have a valid sync pattern, a valid Manchester II biphase modulation pattern, and a valid parity bit is not delivered to higher layers.

The receivers of all terminals that are not transmitting data should monitor all labels being transmitted on the bus. Receivers should check labels against programmed entries in the receive personality Programmable Read-Only Memory (PROM). Labels not destined for this terminal should be discarded.

#### 46.4.2 Transmit Data Monitoring

Transmission monitoring of the terminal uses data a terminal's transmitter has placed on the bus. The goal of the transmission monitoring is detection of events like prevention of impersonation (which happens when a transmitter sends with the label of another transmitter) and babbling (the continuous transmitting of a terminal for an extensive period of time). It detects a label authorized for transmission and ensures a correct CID. The transmit monitor prevents transmission on the bus whenever an invalid sync pattern, modulation, or parity condition exists. Furthermore, the monitor also prevents transmission when the word string length exceeds the specified value, or the message length exceeds the specified value, or an illegal label is being transmitted. In case of a monitoring error, the transmitter should inhibit the remainder of that message. Additionally, a terminal heuristically distinguishes between transient and permanent faults leveraging a transmission error counter. In case of seven successive unsuccessful tries, the terminal is disabled.

### 46.4.3 Bus Protocol Monitoring

ARINC 629 also specifies monitoring of essential protocol logic in two separate circuits on the same protocol chip. Each of these circuits should operate from a separate crystal oscillator and obtain the essential three controlling parameters from a different source.

These three rules and parameters are as follows:

1. TI has elapsed.
2. The SG—a quiet period on the bus—has existed on the bus.
3. The TG—another quiet period, unique for each terminal—has existed on the bus since the SG occurred.

During execution, the protocol state machine is extended to agreeing on the rules for the go-ahead signal for the transmitter despite expected differences due to crystal oscillator and similar effects. This dual-logic implementation of the protocol machine minimizes the likelihood of a single-point failure causing a terminal to transmit at the wrong time. The protocol logic should initiate a transmit operation and maintain order on the bus.

These three simple rules ensure orderly transmission, without collisions or contentions, for periodic operation, aperiodic operation, or transitional operation. Whether the bus is periodic is not determined by protocol but determined by the loading of the bus and whether variable word strings are allowed.

### 46.4.4 Protocol Parameter Monitoring

Dual-protocol circuits should control each protocol parameter steered by the LRU program pin strapping. This should be compared to programming in the receive personality PROM, which is a section of memory that contains bus protocol parameters, receive address value, number of word strings in the message, and other key receive message elements.

## 46.5 ARINC 629 in Boeing 777

---

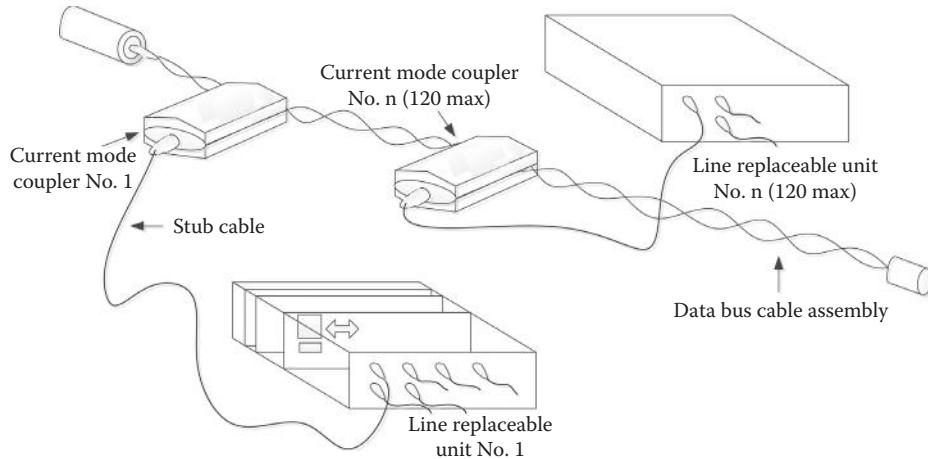

In Boeing 777, multiple new electronics technologies have been introduced in order to provide more functionality with higher reliability and easier maintainability, which essentially means higher value for aircraft customers. One of new technologies selected is the new system bus ARINC 629 described in this chapter in more detail.

ARINC 629 is a time division multiplex system. It includes multiple transmitters with broadcast-type, autonomous terminal access. While ARINC 629 specifies that up to 120 LRUs may be connected together, for Boeing 777 a maximum of 44 LRUs connected with couplers are allowed [1, pp. 2–6].

Boeing 777 leverages the current mode coupling physical layer of ARINC 629 (see Section 46.1.2.1) and utilizes the BP (see Section 46.3.1) in periodic transfer mode mainly during normal operation. LRUs communicate to the bus using a coupler and terminal as shown in Figure 46.13.

The terminal controller incorporates the following features [1, p. 2–2]:

- Local transmit and receive message control
- Optional transmit and receive vectored interrupts
- Manchester II biphase coded serial data format
- Onboard direct memory access (DMA) capability
- Automatic power-on initialization
- Periodic and aperiodic transfer modes
- Label identification of data permits global parameters on bus
- Receiver monitoring and shutdown on error of transmitted data

**FIGURE 46.13** Interconnect of systems using ARINC 629. (From Yeh, Y.C., Design considerations in Boeing 777 fly-by-wire computers, in *The 3rd IEEE International Symposium on High-Assurance Systems Engineering, HASE'98*, p. 64, Washington, DC, IEEE Computer Society, 1998.)

- Receive parity and format checking
- 2-Mbit continuous transmission collision recovery
- Capable of simultaneous transmission collision recovery
- 180-pin lead ceramic grid array package
- 208-pin lead plastic quad flatpack (PQFP) package

The SIM incorporates the following features [1, p. 2–2]:

- Interface between terminal controller and CMC, which converts serial Manchester encoded data into differential voltage doublets and vice versa
- Checks amplitude and polarity of doublets transmitted to the coupler
- Checks symmetry and polarity of doublets received from coupler
- Notifies terminal controller of SIM/coupler failure symptoms
- Inhibits coupler transmission if both channels are bad
- Shuts down the coupler power if an overcurrent condition is detected
- Administers BIST sequence to determine coupler health
- Prevents propagation of shorts and hot faults into LRU from the stub
- Packages available for through-hole and surface mounting

The following lists the features of the stub cable assembly [1, pp. 2–3]:

- Four conductors, made up of either two twisted pairs, each separately shielded with one overall shield, or quad arrangement with all four wires twisted together
- Circumferential shielding at connectors
- Up to 40 m in length using 22 gauges wires, but only up to 17.3 m in Boeing 777 implementation using 24 gauges wires

The CMC incorporates the following features [1, pp. 2–3]:

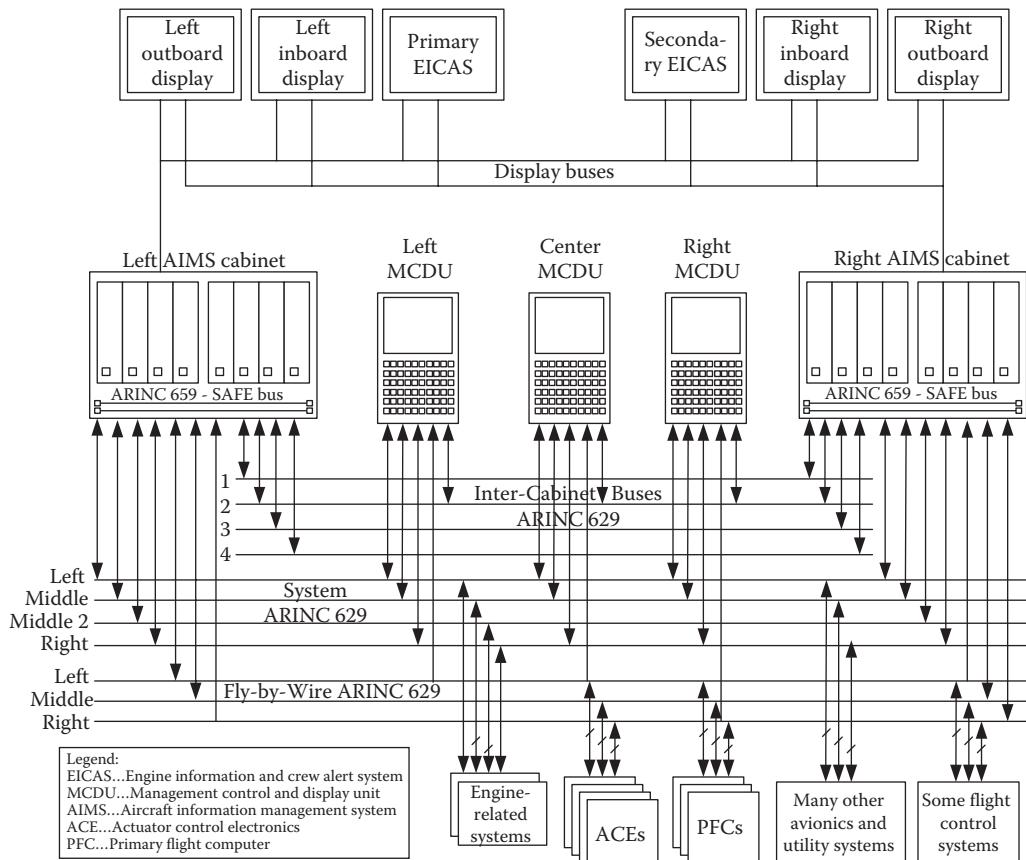

- Inductive nonintrusive *clip on* coupling
- Low bus load and reflection
- Low dynamic signal range

- High noise immunity
- Redundant transmitters and receivers
- Channel-switching capability
- Overcurrent shutdown capability

The bus cable assembly features are the following [1, pp. 2-3]:

- Lightweight twisted pair media (shielded and unshielded)
- Low attenuation
- Impedance-matched fault-tolerant terminations
- Capable of supporting up to 120 mode couplers, but only a maximum of 44 couplers in Boeing 777 implementation
- Up to 100 m in length, but only maximum of 59.6 m in Boeing 777 implementation or 71.8 m on stretch airplane version

The avionics architecture in Boeing 777 is characterized by functional integration compared to predecessor aircrafts. Classical avionics at that time had a federated avionics architecture, where a set of functions is implemented in one or more LRUs. In Boeing 777, this has been replaced by a more integrated architecture where multiple sets of functions are combined in fewer LRUs, some in common cabinets instead of many separate boxes.

**FIGURE 46.14** Boeing B 777 avionics overview. EICAS, engine information and crew alert system; MCDU, management control and display unit; AIMS, aircraft information management system; ACE, actuator control electronics; PFC, primary flight computer. (Courtesy of Honeywell, Morristown, NJ.)

The cabinets and stand-alone LRUs are connected to the airplane interfaces via a combination of ARINC 429, ARINC 629, display buses, and discrete I/O channels. Figure 46.14 shows the most important connected modules; it displays only ARINC 629 and display buses and neither ARINC 429 nor discrete I/O channels. In addition to the cabinets, other flight deck hardware elements that make up the avionics system are six flat panel display units, three control and display units, two electronic flight instrument system (EFIS) display control panels, one display select panel, two cursor control devices, and two display remote light sensors (not all are depicted in Figure 46.14). The system bus in Boeing 777 is mainly ARINC 629 [2]. As can be seen, multiple groups of bus called system ARINC 629 and fly-by-wire ARINC 629 buses are deployed. For the flight control ARINC 629, LRUs receive data on all three ARINC 629 buses but transmit on only one ARINC 629 bus.

### 47.1 Introduction

---

The Commercial Standard Digital Bus (CSDB) [1–4] is one of several digital serial integration data buses that currently predominate in civilian aircraft. The CSBD finds its primary implementations in the smaller business and private general aviation (GA) aircraft but has also been used in retrofits of some commercial transport aircraft.

Rockwell Collins developed CSDB, a unidirectional data bus. The bus used in a particular aircraft is determined by which company the airframe manufacturer chooses to supply the avionics.

CSDB is an asynchronous linear broadcast bus, specifying the use of a twisted, shielded pair cable for device interconnection. Two bus speeds are defined in the CSDB specification: a low-speed bus operates at 12,500 bits per second (bps) and a high-speed bus operates at 50,000 bps. The bus uses twisted, unterminated, shielded pair cable and has been tested to lengths of 50 m.

The CSDB standard also defines other physical characteristics such as modulation technique, voltage levels, load capacitance, and signal rise and fall times. Fault protection for short circuits of the bus conductors to both 28 volts direct current (VDC) and 115 volts alternating current (VAC) is defined by the standard.

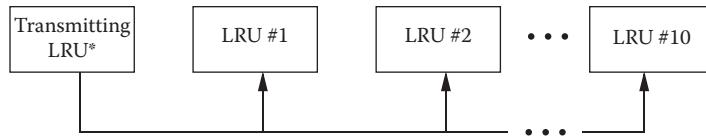

FIGURE 47.1 Unidirectional CSDB communication. \*LRU, line replacement unit.

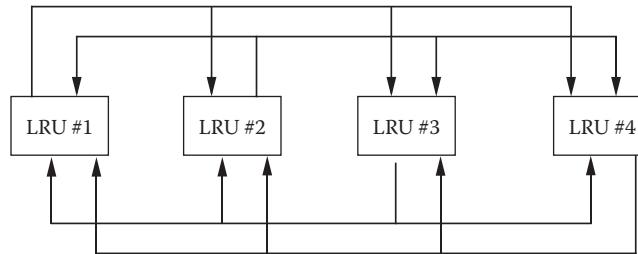

FIGURE 47.2 Bidirectional CSDB communication.

## 47.2 Bus Architecture

Only one transmitter can be attached to the bus, but it can accommodate up to 10 receivers. Figure 47.1 illustrates the unidirectional bus architecture.

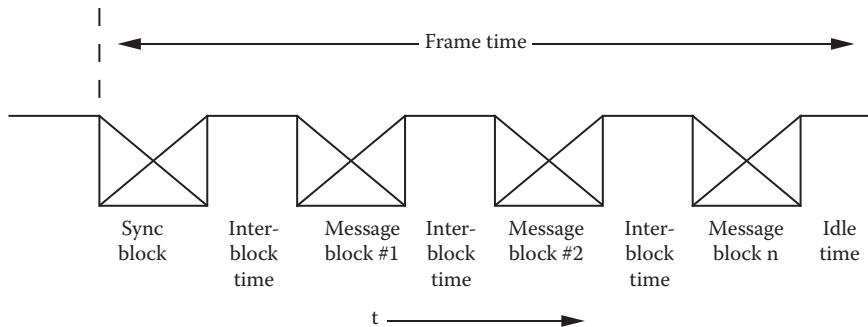

Bidirectional transmission can take place between two bus users. If a receiving bus user is required to send data to any other bus user, a separate bus must be used. Figure 47.2 shows how CSDB may implement bidirectional transmissions between bus users. It can be seen that if each bus user were required to communicate with every other bus user, a significantly greater amount of cabling would be required. In general, total interconnectivity has not been a requirement for CSDB-linked bus users.

It is possible to interface CSDB to other data buses. When this is done, a device known as a gateway interfaces to CSDB and the other bus. If the other bus is ARINC 429 compliant, then messages directed through the gateway from CSDB are converted to the ARINC 429 protocol, and vice versa. The gateway would handle bus timing, error checking, testing, and other necessary functions. The system designers would ensure that data latency introduced by the gateway would not cause a “stale data” problem, resulting in a degradation of system performance. Data are stale when they do not arrive at the destination line replaceable unit (LRU) when required, as specified in the design.

## 47.3 Basic Bus Operation

In Section 2.1.4 of the CSDB standard [1], three types of transmission are defined: (1) continuous repetition, (2) noncontinuous repetition, and (3) burst transmissions. Continuous repetition transmission refers to the periodic updates of certain bus messages. Some messages on CSDB are transmitted at a greater repetition rate than others. The CSDB standard lists these update rates, along with the message address and message block description. Noncontinuous repetition is used for parameters that are not always valid or available, such as mode or test data. When noncontinuous repetition transmission is in use, it operates the same as continuous repetition. Burst transmission initiates an action (such as radio tuning) or may be used to announce a specific event. Operation in this mode initiates 16 repetitions of the action in each of 16 successive frames, using an update rate of 20 per second.

For CSDB, bytes consist of 11 bits: a start bit, 8 data bits, a parity bit, and a stop bit. The least significant bit (bit 0) follows the start bit. The CSDB standard defines the message block as “a single serial message consisting of a fixed number of bytes transmitted in a fixed sequence” (GAMA CSDB 1986) [1].

**FIGURE 47.3** CSDB data frame structure.

Essentially, a message block consists of a number of bytes concatenated together, with the first byte always being an address byte. A status byte may or may not be included in the message block. When it is, it immediately follows the address byte. The number of data bytes in a message block varies.

Data are sent as frames consisting of a synchronization block followed by a number of message blocks. A particular frame is defined from the start of one synchronization block to the start of the next synchronization block. A “sync” block consists of N bytes of the sync character, which is defined as the hexadecimal character “A5.” The sync character is never used as an address. While the data may contain a sync character, it may occur in the data a maximum of N – 1 times. Frames consist of message blocks preceded by a sync block. The start of one sync block to the start of the next sync block is one frame time. Figure 47.3 shows what transpires during a typical frame time.

## 47.4 CSDB Bus Capacity

The CSDB is similar to ARINC 429 in that it is an asynchronous broadcast bus and operates using character-oriented protocol. Data are sent as frames consisting of a synchronization block followed by a number of message blocks. A particular frame is defined from the start of one synchronization block to the start of the next synchronization block. A message block contains an address byte, a status byte, and a variable number of data bytes. The typical byte consists of one start bit, eight data bits, a parity bit, and a stop bit.

The theoretical bus data rate for a data bus operating at 50,000 bps with an 11-bit data byte is 4545 bytes per second. For CSDB, the update rate is reduced by the address byte and synchronization block overhead required by the standard.

The CSDB interblock and interbyte times also reduce bus throughput. According to the specification, there are no restrictions on these idle times for the data bus. These values, however, are restrained by the defined update rate chosen by the designer. If the update rate needs to be faster, the interblock time and the Interbyte time can be reduced as required, until bus utilization reaches a maximum.

## 47.5 CSDB Error Detection and Correction

Two methods of error detection are referenced in the standard. They are the use of parity and checksums. A parity bit is appended after each byte of data in a CSDB transmission. The burst transmission makes use of the checksum for error detection. As the General Aviation Manufacturers Association (GAMA) specification states, “It is expected that the receiving unit will accept as a valid message the first message block that contains a verifiable checksum” (GAMA CSDB 1986) [1].

## 47.6 Bus User Monitoring

Although the CSDB specification defines many parameters, there is no suggestion that receivers should monitor them. The bus frame, consisting of the synchronization block and message block, may be checked for proper format and content. A typical byte, consisting of start, stop, data, and parity bits, may be checked for proper format.

The bus hardware should include the functional capability to monitor these parameters. Parity, frame errors, and buffer overrun errors are typically monitored in the byte format of character-oriented protocols. The message format can be checked and verified by the processor if the hardware does not perform these checks.

## 47.7 Integration Considerations

The obvious use of a data bus is for integrating various LRUs that need to share data or other resources. The following sections examine various levels of integration considerations for CSDB, including physical, logical, software, and functional considerations.

### 47.7.1 Physical Integration

The standardization of the bus medium and connectors addresses the physical integration of LRUs connected to the CSDB. These must conform to the Electronic Industries Association (EIA) Recommended Standard (RS)-422-A (1978), "Electrical Characteristics of Balanced Voltage Digital Interface Circuits." The CSDB standard provides for the integration of up to 10 receivers on a single bus, which can be up to 50 m in length. No further constraints or guidelines on the physical layout of the bus are given.

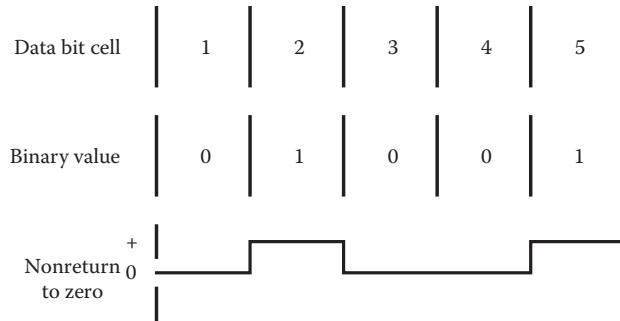

Each LRU connected to a CSDB must satisfy the electrical signals and bit timing that are specified in the EIA RS-422-A. Physical characteristics of the CSDB are given in Table 47.1. Figure 47.4 shows the nonreturn to zero (NRZ) data format used by CSDB LRUs. NRZ codes remain constant throughout a bit interval and either use absolute values of the signal elements or differential encoding in which the polarity of adjacent elements is compared to determine the bit value.

Typical circuit designs for transmitter and receiver interfaces are given in the CSDB standard. Protection against short circuits is also specified for receivers and transmitters. Receiver designs should include

**TABLE 47.1** CSDB Physical Characteristics

Modulation Technique	Nonreturn to Zero
Logic sense for logic "0"	Line B positive with respect to line A
Logic sense for logic "1"	Line A positive with respect to line B
Bus receiver	High impedance, differential input
Bus transmitter	Differential line driver
Bus signal rates	Low speed: 12,500 bps High speed: 50,000 bps
Signal rise time and fall time	Low speed: 8 $\mu$ s
Receiver capacitance loading	High speed: 0.8–1.0 $\mu$ s Typical: 600 pF
Transmitter driver capability	Maximum: 1,200 pF Maximum: 12,000 pF

*Source:* Commercial Standard Digital Bus, 8th edn., Collins General Aviation Division, Rockwell International Corporation, Cedar Rapids, IA, January 30, 1991.

**FIGURE 47.4** Nonreturn to zero data example.

protection against bus conductor shorts to 28 VDC and to 115 VAC, and transmitter designs should afford protection against faults propagating to other circuits of the LRU in which the transmitter is located.

To ensure successful integration of CSDB LRUs and avoid potential future integration problems, the electrical load specification must be applied to a fully integrated system, even if the initial design does not include a full complement of receivers. As a result, additional receivers can be integrated at a later time without violating the electrical characteristics of the bus.

### 47.7.2 Logical Integration

The logical integration of the hardware is controlled by the CSDB standard which establishes the bit patterns that initiate a message block and the start bit, data bits, parity bit, and stop bit pattern that comprises each byte of the message. The system designer, however, must control the number of bytes in each message and ensure that all the messages on a particular bus are of the same length.

### 47.7.3 Software Integration

Many software integration tasks are left to the system designer for implementation; hence, CSDB does not fully specify software integration. The standard is very thorough in defining the authorized messages and in constraining their signaling and update rates. The synchronization message that begins a new frame of messages is also specified. However, the determination of which messages are sent within a frame for a particular bus is unspecified. Also, there are no guidelines given for choosing the message sequence or frame loading. The frame design is left to the system designer.

In general, the sequencing of the messages does not present an integration problem since receivers recognize messages by the message address, not by the sequence. However, this standard does not disallow an LRU from depending on the message sequence for some other purpose. The system designer must be aware of whether any LRU is depending on the sequence for something other than message recognition, because once the sequence is chosen, it is fixed for every frame.

The bus frame loading is more crucial. There are three types of messages that can occur within a frame: continuous repetition, noncontinuous repetition, and burst transmissions. The system designer must specify which type of transmission to use for each message and ensure that the worst maximum coincidence of the three types within one frame does not exhaust the frame time. The tables of data needed to support this system design are provided, but the system designer must ensure that no parts of the CSDB standard are violated.

### 47.7.4 Functional Integration

The CSDB standard provides much of the data needed for functional integration. The detailed message block definitions give the interpretation of the address, status byte, and data words for each

available message. Given that a particular message is broadcast, the standard completely defines the proper interpretation of the message. The standard even provides a system definition consisting of a suite of predefined buses that satisfy the integration needs of a typical avionics system.

If this predefined system is applicable, most of the system integration questions are already answered. But if there is any variation from the standard, the designer of a subsystem in a CSDB integrated system must inquire to find out which LRUs are generating the messages that the subsystem needs, on which bus each message is transmitted, at what bus speed the messages are transmitted, and the type of transmission. The designer must also ensure that the subsystem provides the messages required by other LRUs. The system designer needs to coordinate this information accurately and comprehensively. The system design must ensure that all the messages on a particular bus are of the same length and must also control the data latencies that may result as data are passed from bus to bus by various LRUs. All testing is left to the system designer.

There are no additional guidelines published for the CSDB. Whatever problems are not addressed by the standard are addressed by Collins during system integration. Furthermore, Collins has not found the need to formalize its integration and testing in internal documents since CSDB-experienced engineers do this work.

## 47.8 Bus Integration Guidelines

---

The CSDB, like the ARINC 429 bus, has only one LRU that is capable of transmitting with (usually) multiple LRUs receiving the transmission. Thus, the CSDB has few inherent subsystem integration problems. However, the standard does not address them. The preface to the CSDB standard clearly states its position concerning systems integration: “This specification pertains only to the implementation of CSDB as used in an integrated system. Overall systems design, integration, and certification remain the responsibility of the systems integrator” (GAMA CSDB 1986) [1].

Although this appears to be a problem for the reliability of CSDB-integrated systems, the GA scenario is quite different from the air transport market. The ARINC standards are written to allow any manufacturer to independently produce a compatible LRU. In contrast, the GAMA standard states in its preface that “This specification... is intended to provide the reader with a basic understanding of the data bus and its usage” (CSDB 1986) [1].

The systems integrator for all CSDB installations is the Collins General Aviation Division. That which is not published in the standard is still standardized and controlled because the CSDB is a sole source item.

Deviations from the standard are allowed, however, for cases in which there will be no further interfaces to other subsystem elements. When variations are made, the change first must be approved in a formal design review and the product specification is then updated accordingly. Integration standards and guidelines for CSDB include the CSDB standard and EIA RS-422-A by the Electronic Industries Association.

## 47.9 Bus Testing

---

The CSDB connects avionics LRUs point-to-point to provide an asynchronous broadcast method of transmission. Before the bus was used in the avionics environment, it was put through validation tests similar to those used on other commercial data buses. These included the environmental tests presented in RTCA DO-160 and failure analyses. Most environmental tests were done transparently on the bus after it was installed in an aircraft.

As with other avionics data buses, Collins had to develop external tests to show that the bus satisfied specifications in the standard. Test procedures of this nature are not included in the CSDB standard.

**TABLE 47.2** Aircraft and Their Use of the CSDB

Boeing 727	Retrofit
Boeing 737	Retrofit
McDonnell-Douglas DC-8	Retrofit
Saab 340, Saab 2000	Primary integration bus
Embraer	Primary integration bus
Short Brothers SD330 and SD360	Primary integration bus
ATR42 and ATR72	Primary integration bus
De Havilland Dash 8	Primary integration bus
Canadair Regional	Primary integration bus

Source: Rockwell Collins, Cedar Rapids, IA.

Internal bus tests that the CSDB standard describes include a checksum test and a parity check. Both of these are used to ensure the integrity of the bus's data. Care should be taken when using these tests because their characteristics do not allow them to be used in systems of all criticality levels.

Simulation is used for development and testing of LRUs with a CSDB interface. To simulate an LRU connection to the bus, manufacturers make black box testers to generate and evaluate messages according to the electrical and logical standards for the bus. These consist of a general-purpose computer connected to bus interface cards. The simplest ones may simulate a single LRU transmitting or receiving. The more complex ones may be able to simulate multiple LRUs simultaneously.

These are not the only external and internal tests that the CSDB manufacturer can perform. Many more characteristics that may require testing are presented in the CSDB specification. Again, it remains the manufacturer's responsibility to prove that exhaustive validation testing of the bus and its related equipment has met all the requirements of the Federal aviation regulations.

## 47.10 Aircraft Implementations

This section gives a sampling of the aircraft in which the CSDB is installed. Table 47.2 lists some of the commercial transport aircraft and regional airliners using CSDB. CSDB is used both in retrofit installations and as the main integration bus. Additionally, a number of rotorcraft use the CSDB to communicate between the Collins-supplied LRUs.

## Defining Terms

**Asynchronous:** Operating at a speed determined by the circuit functions rather than by timing signals

**Checksum:** An error detection code produced by performing a binary addition, without carry, of all the words in a message

**Frame:** A formatted block of data words or bits used to construct messages

**Gateway:** A bus user that is connected to more than one bus for the purpose of transferring bus messages from one bus to another, where the buses do not follow the same protocol

**Linear Bus:** A bus where users are connected to the bus medium, one on each end, with the rest connected in between

**Parity:** An error detection method that adds a bit to a data word based on whether the number of "one" bits is even or odd

**Synchronization Block:** A special bus pattern, consisting of a certain number of concatenated "sync byte" data words, used to signal the start of a new frame

### 48.1 SAFEbus

---

SAFEbus\* is the only backplane or local area network standard (ARINC 659) [1] that provides fail-op/fail-safe fault tolerance with near-unity coverage for all of its components—signal lines, terminations, interface electronics, clock sources, and power supplies. This coverage includes tolerating a Byzantine fault. SAFEbus provides a time-based protocol that delivers messages with a precision on the order of 100 ns over a backplane network. The SAFEbus protocol can be implemented in an integrated circuit or FPGA with just 70,000 gates.

#### 48.1.1 Background

In the late 1980s, there was a push toward integration of multiple functions on a common computing and input/output (I/O) platform, also referred to as integrated modular avionics (IMA). This push was due to the advantages of IMA systems over then prevalent federated architectures. The advantages are decreased size, cost, and weight, increased reliability, less-frequent maintenance, and more flexibility. The success of an IMA system hinges on a backplane–bus connecting line-replaceable modules (LRMs). The backplane–bus must be designed to support the requirements of *space and time partitioning*. These requirements are derived from the concept of *robust partitioning* that prevents functions on a common platform from adversely influencing each other, even when some functions may be faulty. Honeywell designed SAFEbus as a backplane for the Aircraft Information Management System (AIMS), which is the IMA part of the avionics for the Boeing B-777 airplane.

Boeing provided some additional design requirements. One requirement was for the number of days the Boeing 777 could be dispatched without maintenance following a failure. The goal was to allow a plane with a failure in an AIMS component to follow its normal schedule, which will eventually bring it to a maintenance base. This requirement meant that individual components of the AIMS system had to be

---

\* SAFEbus is a registered trademark of Honeywell International, Inc.

reliable and that the system as a whole had to be fault tolerant. A second design requirement was that the backplane–bus interface not force complexity on the functions in an LRM. Some LRMs might be high-performance processors, but others might be simple hardwired logic. A third requirement, implicit in the notion of an integrated cabinet, was that the design support a multiprocessor architecture. In particular, the backplane had to provide adequate net throughput for the initial set of functions together with 50% extra capacity to allow for growth. Fourth, the integrity requirements for the avionics system as a whole meant that the backplane–bus had to exhibit total fault containment. There had to be less than one chance in a billion per hour of operation that an error occurring within the backplane system would be passed undetected from or to the application software. Finally, the design had to be one that would support the certification of the system and the recertification of modified functions. In particular, the design could not be one that would force the recertification of all functions when only one function was modified. Honeywell designed SAFEbus because no existing backplane–bus met these requirements. SAFEbus builds on the multiprocessor flight control system (M<sup>2</sup>FCS) [2] research done for the US Air Force.

SAFEbus is standardized as ARINC 659 *backplane data bus* [3]. This is in a family of associated standards including ARINC 653 Avionics Application Software Standard Interface, ARINC 651 Design Guide for Integrated Modular Avionics, and ARINC 650 Integrated Modular Avionics Packaging and Interfaces.

## 48.2 Protocol Overview

---

The SAFEbus protocol is heavily dependent on its hardware. In order to understand the SAFEbus protocol, one needs to know the basic building blocks of the hardware architecture. The SAFEbus interface logic within each LRM uses paired hardware; each half of the pair consists of a bus interface unit (BIU) ASIC, a table memory, an intermodule memory (IMM), and backplane transceivers. This logic is paired to provide immediate fault detection and containment. The backplane–bus lines are configured in a unique fault-tolerance topology that lies somewhere between quad redundancy and dual–dual redundancy [4]. This topology simultaneously provides high integrity and availability (see Figure 48.1). SAFEbus consists of two self-checking buses (SCBs), A and B, called bus pairs. Each SCB is itself composed of two buses: x and y. Figure 48.2 presents a nomenclature of the different bus-related items. One of the BIUs in an LRM transmits data on one of the buses in each SCB, and its partner BIU transmits on the other bus within each SCB. The data on any two buses, which come from different BIUs, are compared at each receiving LRM. Only bit-for-bit identical data are written into the IMMs. A transmitting LRM checks its transmission using a local loopback. That is, the receiving circuitry in the transmitting LRM also checks what is actually put on the bus for errors. Such self-checking ensures a babbling LRM will be self-detected and will remove itself from SAFEbus. This removal is enforced within an LRM by having each BIU control the other BIU's drivers. If either BIU thinks it should not be transmitting, neither BIU can transmit. Each bus consists of three wires: two for data and one for clock. Thus, the entire SAFEbus set of buses uses a total of 12 wires. The data are transmitted synchronously, 2 bits at a time, at 30 MHz (for throughput of 60 Mb/s). A *bit time* is the time it takes to send 1 bit on one wire. Using multiple wires, 2 bits and 1 clock cycle are sent during 1 bit time. For time, the term *bit time* is preferred to *clock period* because there are multiple clocks within each BIU. SAFEbus uses the wired-OR-capable backplane transceiver logic (BTL) defined in the IEEE 1194 standard. The wired-OR drivers and the use of extended clock pulse widths allow SAFEbus to do some out-of-band signaling that supports some features of the protocol.

Table 48.1 defines some SAFEbus terminology that is further described in this paragraph. The bus time is divided into *windows* of design-time-configurable sizes. Each window is sized to contain either one message (from 1 to 256 32-bit words) or one synchronization pulse or some fixed idle time. A set of static cyclic schedules defines the sequence of windows and the size of each window, which LRM(s) may transmit during each window and which LRM(s) may receive a message from the window. Each window

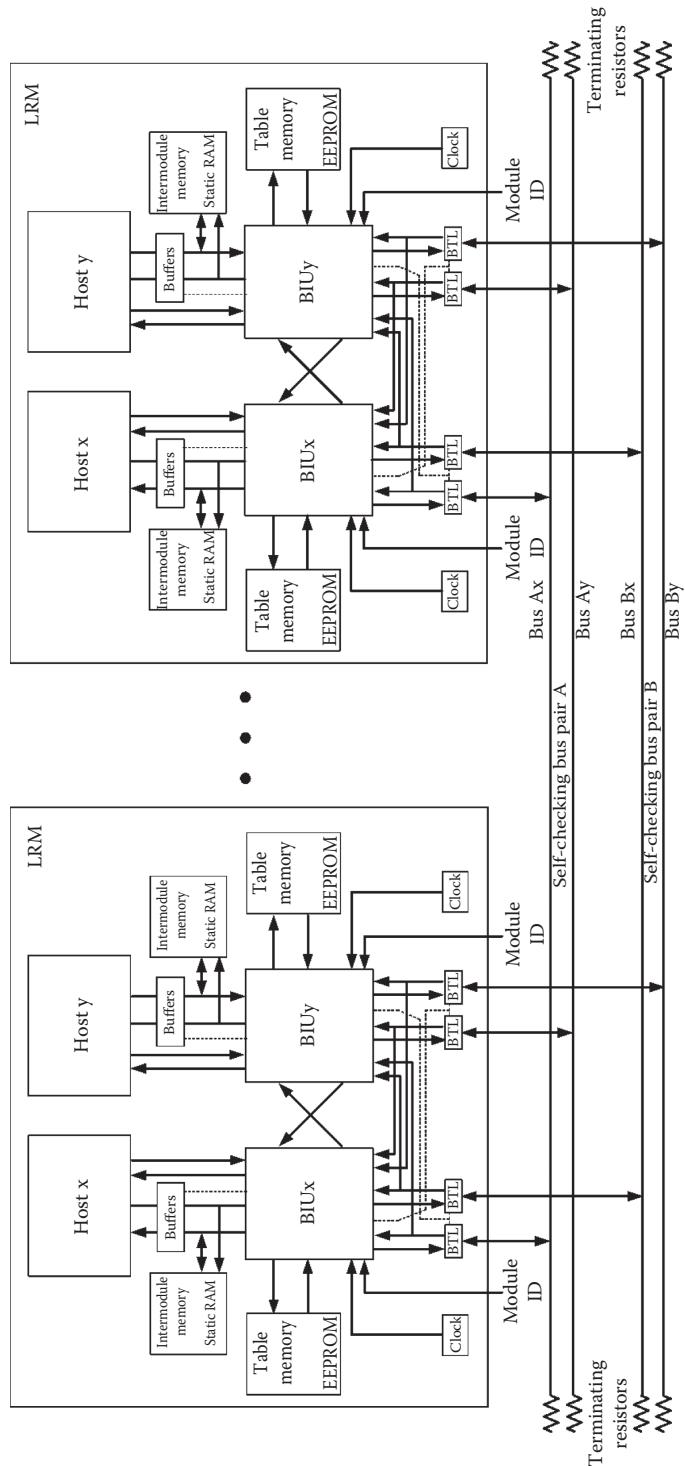

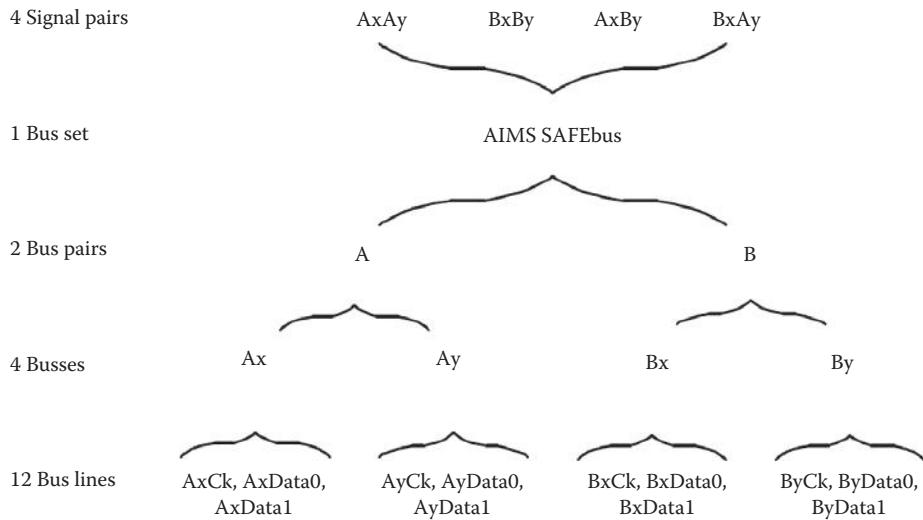

FIGURE 48.1 SAFEbus interface logic.

**FIGURE 48.2** SAFEbus nomenclature.

ends with a small, fixed intermessage gap time. A typical intermessage gap is 2–4 clock periods (i.e., about 50 ns). Fixed idle time may be inserted to adjust the duration of the full cycle or the time between messages, to a precision of 33 ns.

Messages that are to be transmitted or have been received over the backplane are placed in buffers in IMMs, which are pseudo-dual-port memories shared by the host(s) and the BIUs. This organization permits a simple host interface, because all the hosts can view SAFEbus as a shared multiport memory.

**TABLE 48.1** SAFEbus Terminology

Term	Explanation
BIU	Bus interface unit.
Command	Defines what a BIU does during a window (TX, RX, skip, sync, send interrupt to host).
Frame	A cyclical repeating sequence of windows (NB, in SAFEbus and avionics generally); <i>frame</i> refers to a repetition of an execution cycle, whereas in nonavionics data communication, <i>frame</i> is often roughly synonymous with <i>message</i> .
IMM	Intermodule memory (shared message buffer memory between the BIU and its host).
Intermessage gap	The constant reserved minimum idle time between transmissions on the bus.
LRM	Line-replaceable module (a node on SAFEbus).
Message	A single, unique transmission of data on SAFEbus; has a length (in words) fixed at design time.
Table	One or more sequences of commands controlling one or more frames plus their resync jump points and a BIU configuration area.
Table memory	The nonvolatile memory that stores one or more tables.
Window	The bus time reserved for a message, sync pulse, or idle plus the trailing intermessage gap; has a duration (in bit times) fixed at design time.

## 48.3 Protocol Services

### 48.3.1 Communication Services

SAFEbus provides data communication with very low jitter (on the order of 100 ns) that is fail-op/fail-safe with near-unity coverage, even with a Byzantine failure.

The data for a message that is to be transmitted over SAFEbus are calculated typically by independent self-checking pair hosts. As with all self-checking pairs, these data are bit-for-bit identical in the fault-free case. The hosts write these data into buffers in the IMMs. Associated with each buffer is a buffer control word (BCW). Whenever a host completes assembling a message buffer in the IMM, it sets a bit in the BCW to say that the buffer is ready for transmission.

The SAFEbus protocol is driven by sequences of commands stored in the BIUs' table memories (see Section 48.3.7.1). Each command corresponds to a single window on the bus. The command indicates whether the BIU should transmit, receive, or ignore the message in that window. The BIUs in every LRM on SAFEbus are synchronized to equivalent points in their respective tables, and mechanisms are provided to quickly attain synchronization if it is ever lost. The tables also contain the local address (in the IMM) of the data to be transmitted or received. The commands in each BIU's Table are organized into multiple frames. Each frame controls a repetitive sequence of windows, and each frame has a fixed total period.

According to a schedule stored in its table memory, each BIU checks its IMM for the buffer assigned to the next time window. If that buffer's BCW says the buffer is ready for transmission, the BIU begins prefetching the message from the IMM. An LRM broadcasts its messages on the four buses when it is scheduled to do so. The two BIUs in an LRM are synced to within 2 bit times of each other via the SAFEbus protocol on the buses (no *backdoor* sync between them). Because a BIU does not know if it is faster or slower than its partner, it turns on its partner's drivers 2 bit times before its first bit transmission and off 2 bit times after its last bit transmission for each message. Off-line scheduling ensures that messages from different sources never collide, taking into account worst-case clock drifts, metastability behavior, resync intervals, read timing errors, LRM positions along the bus (the speed of light does make a difference), etc. Time windows for messages can be set up such that up to four LRMs share a time window in a master/shadow arrangement, using a minislotting scheme to arbitrate for that window.

Receiving BIUs write validated input data into buffers within each of their IMMs. At the completion of a message, the BCWs associated with each buffer are updated with status that includes whether the buffer has valid data and what time it arrived. The fact that the BIUs are synchronized to protocol time allows each of them to independently write identical BCW time stamps into each one of their IMMs without doing an exchange of the received time between the BIUs. Protocol time is measured in bit times from the first window transmitted. The time of each SAFEbus event (e.g., message reception) is the protocol time of the window for which it occurred.

One of the benefits of the table-driven protocol is extremely high efficiency. Control applications typically generate short messages, and most serial protocols perform poorly when messages are short. Efficiencies of between 10% and 30% are typical. In contrast, the SAFEbus protocol is over 89% efficient for a continuous stream of 32-bit messages. Ethernet messages with the same payload would be less than 5% efficient. Because buffer addresses are kept in the tables, they do not need to be transmitted on the bus. The use of transmit and receive commands in the individual tables eliminates the need to send source or destination LRM addresses. Within a message, all clock periods contain data (zero overhead). And because transmissions are scheduled, no transmission time is consumed arbitrating between contending BIUs (with the rare exception of the optional use of master/shadow that typically consumes about 9 bit times per arbitration).

#### 48.3.1.1 Determinism and Partitioning

SAFEbus' determinism and support for robust partitioning warrants more detailed examination, since no other protocol provides these features to this extent. When a system has functions with different

levels of criticality, the functions must be partitioned both in space and in time. Space partitioning means that no function can prevent another from obtaining adequate memory space and that the memory space assigned to one function cannot be corrupted by the behavior of another function. Memory management units (MMUs) are usually adequate for simple uniprocessor main memory. But problems arise with multiport memory (including network interfaces) and *memory* that must be shared (CPU registers, cache, I/O registers). Time partitioning means that one function's demand for shared hardware resources will never prevent another function from obtaining a specified level of service and, more importantly, that the timing of a function's access to these resources will not be adversely affected by variable demand or by failure of another function.

Any protocol that includes a destination memory address in a message is a space-partitioning problem. It is extremely difficult to verify correct address usage in a partitioned multiprocessor. To ensure correct usage, the BIU would have to duplicate the typical processor memory management (MMU) function. Then, a difficult protocol would have to be implemented to ensure all BIUs used the same MMU information.

Protocols that use contention arbitration cannot be made strictly time deterministic. Such arbitration is meant to ensure that when two modules contend for the bus, the one with the highest priority request is granted access. But minor jitter in the execution of functions can change which modules contend for the bus on any given bus cycle. As a result, the order in which the modules obtain access can vary from one arbitration to another in ways that cannot be predicted at design time.

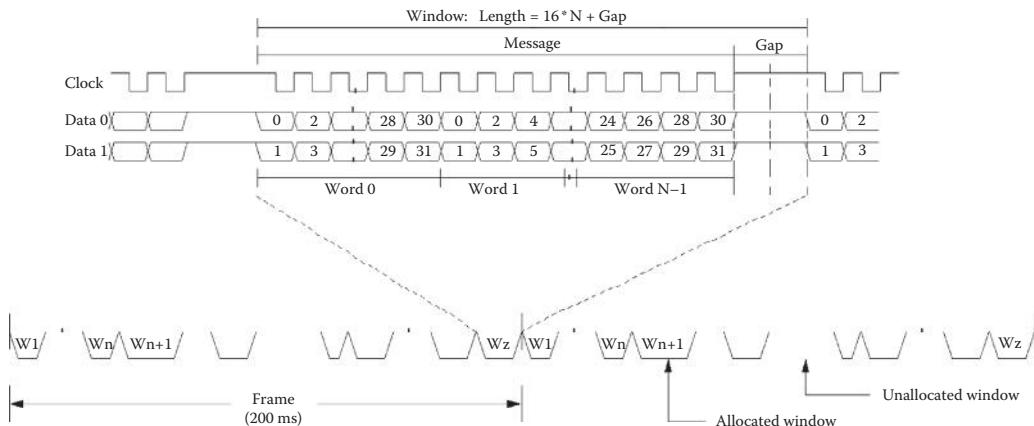

SAFEbus achieves both time and space partitioning by placing all message location (IMM) and bus-timing information in its table memories that are frozen at design time. This table information is held in the BIUs' table memories where it cannot be corrupted by any errant software or communications errors. The contents of these memories can be changed only by a very-well-guarded interface (see Section 48.3.6).

To extend SAFEbus' time determinism to include the functions' software, the software execution can be synchronized with the execution of the commands in the bus table. Thus, the software is at the same point during the same bus transmission window in every frame. One benefit is that message latencies can be reduced to insignificance. Results can be scheduled to be transmitted just after they are generated, and input data can be delivered just before they are needed (software never has to ask for input data to be transferred over SAFEbus as data are sent autonomously). A second benefit is that there is less latency jitter on cabinet outputs, which means that a SAFEbus IMA can be used in tighter control loops. A third benefit is that double buffering is rarely necessary because it is possible to schedule the transmission of a data block for a time when it is known that software will not be reading it or modifying it. The elimination of double buffers means the IMMs can be smaller and memory access faster. While the use of software synchronized to the bus and single buffers is the preferred operation, SAFEbus does allow for asynchronous software and double buffering.

#### 48.3.1.2 Data-Message Structure

There are two data-message types: basic and master/shadow. The basic message structure has been chosen to maximize the efficiency of data transmissions. The master/shadow structure supports data transfers by redundant or aperiodic functions.

*Basic and master/shadow message structures.* Basic messages have a simple structure (see Figure 48.3). Each message consists of a string of 1–256 32-bit data words followed by a programmable intermessage gap of 2–9 bit times. The master/shadow mechanism allows LRM s or applications to be reconfigured or spared without disturbing the traffic pattern on the bus. Master/shadow windows are identified by a field in the associated table command. As many as four transmitters can be assigned to one master/shadow window. Time-slot arbitration determines which of the transmitters actually gets control of the window. If the master is alive and has fresh data to send, it starts transmitting at the beginning of the window. The first shadow begins transmitting *delta* bit times into the window, only if the master did not use its opportunity to transmit. The second shadow begins transmitting two *delta* bit times into the window, only if the master and the first shadow did not use their opportunities to transmit.

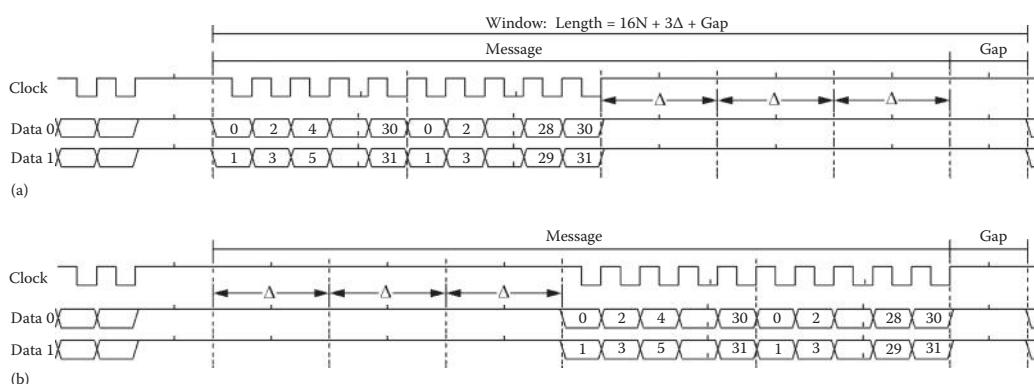

**FIGURE 48.3** Basic message structure.

Finally, the third shadow begins transmitting three delta bit times into the window, only if none of the other candidate transmitters use their opportunities to transmit. Delta is a programmable value that is typically set at 1 bit time larger than the selected intermessage gap (values from 3 to 10 bit times may be selected). The selected value depends on the propagation characteristics of the backplane. Examples of the transmission over SAFEbus when the master or third shadow transmits are shown in Figure 48.4.

Time-slot arbitration could reintroduce nondeterminism, but strict measures have been taken to eliminate this danger. First, the total size of a master/shadow window is always the size of its message's data plus three deltas, no matter what happens during arbitration. Thus, the time window remains the same size no matter which transmitter *wins* the arbitration. Second, recipients of a master/shadow message always place the data in the same memory location, no matter which transmitter wins the arbitration. Third, delta can be made large enough to guarantee that the candidate transmitters will never mistake a busy bus for an idle one and begin transmitting in error. Fourth, recipients of a message from this window will be alerted to the presence of this message at exactly the same time after the end of the window, regardless of which LRM wins the arbitration. This allows completely transparent redundancy among the master and the shadows.

The master/shadow mechanism also can be used for sharing bandwidth among asynchronous functions. Of course, partitioning is not maintained in such windows.

**FIGURE 48.4** Master/shadow message structure: (a) master transmits and (b) shadow 3 transmits.

### 48.3.1.3 Bus Encoding

To improve error-detection coverage, data on the four SAFEbus serial lines are encoded in four different ways. Data on bus Ax have normal polarity. Data on bus Bx are inverted. On bus Ay, every other bit is toggled, starting with the second bit. Bus By is the inverse of bus Ay. This is illustrated in Figure 48.5. This encoding can be seen as a form of *encryption* in which the four buses Ax, Ay, Bx, and By are XORed with the running keys “0000...,” “0101...,” “1111...,” and “1010...,” respectively [5].

One type of failure that this encoding catches is bus-to-bus shorts. With identical data on all four buses, a short between the buses could not be detected until another failure occurred such that the failure propagated from the bus with the second fault to the bus with which it was shorted. Having a first fault lay dormant for indefinitely long periods of time and then to make its appearance exactly when a second failure occurs cannot be tolerated. This problem is largely ignored by homogeneous fault-tolerant architectures. One way to mitigate this problem is to do periodic scrubbing of the buses by putting different data on the buses that would ordinarily be the same and see that they actually are received as different. There are a number of problems with this approach. The scrubbing has to disrupt normal communication and it has to disable some of the fault-tolerance features. The latter is dangerous and must be invoked only with a complex set of interlocks. Because of these complications, scrubbing is not continuous and there is an engineering trade-off between the scheduling of scrubbing and exposure time to these latent faults. The use of this bus encoding detects these shorts within 2 bit times of the short onset and without requiring scrubbing.

This encoding scheme can detect unipolar transient upsets that affect several data lines simultaneously. It also allows quick detection of bus collisions caused by a malfunctioning BIU pair (a specific dual-fault scenario that is beyond the basic SAFEbus fault hypothesis). Because bus lines are *wired OR*, if a faulty LRM tries to transmit at the same time as another LRM, illegal encodings appear within 2 bit times of the LRMs starting to transmit differing data.

An additional virtue of this encoding scheme is that power consumption is independent of the data being transmitted. Two bus lines are always high and two are always low (constant average

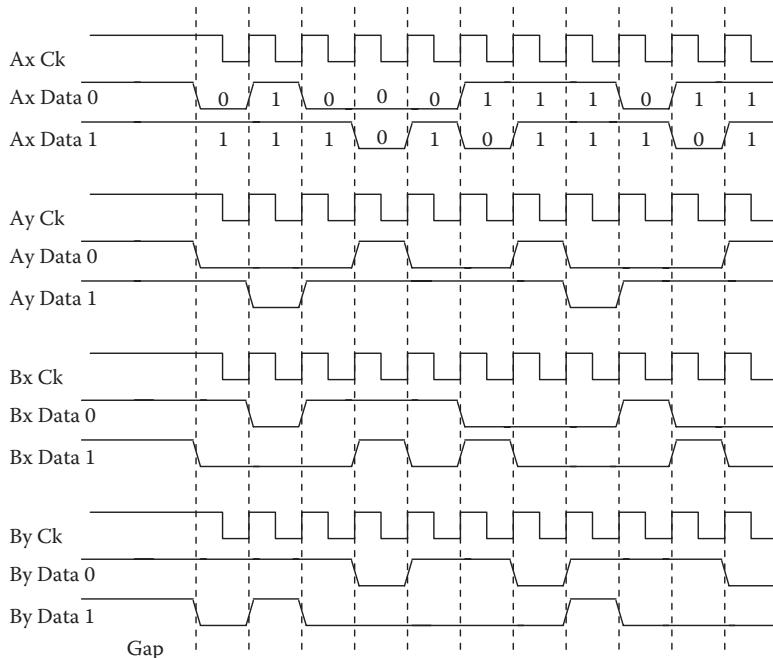

FIGURE 48.5 Bus encoding example.

DC power). When the data change, two of the buses change state and two do not (constant average AC power). Because power consumption is constant, the power supply does not have to be designed for a worst-case data pattern. The fact that bus pairs A and B are inverses of each other provides some of the characteristics of differential signaling, without an additional doubling of the number of signal lines required.

#### 48.3.1.4 Out-of-Band Signaling Pulses

Because SAFEbus messages are pure data (no message-framing overhead) and all data values are used, the only way that protocol-specific information can be conveyed is through the use of out-of-band signaling. One method SAFEbus has for out-of-band signaling uses the clock lines. For data transfer, the clock lines are alternating low for one-half bit time and high for one-half the time (as depicted in Figure 48.3). For out-of-band signaling, the clock lines are driven low for 4 bit times, creating a uniquely identifiable pulse, called the sync pulse. There are four possible variants of this signal depending on the values of the Data0 and Data1 lines during this pulse. Two of these variants are used for synchronization: one of them is used for a debugging mechanism (see Section 48.3.4.1), and one is not used.

The other out-of-band signaling method that the SAFEbus uses drives data lines low, while the clock lines remain high. Of the three variants that are possible with this method, SAFEbus only uses one. It drives Data0 low to indicate initial resync (see Section 48.3.3).

#### 48.3.2 Clock Synchronization

SAFEbus' long resync and the short resync messages both perform precision (sub-bit time level) clock synchronization. The purpose of this synchronization mechanism is to maintain separation of adjacent messages in the presence of oscillator drift and keep the two BIUs in an LRM within 2 bit times of each other. Since the mechanism is the same for both and the short resync message is simpler, only the short resync message will be discussed here. The additional functionality of the long resync message is described in Section 48.3.3. The short resync message is shown in Figure 48.6. It consists of the sync pulse on the clock lines and both data lines being high. To provide availability, all LRMs transmit the sync pulse. The multiple drives are combined into a single pulse by the *wired-OR* action of the open-collector BTL drivers. While all LRMs are scheduled to transmit this pulse at the same time, only one needs to succeed. Because of clock drift, each of the LRMs might turn on its driver at slightly different times. However, these resync pulses happen often enough such that the drift can never be more than the width of the pulse. Thus, this pulse can appear to be from 4 bit times up to eight times wide. When a BIU sees this pulse, it freezes its internal time, and at the end of the pulse, it releases the freeze. It uses an internal effective 4 $\times$  clock to sample the clock lines. This is shown in Figure 48.7. Because each BIU's time was frozen, its time will have fallen behind real time. The BIUs then enter a catch-up phase where the internal time counters are incremented at a 2 $\times$  rate until the internal time has caught up with

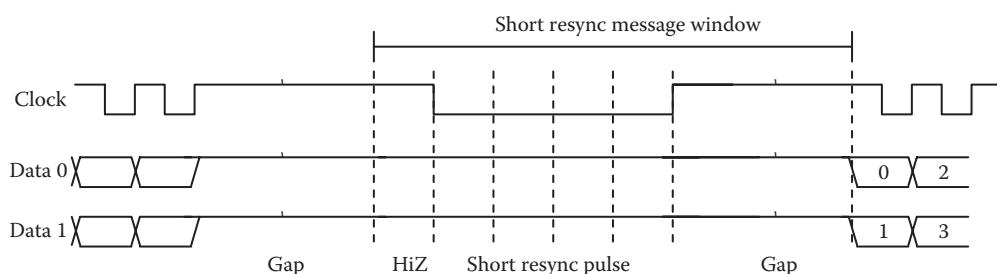

FIGURE 48.6 Short resync message.

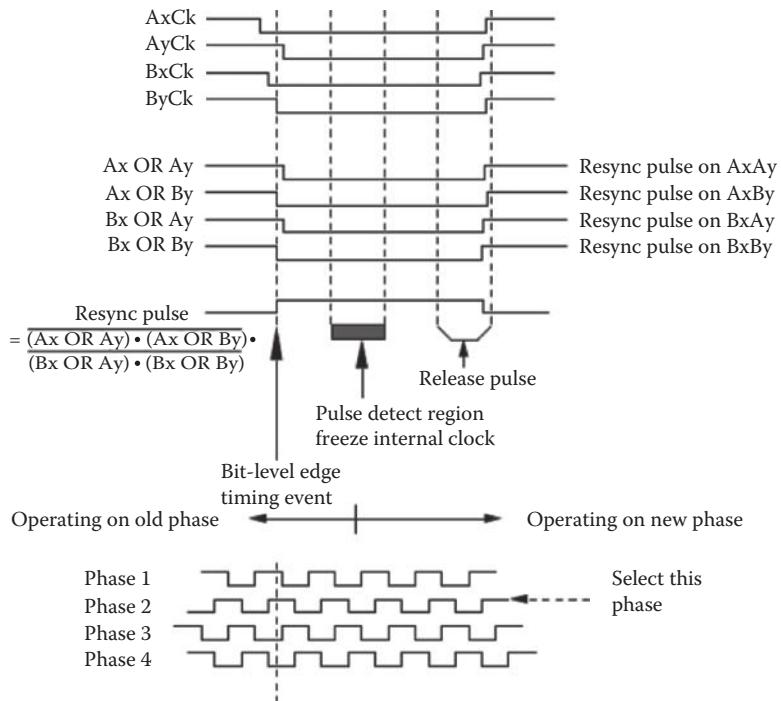

FIGURE 48.7 Resynchronization pulse timing.

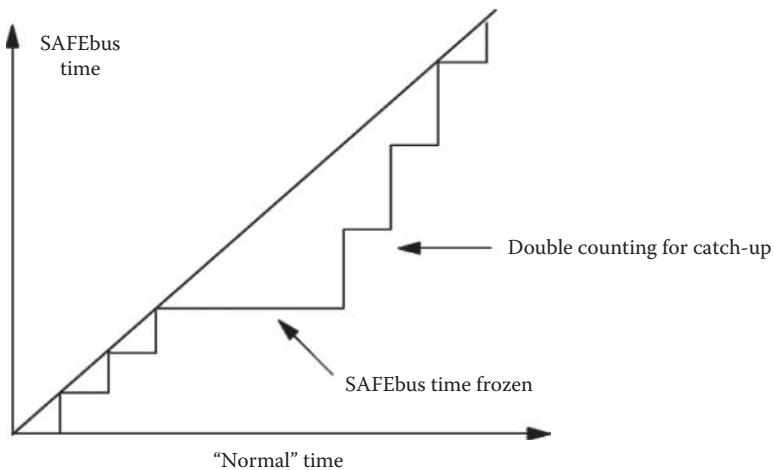

FIGURE 48.8 Time adjustment.

real time (Figure 48.8). The duration of this catch-up phase is equal to the freeze duration. This allows all BIUs to have identical times after each resync event without ever causing time to go backward in any BIU.

The aggregate effect of this resync mechanism is that the slower of the two BIUs in the quickest LRM paces the system time base. Each BIU maintains a counter (called SAFEbus time) driven by its synchronization-corrected oscillator. The synchronization mechanisms make the values in these counters identical in all BIUs with respect to the time that protocol events happen (e.g., the receipt of a message). The time value may be used to time stamp data.

### 48.3.3 Restart, Reintegration, Integration

*Synchronization states.* Figure 48.9 shows the major synchronization states of a BIU and their transitions. The major states are as follows:

*Initializing.* While in this state, the BIU performs such operations as table memory cyclic redundancy checks (CRCs) BIU configuration area loading, and IMM tests. The full-resolution SAFEbus time register value is not valid in this state. IMM access is disabled during much of the initialization process, while the BIU performs IMM pattern testing.

*Out\_of\_Sync.* While in this state, the BIU hunts for resynchronization messages transmitted over SAFEbus and attempts to synchronize with them if they are present. If enough time elapses without a synchronization message being seen, the BIU issues an initial sync pulse to start up the backplane. The full-resolution SAFEbus time register value is not valid in this state.

*In\_Sync.* While in this state, the BIU executes command sequences out of a table command sequence area in the table memory. It transmits when executing an appropriate transmit command (and data are fresh) and receives data when executing a receive command. Synchronization is maintained via the transmission and reception of programmed synchronization messages. The full-resolution SAFEbus time register value is valid in this state.

*Halted.* This is a substate of the In\_Sync state. The BIU enters the halted state when it is executing in debug mode and encounters a breakpoint or completes a single-step operation.

*Disconnected.* While in this state, the BIU suspends all transmission and reception activity on SAFEbus. The host may still read and write memory and BIU registers, but no backplane data will get written into memory. The BIU will enter this state if commanded to by the host or if initialization fails or if it receives a long resync message with mismatching version while in the Out\_of\_Sync state.

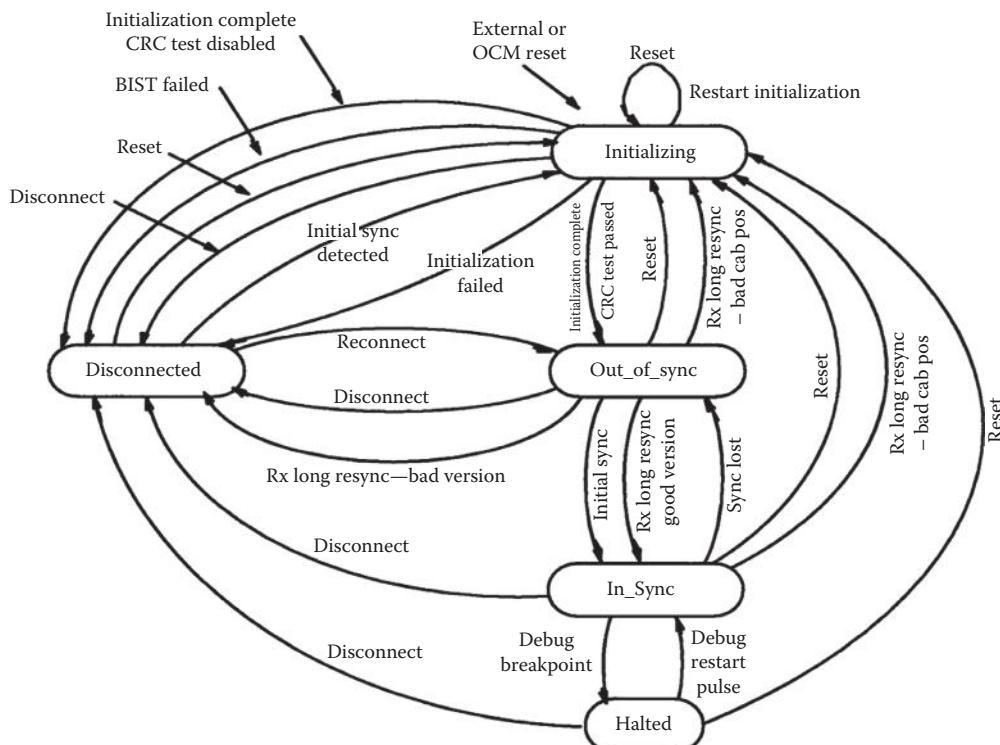

FIGURE 48.9 Synchronization state diagram.

It leaves this state if commanded by the host or if an initial sync pulse is detected on SAFEbus. The full-resolution SAFEbus time register value is not valid in this state.

*Synchronization messages.* Three uniquely identifiable transmission patterns are provided to support bit-level and frame-level synchronization of the SAFEbus backplane. The initial sync message is used to initialize the SAFEbus after a power-up or in the pathological case of a cabinet-wide loss of synchronization. The short resync message is provided to maintain bit-level synchronization between all BIUs in the cabinet by correcting for oscillator drift between BIUs. The long resync messages are provided to allow lost modules to regain synchronization with an active bus. Long resync messages come in two variants. The entry resync variant is provided simply to allow lost modules to resync to the current frame. The frame change variant is provided to switch between different frame programs in the current table. Both versioned and unversioned forms of the long resync messages exist. Long resync messages also implement the bit-level resynchronization operation (as provided by the short resync message).

*Long resync.* The structure of the long resync message (Figure 48.10) is separated into two distinct subwindows. The long resync pulse subwindow starts with a unique long resync pulse identified by a low level on the clock lines with all associated Data0 lines low. The pulse is nominally 4 bit times long followed by a maximum gap. The long resync pulse is transmitted by all BIUs that are executing either a transmit or receive long resync command.

The second part of the long resync message is the long resync information subwindow. A single, unique BIU must transmit in the long resync information subwindow. This consists of an 8-bit resync code (a value from 0 to 255), a 1-bit versioned frame indicator, 1 bit of reserved space, a 4-bit cabinet position, 7 bits of reserved space, 43 bits containing SAFEbus time, and a 32-bit table version. The resync code allows the BIU to determine which of 256 locations in the table it should jump to in order to align itself with the other BIUs. In software, this would be called an indirect jump. The code indexes into a resync jump table (see Figure 48.13), which contains addresses that point to the main table command sequence area command that should follow this long resync message in the normal sequence of command execution. The version frame indicator, cabinet position, and table version are used as part of versioning enforcement as described in Section 48.3.7.3. The SAFEbus time field is used to supply this information to LRMs receiving this message while not in sync.

Long resync messages can be sent master/shadow, which combines the properties of both these message types. This benefits the multiway trade-off among fault tolerance, bandwidth used, and resynchronization latency.

*Frame change.* A variant of the long resync message is the frame change message. The message form is identical. The differences are in the way that it is used. In the long resync message, the resync code points to the next command in the normal sequence. In the frame change message, the code points elsewhere, usually to another frame. The frame change is a conditional jump. An LRM that is scheduled to transmit a frame change cannot do so unless its host writes a code into the BIU that matches the frame's code (a *lock and key* mechanism). A tightly controlled mechanism is provided to switch between frames based on explicit commands generated by Level A operating system (OS) software using the *lock and key*. Normally, *lock and key* fault-containment mechanisms are very weak. However, in the case of SAFEbus, this mechanism is protected against hardware failures by the use of self-checking pair hardware, and it is protected against software failures through the use of an MMU, which limits the lock's access only to the Level A software.

If the frame change message is not transmitted, the *jump* is not taken and the command/window sequence continues with the command, which is next after the frame change in the table. If the frame change message is transmitted, the *jump* is taken and all LRMs fetch their next command from the location pointed to by the frame change's resync code. The use of this feature is described in Section 48.3.6.1.

*Initial sync.* Initial sync messages (Figure 48.11) are transmitted by an Out\_of\_Sync BIU that waits longer than the initial sync wait limit without seeing any resync pulses on the backplane. All BIUs that are out of sync at this point will use the initial sync message to synchronize into an unversioned initial frame. The initial sync message starts with the initial sync pulse. It has a unique pattern identified by a

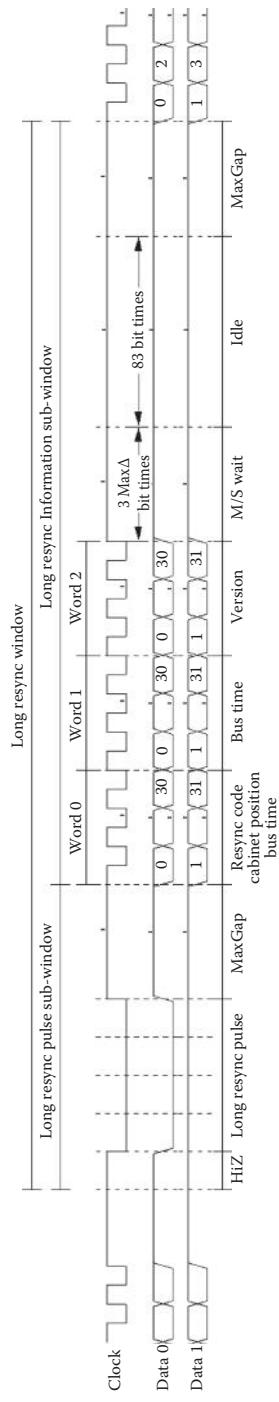

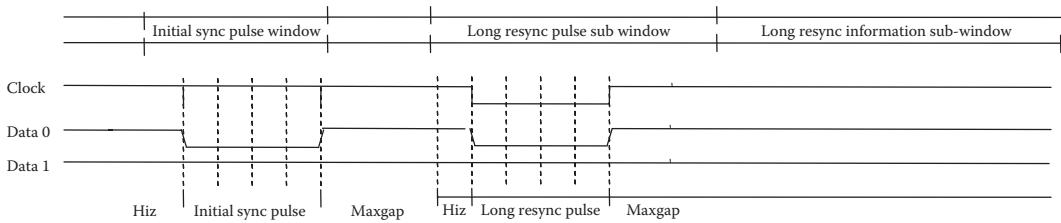

FIGURE 48.10 Long resync message.

**FIGURE 48.11** Initial sync message.

signal pair of buses with a low level on the Data0 line and a high level on the clock line for at least 2 bit times. In addition, for a bus to be considered part of an initial sync pulse signal pair, the Data0 line must have been high at one point during the time while the BIU waited for the initial sync wait limit. The pulse is nominally 4 bit times long.

To more accurately resync the clocks and to allow the BIU time to fetch the command for the first message in the initial frame, the initial sync pulse is followed by a long resync message with no BIU transmitting the information subwindow. The missing information is assumed to be zero. In particular, the resync code is zero and the SAFEbus time is zero. The BIU will enter the In\_Sync state at the first bit time of the gap that separates the idle data portion of the long resync message from the first window of the initial frame. The first bit time of the initial frame occurs  $(106 + 6\text{Max}\Delta + 2\text{MaxGap})$  bit times after the leading edge of the long resync pulse that follows the initial sync pulse.

#### 48.3.4 Diagnostic Services

SAFEbus uses masking fault tolerance, which does not need the complicated diagnostic services required by other protocols, for example, it does not need to keep track of membership. However, it does supply a rich set of diagnostic mechanisms and information for maintenance purposes. This includes full built-in self test (BIST) capability via dual (x and y) IEEE 1149.1 (JTAG) test buses. The x JTAG bus connects only to the x BIU, and the y JTAG (Jaintest action group) bus connects only to the y BIU in order to prevent fault propagation from the two sides of the self-checking pair. For commanded BIST, the BIU goes off-line and scans a set of pseudo randomly generated test vectors into the logic, clocks it through the logic, and accumulates the result of the clocking into the BIST signature result register. The BIST also includes scrubbing of all the critical fault-tolerant circuitry within the BIUs. For scrubbing protection mechanisms, the hardware is invoked to test if the protection mechanism is really invoked when a failure occurs.

##### 48.3.4.1 Debugging Mechanisms

Another unique feature of SAFEbus is its ability to breakpoint and single-step an entire system, including the processors connected to SAFEbus. This is the same as the breakpoint and single-step functionality commonly seen in software debuggers, but on a systemwide basis. The reason this is possible is because SAFEbus acts as the central clock for the system, providing the timing ticks that the OSs of the processors attached to it use for dispatching tasks. If the SAFEbus freezes, so do all of the processors.

A breakpoint can be set for any time within the global SAFEbus timeline. A breakpoint can also be initiated by driving the Ck, Data0, and Data1 lines low simultaneously for at least 4 bit times. To resume from a breakpoint, some LRM transmits a short resync pulse.

Because setting a breakpoint can be dangerous during normal operation, breakpoints are only enabled for special test table versions. This is indicated by the upper 2 bits of the table version being 11.

#### 48.3.5 Fault Isolation

SAFEbus, with its self-checking approach, provides near-perfect coverage. The checking at the receiving end provides near-perfect error-detection coverage for many faults, including Byzantine faults [6].

It provides better coverage than signature-based error-detection techniques (such as CRCs) [7] while simultaneously not incurring the overhead of these schemes.

Recapping Figure 48.1, SAFEbus consists of four buses (Ax, Ay, Bx, and By) that connect several self-checking pair LRMs. Each of the four buses and each half of an LRM are independent fault-containment zones. If there are N LRMs, there are  $2 \times N + 4$  fault-containment zones. Each of the BTL bus interface parts is in its associated bus' fault-containment zone and gets its power supply from that bus. Thus, the fault-containment zone boundaries are between the BTL parts and the BIU parts. Names ending in x and y denote redundant parts for integrity. Bus names beginning with A and B denote redundant bus pairs for availability. The BTL drivers are connected such that BIUx transmits only on Ax and Bx and BIUy transmits only on Ay and By. Thus, a faulty BIUx can contaminate only buses Ax and Bx, and a faulty BIUy can contaminate only buses Ay and By.

The dashed lines in this diagram are control signals. In particular, BIUx enables BIUy's bus drivers and BIUy enables BIUx's bus drivers. Thus, an LRM cannot transmit unless both BIUx and BIUy agree to do so. The set of buses is fail-op, fail-stop. Each LRM is fail-stop. N redundant LRMs are N-1 fail-op, fail-stop. The major failure scenario that SAFEbus does not cover is two simultaneous active faults in the same LRM that are somehow complementary to escape the bit-for-bit checking and cross-coupled driver enables. This has a probability that has been calculated to be much less than  $10^{-10}$ .

#### 48.3.5.1 Babble Protection

To detect errors, the transmitting LRM checks what it actually puts on the bus. If a BIU sees a miscompare, it stops transmitting and it disables its partner's drivers. The dual nature of this comparison ensures that a babbling module cannot stay on the bus. This is an availability feature rather than an integrity feature. Integrity fault containment is done by the receivers. This availability feature is only applicable to master/shadow windows. In order to prevent loss of resources due to transient failures, LRMs are allowed to restart for a limited time by implementation of a strike counter. This strike counter is incremented for each fault found in a specific interval (say, a maximum of three failures are allowed within 10 min). This ensures that transient faults are dealt with in a constructive manner and permanent or intermittent faults are isolated after the LRM has hit the strike counter limit.

#### 48.3.5.2 Byzantine Protection

SAFEbus has a unique way of tolerating Byzantine faults. Because the transfer of a message from one LRM to another LRM uses four fault zones, it is possible for it to tolerate one Byzantine fault. The BTL receivers are cross-linked to the two BIUs such that each receiving BIU gets a copy of the message from all four buses. This can be seen as the first round of the classical Byzantine exchange. Each BIU creates two 4-bit status vectors, collectively called the *syndrome*, for each 16 bits received within a message.\* The first vector has a bit for each bus saying whether anything came in from that bus. The second vector is the result of the comparisons: Ax = Ay, Bx = By, Ax = By, Ay = Bx. The BIUs exchange their syndromes. From these 8 bits, the two BIUs can determine which (if any) of the data bus inputs have arrived error-free. If there is such an error-free source, both BIUs select it as the source data. This can be seen as the second round of the classical Byzantine exchange. This prevents Byzantine failures arriving from outside a pair from confusing a pair into thinking that one of the halves of the pair is faulty. If a message arrives with uncorrectable errors, the BCW associated with its buffer is updated to that status. A self-checking pair host reading a BCW status that indicates an error is not allowed to read the data buffer because differing data in the two IMMs could cause the host pair to split.

While the syndrome exchange prevents a Byzantine fault from splitting a pair, an additional mechanism is needed for Byzantine agreement among pairs. Before SAFEbus, Byzantine algorithms

---

\* The granularity of 16 bits was chosen as an engineering trade-off between the desire for a smaller size to increase availability and the desire for larger size to minimize metastability errors and to make it easier to meet timing constraints on the exchange between the BIUs.

either did a full exchange of an entire message's content or used signatures. The problem with the former method is the large amount of bandwidth it requires. The problem with the latter method is that it does not provide full coverage. SAFEbus introduced a new method: hierarchical Byzantine agreement. In this method, a lower-level agreement prevents Byzantine faults from affecting a pair, as described earlier. An upper-level agreement only needs to send 1 bit of information from every receiving LRM of the message. This bit would indicate whether the LRM rejected the message as being faulty or not. Because the SAFEbus granularity is 32 bits, it can send 32 bits just as well as 1 bit. Using 32 bits allows this upper level of exchange to be implemented with no additional hardware and with no software. All that is done is to have the buffer for this upper-level round of exchange be placed into the IMM such that the data word of this buffer overlaps with the BCW for the original message. Thus, what is exchanged on this upper level is the BCW of the original message. If the original message was rejected, the BCW is zero.

#### 48.3.5.3 Availability versus Integrity Trade-Off

The syndrome exchange mechanism includes an option to select a preference for availability or integrity, for those cases where there is not a generally applicable best choice, for example, if  $Ax = Ay$  and  $Bx = By$ , but  $Ax \neq By$  and  $Bx \neq Ay$ . This can only happen if there are at least two identical bit errors (after decode). A receiver cannot tell if pair A or pair B is correct. For integrity, both have to be thrown out because neither can be trusted. For availability, either A or B could be arbitrarily chosen.

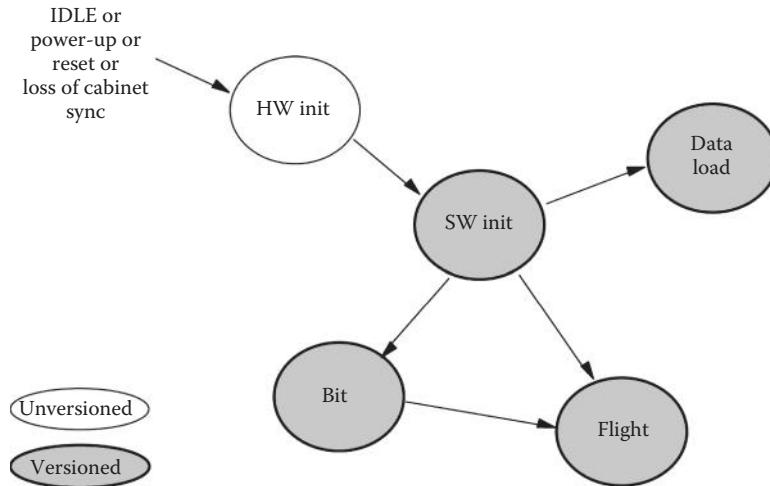

#### 48.3.5.4 Zombie Module Protection

Each LRM that plugs into SAFEbus must contain a table of commands that is compatible with all other LRMs on that SAFEbus. One mechanism for preventing LRMs with an incompatible table would be to have the LRMs exchange table version information at start-up. However, such a scheme would not cover the scenario where an LRM is dead or comatose at start-up and then *wakes up* in the middle of a critical operation with an incompatible table. This is called the *zombie module* problem. To solve this, SAFEbus requires all LRMs joining a SAFEbus that has active traffic to compare the table version information in a long resync message to its own. It is allowed to join the network only if the versions are compatible. See Section 48.3.7.3 for details on version enforcement.

### 48.3.6 Configuration Services

The SAFEbus tables are loaded into each BIU's table memory using the same dual IEEE 1149.1 (JTAG) test buses that are used to support BIST. These table memory images can contain multiple tables so that one LRM can play several different roles depending on which slot and in which cabinet the LRM is located. This mechanism can reduce the number of spares required to be held in maintenance facilities. For example, the Boeing 777 AIMS cabinets had one I/O module (IOM) design that was used in eight places. This reduced the number of types of spares required from eight down to one and reduced the total number of spares needed to be held in the logistics pipeline. In theory, this could also allow for onboard sparing and manual reconfiguration. Each slot in every SAFEbus cabinet has five slot ID pins that can allow up to 32 slots per cabinet. To prevent wrong-ID masquerade faults, these pins are protected by parity and cross compare between the two-halves of a pair. Each cabinet also has a cabinet ID. To eliminate the need for cabinet ID pins on every slot, SAFEbus allows some subset of LRMs within the cabinet to have these pins, and then these LRMs broadcast this cabinet ID in their long resync messages' cabinet position field. With the existing 4 bits of cabinet position and 5 bits of four slot IDs, SAFEbus can currently accommodate up to 512 slots systemwide. The long resync message has seven spare bits adjacent to this field that could be used to expand this to a total of 65,536 systemwide slots.

After the tables have been loaded, SAFEbus can be used to download software and other data. To optimize bandwidth usage, special frames can be used for these downloads (as described in Section 48.3.6.1).

**FIGURE 48.12** Example frames and their frame change transitions.

#### 48.3.6.1 Frame Changes

This section provides an example for frames to do hardware initialization (HW Init), software initialization (SW Init), data loading, built-in self-test (BIST), and normal application communication, plus the frame change transitions between them. The following is a brief textual description of each frame:

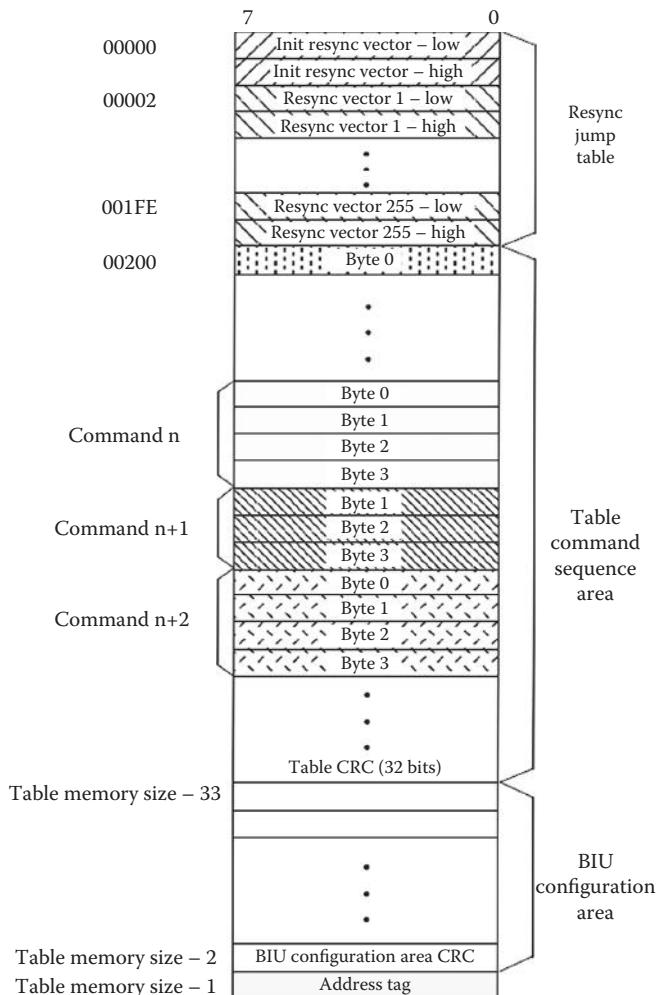

1. The HW Init frame follows ARINC 659's definition for the initialization frame and, as such, is an unversioned frame. The only data traffic during the HW Init frame is the transfer of version messages from all LRMAs. The HW Init frame is approximately 117  $\mu$ s in duration.
2. The SW Init frame provides time for the processors' environment to be set up before the functional partitions are dispatched in the flight frame.
3. The built-in test (BIT) frame is a versioned frame that provides time to perform power-up BITE.
4. The flight frame is a versioned frame that provides the data transfers for running software partitions.
5. The data load frame is a versioned frame that provides the data load function, using the majority of the SAFEbus bandwidth. While data loading may be performed in the flight frame, a data loading session using the data load frame is much quicker.

Figure 48.12 shows these frames and possible transitions. Note that the frame changes are unidirectional. This means, for example, that once the flight frame starts executing, it cannot be frame changed to any other frame. In order to go from the flight frame to another frame, the SAFEbus must be reset. This is an additional safety precaution against accidental transitions out of flight frame.

#### 48.3.7 Protocol Parameterization

##### 48.3.7.1 Table Memory

As shown in Figure 48.13, a SAFEbus table is divided into three areas: resynchronization jump table, table command sequence area, and BIU configuration area. The resynchronization jump table is used by the BIU to rapidly locate the address in the table memory corresponding to the resync code (see Section 48.3.3). The majority of the table memory is used for the cyclic command sequences that control frames. More than one frame schedule can be present for different system *modes* (such as system initialization, ground checkout, flight operation, software loading), with each mode having a different schedule. The different frames for different modes are contained within a single table command

**FIGURE 48.13** Table memory structure.

sequence area. Therefore, this selection is in addition to the selection of different tables depending on location (slot and cabinet) roles. The BIU configuration area contains information for BIU customization options such as memory speeds, host interface characteristics, selection of availability or integrity as preferred for those cases where one is not universally preferred over the other, intermessage gap, master/shadow delta, and SAFEbus time increment rate. The contents of the table memories that are associated with the two BIUs on a single module are bit-for-bit identical. However, the table memory contents are different for each module on SAFEbus. This is because the local IMM addresses can be different and the commands are different for TX versus RX, master versus shadow, etc.

#### 48.3.7.2 Frame Description Language

SAFEbus uses a frame description language to define the contents of each frame. This is an intermediary language that can be produced by off-line schedulers. A back-end tool specific to each BIU design translates this FDL into a bit image that can be loaded into table memories. This language has been standardized by ARINC 659 to allow decoupling between vendors of scheduling tools and vendors of BIU hardware. For AIMS, a software tool parses a database of ICD information and generates a schedule that has much more freedom than schedulers for most time-triggered protocols.

### 48.3.7.3 Table Versioning

The SAFEbus protocol includes a mechanism to ensure that only LRM<sub>s</sub> with compatible tables are allowed to transmit on the bus. To support this mechanism, SAFEbus uses two types of frames: unversioned and versioned. Unversioned frames allow LRM<sub>s</sub> of any SAFEbus version to communicate. These frames are used for LRM<sub>s</sub> to exchange their table version information with each other. Such frames always operate with the maximum programmable gap size between messages in order to be compatible with even the slowest LRM implementations.

After power on, all LRM<sub>s</sub> enter a standard unversioned initialization frame in which each of the possible 32 LRM<sub>s</sub> that could exist on one SAFEbus is given a window in which to transmit their table version information. Up to eight of the LRM<sub>s</sub> are given the authority to do a frame change from the initialization frame to either a versioned frame or another unversioned frame. The decision of which frame change to do is an application-dependent function that uses the gathered table version information as input.

The version field in the frame change command informs all BIU<sub>s</sub> of the destination frame's version. BIU<sub>s</sub> with a table version that does not match the destination frame's version cannot follow the frame change and will drop out of sync. BIU<sub>s</sub> with a table version not matching a currently running frame are prevented from joining the bus traffic because they cannot sync to the versioned long resync messages. Most normal application operations are done in a versioned frame.

## 48.4 Communication Interface

All data communications between modules on the SAFEbus backplane occur via buffers stored in the IMM address space. Two buffer formats are provided: controlled and noncontrolled.

The controlled buffer memory format consists of a single BCW followed by one or two data sub-buffers (depending on whether the data item requires double buffering) of up to 256 words each. See Figure 48.14.

When a BIU executes a command to transmit from a controlled buffer, it determines the buffer type from the command. The BIU then reads the BCW and checks the TX Fresh bit and the Ping/Pong bit (if the buffer type is double buffered). If the TX Fresh bit is set, the BIU transmits the data and writes the BCW back with the TX Fresh bit cleared to 0. If a transmission failure occurs, the entire BCW is set to 0.

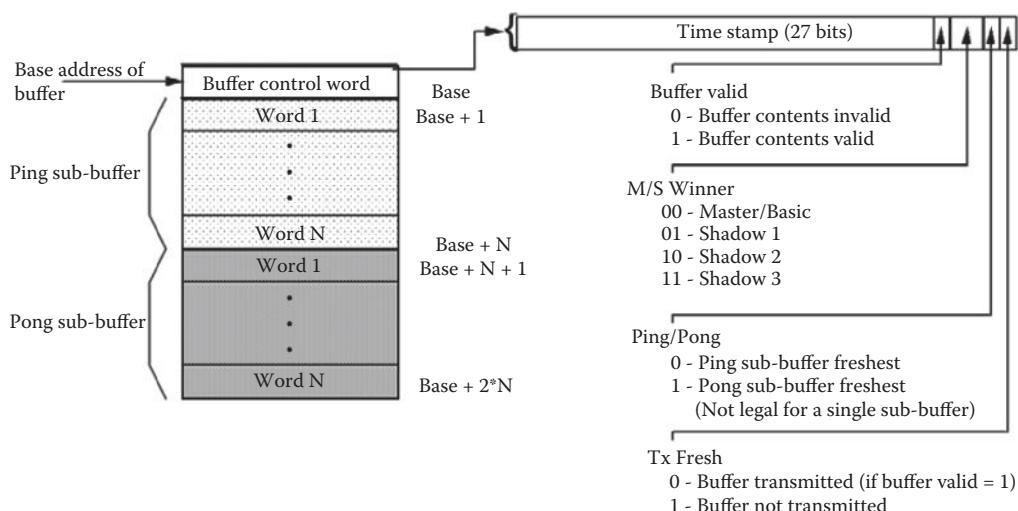

FIGURE 48.14 IMM buffer structure.

When a BIU executes a command to receive into a controlled buffer, it determines the buffer type from the command. If the buffer type is double subbuffered, the BIU reads the BCW and tests the Ping/Pong bit to determine where to place the data. The BIU then places the received and validated data into the stale subbuffer (always Ping for single subbuffers) and then forms a BCW with the current SAFEbus time, buffer valid set, master/shadow winner bits set appropriately, Ping/Pong set to the buffer just written, and TX Fresh bit cleared to 0. If errors occur in reception after the BIU modifies a location in the buffer, the entire BCW is set to 0. When the host reads a controlled receive buffer, it must first read the BCW. If the BCW is 0, a self-checking pair host cannot read any other words in the buffer because erroneous receive data that cause the BCW to be set to zero are not guaranteed to be identical between the x and y sides of the pair. If it is nonzero, the host can read the subbuffer indicated as freshest by the Ping/Pong bit. This bit is valid for both buffer types, since single subbuffered controlled buffers will always have the Ping/Pong bit set to Ping (0). When the host writes a controlled transmit buffer, it must first read the BCW. If it is nonzero, the host can write the subbuffer indicated as not being the freshest by the Ping/Pong bit. The host then sets the TX Fresh bit by requesting the BIU to do a Set\_Ping or Set\_Pong operation depending upon the subbuffer to be transmitted.

The noncontrolled format consists of 1–256 words without a BCW. No freshness indication or validity information is provided in such a buffer. If such indications are required, they must be provided by the user in the data itself. The BIU considers a noncontrolled buffer to be fresh whenever it attempts to transmit the contents of the buffer.

The BIUs contain special *coincidence* circuitry to detect the case that the host pair is updating the BCW at the same time that the BIUs are trying to read it. Even though these memories are only pseudo-dual port instead of true dual port, the independence of the clocks between the BIUs and between the BIUs and the host pair means that read–write order can be different between the x and the y sides of the pairs. The coincidence circuitry ensures that the BIUs see the same order. If this were not done, it is possible that the two BIUs could disagree on whether a buffer was ready to transmit. A coincidence mechanism similar to that used for the BCW on transmit is also used on receive to prevent the hosts from getting inconsistent data.

Synchronization of the bus schedule and the application software's execution is done by embedding interrupt commands in the SAFEbus tables. On receiving this interrupt, the processor's OS releases an

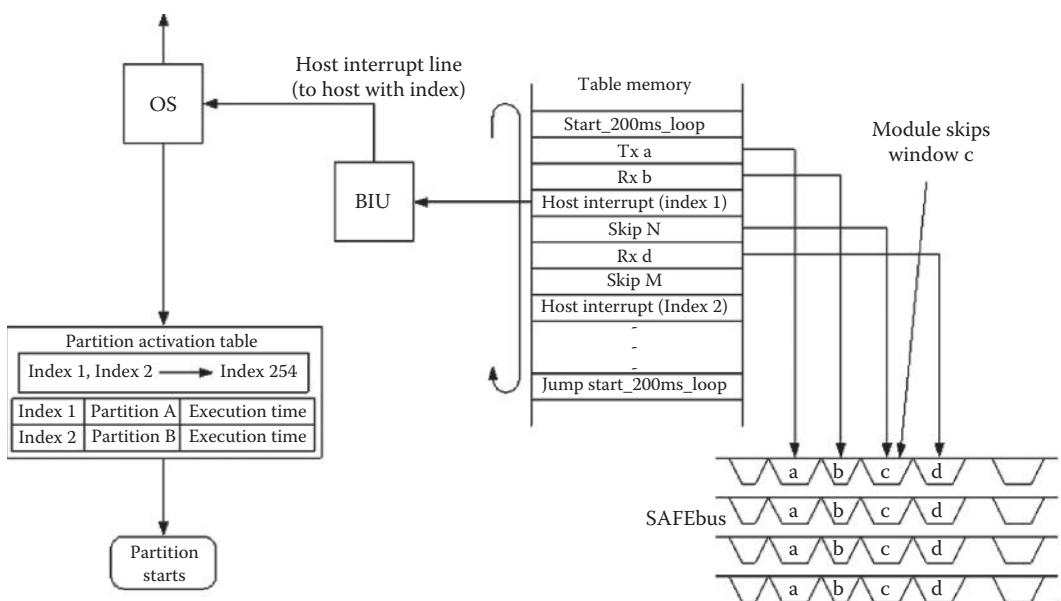

FIGURE 48.15 Data stream time partitioning.

application task (or task set) for execution. This interrupt takes the place of the clock or hardware timer other OSs or real-time executives employ. That is, this SAFEbus interrupt becomes the OS' real-time clock tick. As part of the time and space partitioning, the tasks are grouped into sets of *partitions*. Tasks in one partition are guaranteed not to interfere with tasks of another partition in a mechanism similar to processor virtualization. See Figure 48.15.

## 48.5 Validation and Verification Efforts

---

SAFEbus was part of the Boeing 777 airplane certification and passed rigorous testing for design requirements to support Level A applications, the highest level of safety requirements. Newer versions of the Boeing 777 use upgrades to the original SAFEbus BIU design, which also have been certified. Derivatives of SAFEbus have been certified on several other aircraft.

SAFEbus is standardized as ARINC 659 *backplane data bus* [8]. This is in a family of associated standards including ARINC 653 Avionics Application Software Standard Interface, ARINC 651 Design Guide for Integrated Modular Avionics, and ARINC 650 Integrated Modular Avionics Packaging and Interfaces.

## 48.6 SAFEbus in Boeing 777

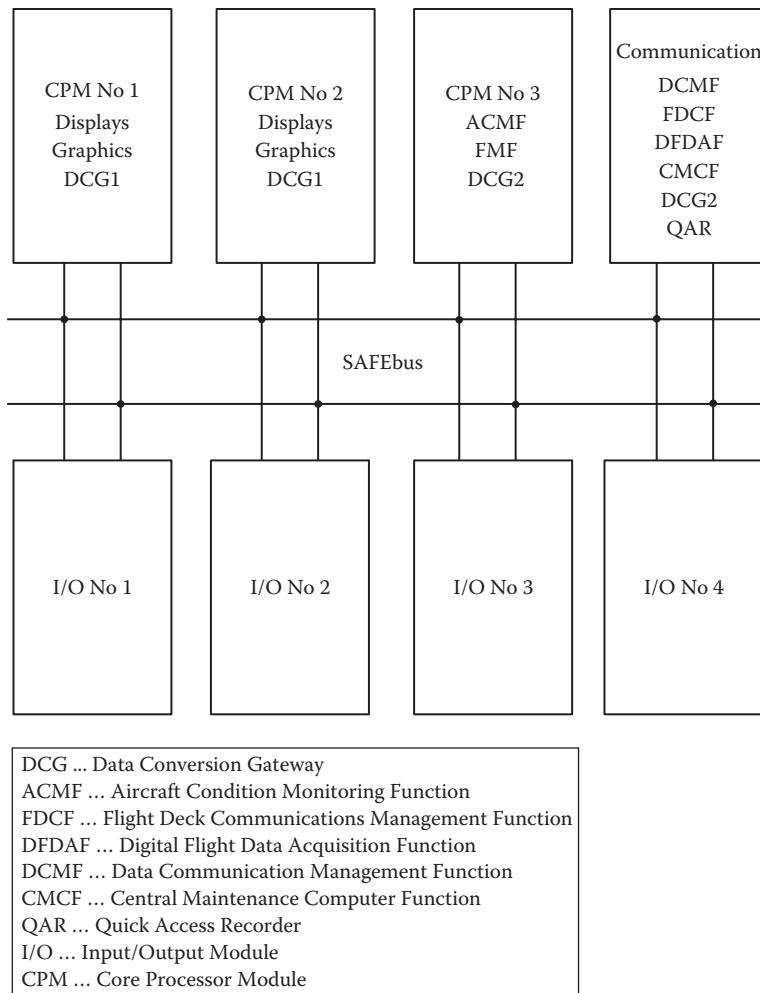

---

The avionics architecture in the Boeing 777 is characterized by functional integration compared to predecessor aircraft. Classical avionics at that time had a federated avionics architecture, where a set of functions is implemented in one or more line-replaceable units (LRUs). In the Boeing 777, this has been replaced by a more integrated architecture where multiple sets of functions are combined in fewer LRUs all in common cabinets instead of many separate boxes. This IMA is formed around the concept of powerful processing modules with a deterministic OS that hosts many applications. This integration offers many benefits, such as lower weight, lower power consumption, increased reliability, less-frequent maintenance, and greater flexibility. Yet because functions share hardware resources, greater care must be taken to ensure they will operate correctly, even if coresident functions fail. Integration increases the risk that unwanted interactions among the functions residing on the shared hardware will lead to unforeseen failures. This is the engineering challenge of integrated architectures [9].

An integrated cabinet typically is larger than a federated LRU, but smaller than the sum of all LRUs that the cabinet replaces. The separate functions in a cabinet share a power supply, general and special I/O units, and processing resources. To increase availability or integrity, functions can be replicated in multiple LRM s or in multiple cabinets. The attraction of the integrated architecture is the economies that can be achieved by sharing resources, like power, mechanical housing, processing, and I/O.

The core avionics of Boeing 777, also called AIMS, attempts to make the execution environment of each function in the cabinet as much like the environment in the discrete LRU as possible. Essentially, all shared resources in the cabinet are rigidly *partitioned* to ensure that one function cannot adversely affect another under any possible operating condition, including the occurrence of faults or design errors in the functions. The best way to ensure adequate partitioning is via strict deterministic control.

Functions must be partitioned both in space (memory and I/O) and in time. Deterministic control over the partitioning of space means that it can be guaranteed that no function can prevent another from obtaining adequate resources like memory space and that the resources are assigned to one function only. In the case where some memory space is assigned to one function, this means that it cannot be corrupted by another function. Preallocated memory areas with hardware-based memory protection such as MMUs prevent contention for memory space. Deterministic control over the partitioning of time means that it can be guaranteed that one function's changing demand for hardware resources will never prevent another function from obtaining a specified minimum level of service and that the timing of a function's access to these resources will not be affected by variable demand or by the failure of another function [10].

**FIGURE 48.16** Overview of one AIMS cabinet module and function allocation (From Witwer, B. *IEEE Transactions on Aerospace and Electronic Systems*, 33, 637, 1997.)

Figure 48.16 provides an overview of one of the Boeing 777 AIMS cabinets. The cabinet comprises three—at that time powerful—core processor modules (CPMs) for computing tasks, running display, and graphic and data conversion gateway applications. One module is dedicated especially to communication (including flight deck communication) and four identical modules to I/O. Other modules like local power modules support all modules located in a cabinet. Furthermore, three slots (for one CPM and two IOMs) are reserved for future growth. The replicated applications hosted on AIMS are as follows, along with the number of redundant copies of each application per shipset in parentheses [12]: displays (4), flight management/thrust management (2), central maintenance (2), data communication management (2), flight deck communication (2), airplane condition monitoring (1), digital flight data acquisition (2), and data conversion gateway (4).

Applications in AIMS use the following shared platform:

1. Common processor, power supply, and mechanical housing
2. Common I/O ports
3. Common backplane–bus (SAFEbus) to move data between CPMs and between CPMs and IOMs
4. Common OS, BIT, and utility software

The CPMs are based on AMD 29k RISC microprocessors using an AMD 29050 for AIMS-1 and HI-29KII for AIMS-2. Each CPM operates two processors in a lockstep configuration, which compares all output of compute applications for consistency similar to SAFEbus. If an error is detected, an error is flagged and all processing is halted ensuring that erroneous data are not propagated to other modules. Once errors are processed, errors are logged, and recovery is attempted. Figure 48.17 depicts the configuration of self-checking processors with SAFEbus.

The predictable time-driven operation of SAFEbus is extended to the processor and OS. The scheduling of the OSs is static and table driven in order to ensure timely partitioning and minimize unwanted interactions between applications running on the same processor. A processor cyclically executes a schedule where different partitions (applications or parts of applications) are assigned different time slots and can use assigned hardware during this period. The time slots of applications (also called partitions) are fixed similar to the time slot of messages on the bus. This means that the dispatcher at partition level is purely time and table driven without any other influence leading to rigid temporal separation. Within the partition time slices, one or more tasks (called processes in [13]) may run, which can be scheduled more flexibly and do share resources. Tasks of one partition may not require separation as they belong to the same partition and, hence, application. The principles of operation and standardized interfaces applied to AIMS have been standardized in ARINC 653 [14–16].

Scheduling of AIMS is described and proposed in [17]. Real-time repetition rates for applications range from 1 to 80 Hz. Synchronization between the AIMS processors is used to control latency and allows the system to *hand over* data at points during the repetition cycle (also called *frame*). When data are shared during cycles and the processors and the network are synchronized, the latency can be minimized. Yet computation and communication are dependent on each other when creating a schedule and can pose a significant challenge for getting a feasible computation and communication schedule that meets all deadlines and ensures data consistency (i.e., neither a process nor the network writes data to a common buffer at the same time). In order to get an idea of the scheduling problem in AIMS, about 3000 unique data items had to be moved with their required frequency in each cabinet. This resulted in 17,000 total messages per period in all cabinets including messages due to oversampling requirements for cabinet-external interactions.

The AIMS cabinets are just one part of the overall avionics. The integrated cabinets are connected to the airplane interfaces via a combination of ARINC 429, ARINC 629, display buses, and discrete I/O channels (see Figure 48.18; note that for clarity, ARINC 429 and discrete channels are not shown). In addition to the cabinet, other flight deck hardware elements that make up the AIMS system are six flat-panel display units, three control and display units, two electronic flight instrument system (EFIS) display control panels, one display select panel, two cursor control devices, and two display remote light sensors. Not all are depicted in Figure 48.18. The system bus in Boeing 777 is mainly ARINC 629 [18], a non-time-triggered, but periodically driven system bus. Boeing 777 avionics is synchronous only within each cabinet (in the domain of ARINC 659), but not at an airplane level.

The synchronization of the bus and software also assists debugging and validation. First, due to the nature of SAFEbus' independent determinism, a function experiences the same system timing whether the cabinet is fully populated or nearly empty. Second, since each processor in a cabinet is synchronized to the bus, the functions running in different processors are implicitly synchronized and timing errors at application level will be more quickly exposed, making the system simpler to debug. In asynchronously scheduled multiprocessor systems, such timing problems show up as intermittent failures, which can be very costly to track down and make it impossible to validate the system. Third, whenever the system is stopped or single-stepped, it passes through a succession of clearly defined states. The clear relationships between the processes, which are defined by the SAFEbus table, make it easier to trace behavior [19].

Many of the elements of Boeing 777 have led to ARINC standards such as the cabinet backplane; SAFEbus has been standardized as ARINC 659 [20] and the system bus as ARINC 629 [21]; and ARINC Report 651 *Design Guidance for Integrated Modular Avionics* is the top-level design guide for IMA.

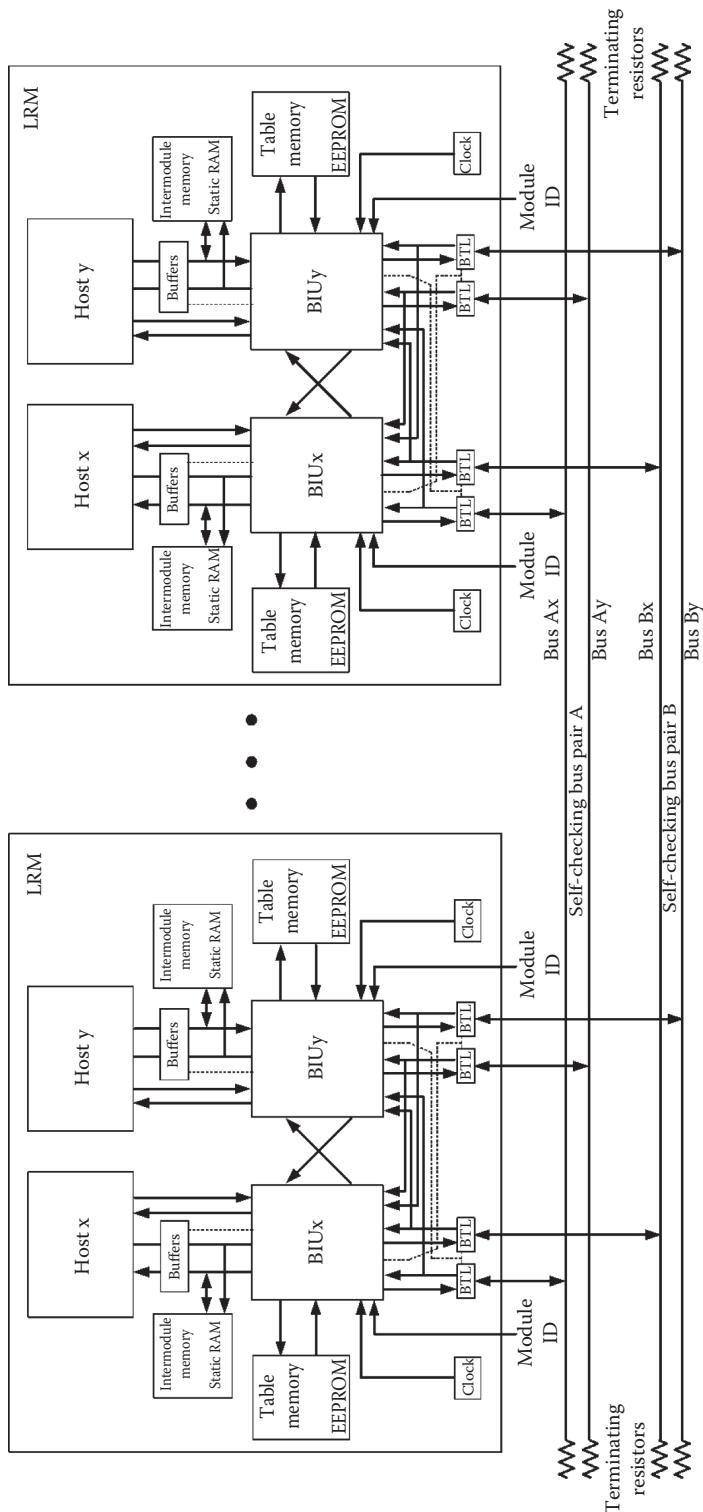

FIGURE 48.17 SAFIEbus architecture overview. (Courtesy of Honeywell, Morristown, NJ.)

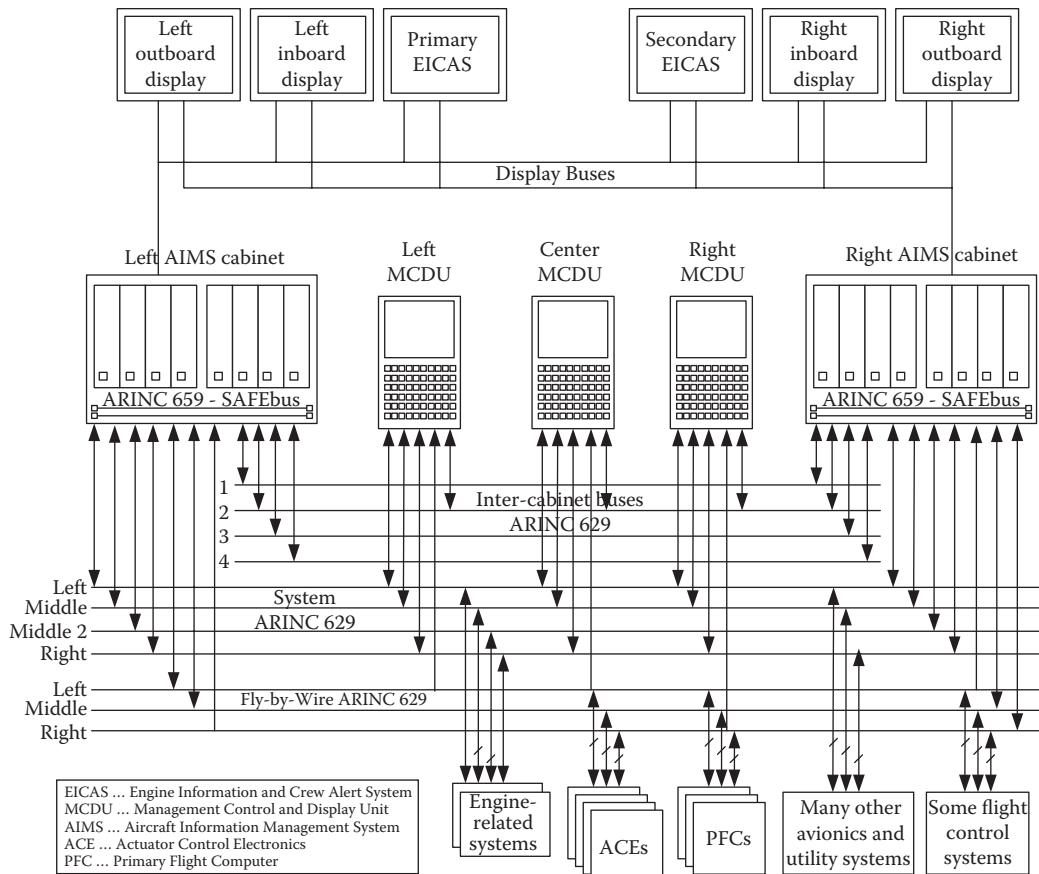

FIGURE 48.18 Boeing B 777 avionics overview. (Courtesy of Honeywell, Morristown, NJ.)

Boeing 777 is said to be the first but not the last plane to leverage IMA extensively. Related to SAFEbus, Versatile Integrated Avionics (VIA) is a derivative of AIMS and also uses SAFEbus on the Boeing 737NG, Boeing 717, McDonnell Douglas MD10, and McDonnell Douglas MD90.

### 49.1 Introduction

---

The evolution of civilian aircraft avionics systems is mainly due to an increasing complexity, which is illustrated by a larger number of integrated functions, a larger volume of exchanged data, and a larger number of connections between functions. Consequently, the growth of the number of multipoint communication links cannot be taken into account by classical avionics mono-emitter data-buses (such as ARINC 429 [ARI01]). A first solution proposed for Boeing 777 led to the design of a new multiplexed data-bus based on CSMA-CA medium access control (ARINC 629 standard [ARI99]). The solution adopted by Airbus for the A380 consists in the utilization of a switched Ethernet technology (AFDX: Avionics Full Duplex Switched Ethernet), which allows a reuse of development tools as well as of existing communication components while achieving better performance and which has been standardized in ARINC 664 [ARI02,ARI03]. This new communication standard represents a major step in the deployment of modular avionics architectures (Integrated Modular Avionics: IMA ARINC 651 [ARI91] and 653 [ARI97]). But the main problem is due to the indeterminism of the switched Ethernet, and a network designer must prove that no frame will be lost by the AFDX (no switch queue overflow) and must evaluate the end-to-end transfer delay through the network (guaranteed upper bound and distribution of delays) according to a given avionics applications traffic.

At least three approaches have been proposed in order to compute a worst-case bound for each communication flow of the avionic applications on an AFDX network configuration. They are based on network calculus, trajectories, and model checking. Such a worst-case communication delay analysis allows the comparison between the computed upper bounds and the constraints on the communication delays of each flow. Moreover, it allows the scaling of switch buffers in order to avoid overflow and frame losses.

This chapter summarizes the assumptions of the AFDX network technology and gives an overview of the different approaches that are used for the worst-case analysis of such networks. The approaches are illustrated on a sample configuration, and results on a realistic avionic configuration are shown. Trends on the dimensioning of avionics networks are also listed.

## 49.2 Civilian Avionics Systems Evolution and ARINC Context

---

Avionics is the generic name given to the electronic systems installed in an aircraft. It includes the calculators and their software, the sensors and actuators, and all the communication links between these elements. Almost every function of the aircraft is nowadays implemented by an avionic system: command controls, autopilot, navigation, information display, or cabin management. In the 1950s, avionics were very simple stand-alone systems as all functions could be executed by a single calculator. Modern avionics began with the replacement of analog devices by their digital equivalent in the 1960s. Since then, the complexity of avionics has never stopped growing: more and more analog devices are outdated by digital equipments, and new functions are added continuously. A few facts clearly illustrate the growth of the avionics' role in civilian aircrafts: From 1983 (A310) to 1993 (A340), the number of avionic systems onboard has increased by almost 50% (from 77 to 115), while the total processing power has been multiplied by 4, from 60 to 250 MIPS. Consequently, the communication needs increase as the number of embedded systems and functions increases [CC93].

Typically, classical avionics uses pieces of equipment that can be seen as hardware and software black boxes that are responsible for one given function. The physical devices adopt a standardized module form, called line-replaceable unit. New concepts based on a better sharing of execution and communication resources have been proposed in the 1990s. IMA introduces the definition of a generic platform called cabinet composed of standard execution and transmission modules, called line-replaceable modules. The global IMA architecture is thus composed of modules housed by cabinets distributed in the aircraft, leading to new intracabinet and intercabinet communication needs.

The Aeronautical Radio INCorporated (ARINC) standardized the traditional ARINC 429 mono-emitter data-bus [ARI01], which has been widely used in the context of classical avionics architectures. IMA is described in two ARINC standards: ARINC 651 for the modular hardware architecture [ARI91] and ARINC 653 for the modular software architecture [ARI97]. More recently, the ARINC 664 brings an answer to communication increase by multiplexing a huge amount of communication over a full-duplex switched Ethernet network [ARI02, ARI03]. It has become the reference communication technology in the context of civilian aircraft avionics as it provides a backbone network for the avionics platform.

ARINC 429 is the earlier and most used standard for civilian aircraft avionics that has been installed on a majority of Airbus and Boeing aircraft. Messages are transmitted over two twisted pairs by the owner of the bus at a bit rate of either 12.5 or 100 kbps to other systems units. The specification defines the electrical transmission characteristics and protocol data units' features [ARI01]. ARINC 429 protocol implements a mono-emitter broadcast bus with up to 20 receivers. The emitter broadcasts a 32-bit data word (with a given periodicity) on the bus. Filtering is done by the receiver according to the label associated to the data. ARINC 429 data-bus provides high determinism but at the cost of extra wiring and limited data rates. In a system with an increasing number of emitting and receiving units, point-to-point wiring becomes a major problem that ARINC 429 technology cannot face any more.

The IMA concept introduces switched Ethernet technology. All the units are directly connected by a point-to-point link to an Ethernet switch, and cascading switches offer the desired connectivity.

Using full-duplex links eliminates the possibility of transmission collisions on the links: the CSMA-CD medium access control protocol is no more needed. So it eliminates the inherent indeterminism of vintage Ethernet and the collision frame loss, but it shifts in fact the problem to the switch level where various flows enter in competition for the use of the resources of the switches. The switch implements the classical IEEE 802.1d bridging algorithm [IEEE98]: It filters and forwards frames from the incoming ports to the outgoing ports. The store-and-forward bridging mechanism reads the destination address of each received frame and retransmits it according to the port-id stored in the forwarding table. If a temporary congestion on an output port of a switch appears, it can significantly increase end-to-end delays of frames and even lead to frame losses by overflow of buffers. This is why dedicated mechanisms have been added to classical full-duplex Ethernet in order to guarantee determinism.

The AFDX has been standardized as ARINC 664 with the help of many avionics manufacturers: Airbus, Boeing, Rockwell Collins, Honeywell, etc [ARI02, ARI03]. The standard defines the subset of deterministic networks whose main characteristics are static configuration, flow segregation, and controlled traffic (traffic policing mechanisms). Thus, an ARINC 664 deterministic network is based upon Ethernet frame definition and IEEE 802.1d switching protocol, but it includes specific mechanisms in order to guarantee the determinism of avionics communications. Main AFDX-specific assumptions deal with the static definition of avionics flows that have to respect a bandwidth envelope (burst and rate) at network ingress point.

The AFDX network architecture is composed of several interconnected switches. The inputs and outputs of the networks are the end systems. Each end system is connected to exactly one switch port, and each switch port is connected to either an end system or another switch. The links are all full duplex. One first-in first-out (FIFO) buffer is associated to each output port.

The end-to-end traffic flow's characterization is standardized by ARINC 664 in its part 7, where the virtual link (VL) paradigm is presented [ARI03]. The idea behind this concept is to segregate the flows for safety reasons. Thus, the VL concept of virtual communication channels statically defines the flows that enter the network and associates some performance properties to each flow. Each VL can be statically mapped on the network of interconnected AFDX switches. Transmitting an Ethernet frame from one end system to another is based on a VL identifier, which is used for deterministic routing of each VL (the switch-forwarding tables are statically defined after the allocation of all VL on the AFDX network architecture). Each VL defines a logical unidirectional connection from one source end system to one or more destination end systems. For example, Figure 49.1 illustrates different kinds of VL:  $vx$  is a unicast VL with path  $\{e3-S3-S4-e8\}$ , while  $v6$  is a multicast VL with paths  $\{e1-S1-S2-e7\}$  and  $\{e1-S1-S4-e8\}$ .

A VL definition includes the bandwidth allocation gap (BAG) value, the minimum frame size ( $s_{min}$ ), and the maximum frame size ( $s_{max}$ ). The BAG is the minimum delay between two consecutive frames of the associated VL (which actually defines a VL as a sporadic flow). BAG and  $s_{max}$  values guarantee an

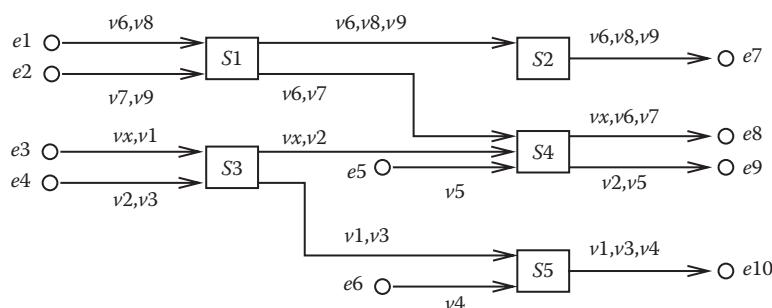

FIGURE 49.1 Illustrative AFDX configuration.

allocated bandwidth for each VL. Moreover, a jitter value is associated to each VL to upper-bound the maximum admissible jitter after multiplexing different regulated VL flows.

From the avionics systems designer point of view, the classical ARINC 429 buses have many interesting features. For example, the single-emitter assumption implies a dedicated link offered to the emitter and thus guaranteed access to the bus, guaranteed bandwidth, and high determinism. Thus, the VL concept is of importance in the definition of the AFDX as it allows direct replacement of ARINC 429 buses, on top of a deterministic ARINC 664 network.

### 49.3 AFDX End-to-End Delay Analysis

---

Let us consider a path  $p_x$  of a VL  $v$ . The end-to-end delay  $D(F_v, p_x)$  of a frame  $F_v$  transmitted on  $p_x$  is defined by

$$D(F_v, p_x) = LD(F_v, p_x) + SD(F_v, p_x) + WD(F_v, p_x)$$

$LD(F_v, p_x)$  is the transmission delay over the links: Thanks to the full-duplex characteristic of the AFDX, there are no collisions on the links. Thus, the transmission delay over a link is  $t_{byte} * s(F_v)$ , where  $t_{byte}$  is the transmission time of one byte and  $s(F_v)$  is  $F_v$  length. Therefore, considering that all the links have the same bandwidth  $c$  (consequently,  $t_{byte}$  is the same for all the links),

$$LD(F_v, p_x) = nbl(p_x) * (t_{byte} * s(F_v))$$

where  $nbl(p_x)$  is the number of links in  $p_x$ .

$SD(F_v, p_x)$  is the delay in switches between input and output ports: The delay in a switch from an input port to an output port is considered as a constant  $td$ , since the only available information about this delay is a guaranteed upper bound of 16  $\mu$ s. Thus,

$$SD(F_v, p_x) = nbs(p_x) * td$$

where  $nbs(p_x)$  is the number of switches in  $p_x$ .

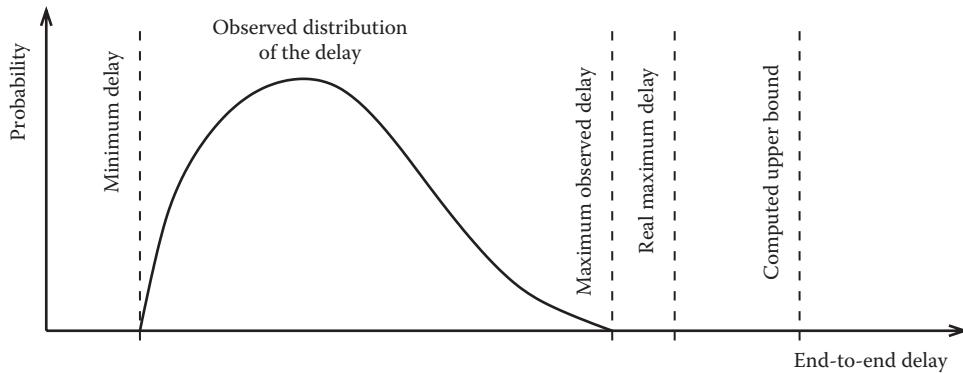

$WD(F_v, p_x)$  is the delay in switches and end system output buffers: This delay highly depends on each output port load at the time where  $F_v$  reaches it.

Consequently,  $D(F_v, p_x)$  can be divided into a fixed part  $LD(F_v, p_x) + SD(F_v, p_x)$  and a variable part  $WD(F_v, p_x)$ . The fixed part can be statically computed since it depends solely on the path  $p_x$ , the length of the frame  $F_v$ , and the bandwidth of the links. The variable part depends on dynamic characteristics, such as the sequence of frames that are emitted by each VL (the length of each frame) and the emission instants of the different VL frames.

The end-to-end delay analysis of a path  $p_x$  of a VL  $v$  has to take into account all the possible scenarios. This analysis should determine the following features of this end-to-end delay.

- The smallest possible value of the end-to-end delay corresponds to the scenarios where the VL  $v$  emits a frame with minimal length  $s_{min}(v)$ , which never waits in output ports. This smallest possible value is denoted  $D_{min}(v, p_x)$ , and it is computed in the following way:

$$D_{min}(v, p_x) = nbl(p_x) * (t_{byte} * s(F_v)) + nbs(p_x) * td$$

**FIGURE 49.2** End-to-end delay features.

- The highest possible value of the end-to-end delay, which corresponds to the worst-case scenario. It is mandatory for the certification of the avionic network. In the general case, finding this worst-case scenario requires an exhaustive analysis of all the possible scenarios. Section 49.6 presents an approach that implements this exhaustive analysis. Such an exhaustive enumeration is impossible for any realistic configuration, since the number of possible scenarios is huge, due to the number of VLs (around 1000). An alternative solution is the computation of a safe upper bound of the end-to-end delay, based on the modeling of the configuration that overestimates the traffic and/or underestimates the service offered by the network (pessimistic assumptions). Sections 49.4 and 49.5 present two approaches that compute a pessimistic safe upper bound of the end-to-end delay of any VL of an industrial AFDX configuration.
- The distribution of the end-to-end delay between its smallest and its highest possible values. This distribution is valuable when prototyping the whole system. This distribution can be obtained thanks to a simulation approach [SRF09]

Figure 49.2 summarizes the characteristics of the end-to-end delay. This delay is always between a minimum and a maximum value. Most of the time, the exact maximum value cannot be computed, and it is lower-bounded by the maximum observed value and upper-bounded by the computed safe upper bound.

## 49.4 Sure Upper Bounds with Network Calculus

Network calculus [Cha00,LBT01] has been proposed for the computation of an upper bound for the delay and the jitter of a flow transmitted over a network. It can be used on a set of sporadic flows with no assumption concerning the arrival time of packets. It has been applied to AFDX [BSF10], and the certification of the AFDX on board of A380 is based on this approach.

The basic application of network calculus to the AFDX is presented in Section 49.4.1. The improvement of this basic approach in the context of AFDX is described in Section 49.4.2.

### 49.4.1 Basic Network Calculus Approach for the AFDX

Network calculus is mathematically based on the  $(\min, +)$  dioid, for which the convolution  $\otimes$  and the deconvolution  $\oslash$  are defined as follows:

$$(f \otimes g)(t) = \inf_{0 \leq u \leq t} (f(t-u) + g(u)) \quad \text{and} \quad (f \oslash g)(t) = \sup_{0 \leq u \leq t} (f(t+u) - g(u))$$

A flow is represented by its cumulative function  $R$ , where  $R(t)$  is the total number of bits sent up to time  $t$ . A flow  $R$  is said to have a function  $\alpha$  as arrival curve if  $\alpha$  is an upper bound of the traffic generated by the flow. Each VL of an AFDX network (a flow) is modeled by a leaky bucket

$$\gamma_{r,b}(t) = b + r * t \quad \text{with} \quad b = s_{\max}(v) \quad \text{and} \quad r = \frac{s_{\max}(v)}{\text{BAG}(v)}$$

where

The burst  $b$  is the capacity of the bucket

The rate  $r$  is the leak rate

A server has a service curve  $\beta$ , which is a lower bound of the service offered by the server. Each output port of an AFDX switch offers a service curve:

$$\beta_{R,T} = R[t - T]^+$$

$T$  is the maximal technological latency of the switch, that is,  $16 \mu\text{s}$

$R$  is the servicing rate (100 Mb/s in our context) and  $[x]^+ = \max(0, x)$ . Thus, in the context of this chapter, the service curve that is offered by each output port is  $\beta_{100,16}$ .

The delay experienced by a flow  $R$  constrained by an arrival curve  $\alpha$  in a node offering a service curve  $\beta$  is bounded by the maximum horizontal difference between curves  $\alpha$  and  $\beta$ . This difference is formally defined by

$$h(\alpha, \beta) = \sup_{s \geq 0} \left( \inf \{ |\tau \geq 0 | \alpha(s) \leq \beta(s + \tau) \} \right)$$

Figure 49.3 illustrates the delay  $h(\alpha, \beta)$  experienced by a flow  $R$  constrained by a service curve  $\alpha = \gamma_{r,b}$  in an output port of an AFDX switch, provided  $R$  is the only flow crossing this output port.

The VLs that compete for a given output port are merged into a single flow by summing their respective arrival curves.

The overall computation is illustrated in the small example in Figure 49.4.

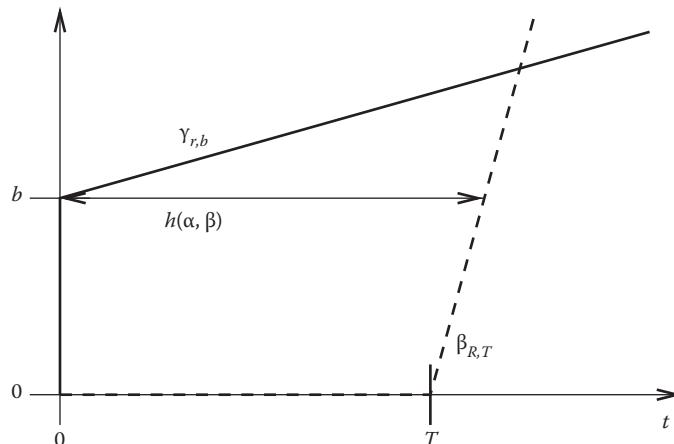

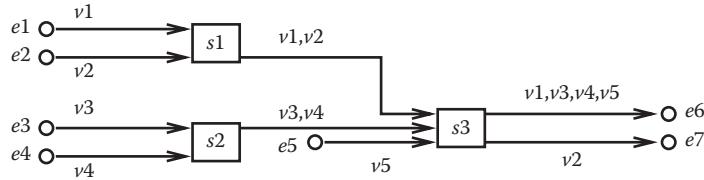

FIGURE 49.3 Maximum delay  $h(\alpha, \beta)$ .

**FIGURE 49.4** Sample AFDX configuration.

This configuration includes five unicast VLS  $v1 \dots v5$ . Their parameters are given in the following table:

	BAG (ms)	$s_{min}$	$s_{max}$	Path
$v1$	4	300 bytes	500 bytes	$e1-S1-S3-e6$
$v2$	4	300 bytes	500 bytes	$e2-S1-S3-e7$
$v3$	4	300 bytes	500 bytes	$e3-S2-S3-e6$
$v4$	4	300 bytes	500 bytes	$e4-S2-S3-e6$
$v5$	4	300 bytes	500 bytes	$e5-S3-e6$

Let us consider VL  $v1$ . Its arrival curve in  $S1$  is

$$\alpha_1 = \gamma_{1,4000}$$

since

$$r = \frac{s_{max}(v1)}{BAG(v1)} = \frac{4000}{4000} = 1 \frac{\text{Mb}}{\text{s}} \quad \text{and} \quad b = s_{max}(v1) = 4000 \text{ bits}$$

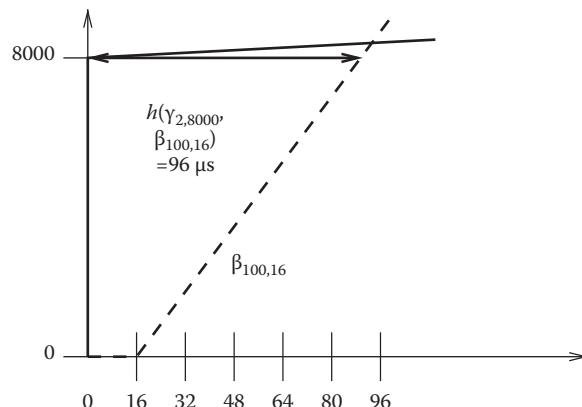

$v1$  shares the output port of  $S1$  with  $v2$ , whose arrival curve in  $S1$  is

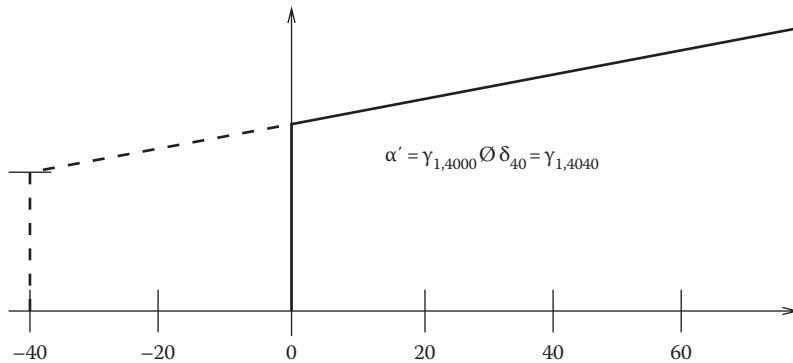

$$\alpha_2 = \gamma_{1,4000}$$

Consequently, the overall arrival curve for the output port of switch  $S1$  is

$$\alpha_1 + \alpha_2 = \gamma_{2,8000}$$

As previously mentioned, the service curve of this port is  $\beta_{100,16}$ . Thus, the delay in this output port is bounded by the maximum horizontal difference between  $\gamma_{2,8000}$  and  $\beta_{100,16}$ , which is 96  $\mu\text{s}$ , as depicted in Figure 49.5.

**FIGURE 49.5** Output port of switch  $S1$ .

**FIGURE 49.6** Output curve after switch S1 or S2.

It includes the technological latency (16 μs), the transmission time (40 μs), and the maximum waiting time in the output buffer (40 μs), since each packet of VL  $v_1$  or  $v_2$  can be delayed by at most one packet of the other VL.

Then, the computation proceeds to switch S3, and it needs the input curves of  $v_1$ ,  $v_3$ ,  $v_4$ , and  $v_5$  in S3. These input curves are the output curves of the VLs in their previous crossed output port, that is, S1 for  $v_1$ , S2 for  $v_3$  and  $v_4$ , and e5 for  $v_5$ . In the general case, the output curve  $\alpha'$  of the flow is given by

$$\alpha' = \alpha \oslash \delta_{jitter}$$

where

$\alpha$  is the input curve of the flow in the port

$jitter$  is the maximum jitter encountered by the flow in the port

$\delta_{jitter}$  is a guaranteed delay service curve

$$\delta_d(t) = 0 \text{ if } t \leq d, \infty \text{ otherwise}$$

Graphically, it comes down to shift the arrival curve  $\alpha$  to the left by the duration of the jitter. The maximum jitter in an output port corresponds to the maximum waiting time in the corresponding buffer. Coming back to  $v_1$ , its maximum jitter when leaving S1 is 40 μs, that is, the maximum waiting time in the output buffer of S1. Then, the input curve  $\alpha'_1$  of  $v_1$  at S3 is obtained by shifting  $\alpha_1$  by 40 μs to the left:

$$\alpha'_1 = \alpha_1 \oslash \delta_{40} = \gamma_{1,4040}$$

It is illustrated in Figure 49.6.

The input curves of  $v_3$ ,  $v_4$ , and  $v_5$  at S3 are, respectively,  $\gamma_{1,4040}$ ,  $\gamma_{1,4040}$ , and  $\gamma_{1,4000}$ . They lead to an overall arrival curve  $\gamma_{4,16120}$  in the output port of S3. Then, the maximum delay for  $v_1$  in S3 is 177.2 μs, leading to a maximum end-to-end delay of 313.2 μs. It is composed of the transmission delay from e1 to S1 (40 μs) and the maximum delay computed for S1 and S3, that is, 96 and 177.2 μs.

Column BNC in the following table summarizes the upper bounds computed with this method for the five VLs of Figure 49.4.

	BNC (μs)	ONC (μs)
$v_1$	313.2	273.6
$v_2$	192.4	192.4
$v_3$	313.2	273.6
$v_4$	313.2	273.6
$v_5$	217.2	177.6

The next paragraph presents an improvement of the basic network calculus approach in the context of AFDX.

#### 49.4.2 Optimizing the Network Calculus Approach for the AFDX

The basic network calculus approach presented in the previous section is pessimistic in the context of AFDX. In particular, it does not take into account the property that frames of different flows sharing a link cannot be transmitted at the same time on this link (they are serialized). Consequently, the burst considered in the overall input curves of the basic network calculus approach can never happen, as soon as at least two flows share the same link. This problem is different from the classical *pay burst only once* case described in [LBT01]. Indeed, the objective of *pay burst only once* is to aggregate successive switches in order to give an optimized aggregated service curve. The aggregation of nodes is not possible in our case, since flows can join and leave a path at any switch of the network.

In the example in Figure 49.4, the input curve of the output port of S3 shared by  $v_1, v_3, v_4$ , and  $v_5$  is  $\gamma_{4,16120}$ . The maximum burst (16120 bits) corresponds to the case where four frames—one for each VL—arrive at the same time in the output port. This is definitely impossible, since  $v_3$  and  $v_4$  share the same link. The grouping technique integrates this serialization. It proceeds in two steps. First, the overall arrival curve is computed for each link. It is the minimum between, on the one hand the sum of the arrival curves of all the flows sharing the considered link, on the other hand the curve bounding the burst to the maximum burst among the curves of the different flows sharing the link and the rate to the rate of the link. This first step is illustrated in Figure 49.7 for a link shared by two flows with arrival curves  $\gamma_{r_1,b_1}$  and  $\gamma_{r_2,b_2}$ .

In the second step, the curves obtained for the different links are added. The gain obtained with this technique is due to the reduction of the maximum burst.

Column ONC in the previous table gives the upper bounds computed with this technique in the example in Figure 49.4. Results are clearly improved, compared with the basic network calculus approach.

A more recent approach, based on trajectories, has been proposed for the worst-case delay analysis of distributed systems. The next section shows how this approach can be applied and optimized in the context of the AFDX. The main goal is to compare this new approach with the network calculus one.

### 49.5 Sure Upper Bounds with Trajectory Approach

The trajectory approach [MM06a, MM06b] has been developed to get deterministic upper bounds on end-to-end response time in distributed systems. This approach considers a set of sporadic flows with no assumption concerning the arrival time of packets. The application of the trajectory approach to the AFDX has been presented in [BSF10]. Main features of the trajectory approach applied to AFDX are summarized and illustrated in Sections 49.5.1 and 49.5.2. The trajectory approach computation is presented in Section 49.5.3.

#### 49.5.1 Main Features of the Trajectory Approach

The approach developed for the analysis of the AFDX considers the results from [MM06a]. A distributed system is composed of a set of interconnected processing nodes. Each flow crossing this system follows

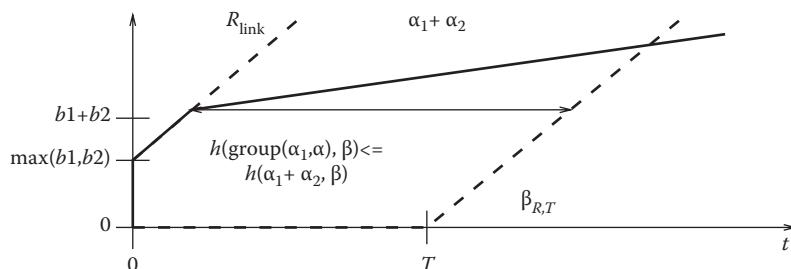

FIGURE 49.7 Grouping of flows.

a static path, which is an ordered sequence of nodes. The trajectory approach assumes, with regard to any flow  $\tau_i$  following path  $P_i$ , that any flow  $\tau_j$  following path  $P_j$ , with  $P_j \neq P_i$  and  $P_j \cap P_i \neq \emptyset$ , never visits a node of path  $P_i$  after having left this path.

Flows are scheduled with a FIFO algorithm in every visited node. Each flow  $\tau_i$  has a minimum interarrival time between two consecutive packets at ingress node, denoted  $T_i$ , a maximum release jitter at the ingress node denoted  $J_i$ , an end-to-end deadline  $D_i$  that is the maximum end-to-end response time acceptable, and a maximum processing time  $C_i^h$  on each node  $N_h$ , with  $N_h \in P_i$ .

The transmission time of any packet on any link between nodes has known lower and upper bounds  $L_{min}$  and  $L_{max}$ , and there are neither collisions nor packet losses on links.

The end-to-end response time of a packet is the sum of the times spent in each crossed node and the transmission delays on links. The transmission delays on links are upper bounded by  $L_{max}$ . The time spent by a packet  $m$  in a node  $N_h$  depends on the pending packets in  $N_h$  at the arrival time of  $m$  in  $N_h$ . The problem is then to upper bound the overall time spent in the visited nodes.

The solution proposed by the trajectory approach is based on the busy period concept. In the FIFO context, a busy period in a node  $N_h$  starts at a time  $t$  when at least a frame is ready for transmission in the node, and there was previously no ready frame. It ends at a time  $t'$  when the packet  $m$  under study has been processed.

The trajectory approach considers a packet  $m$  from flow  $\tau_i$  generated at time  $t$ . It identifies the busy period and the packets impacting its end-to-end delay on all the nodes visited by  $m$ . It enables the computation of the latest starting time of  $m$  on its last node. It leads to the worst-case end-to-end response time of the flow  $\tau_i$ . This computation will be illustrated in the context of AFDX.

The elements of the system considered in the trajectory approach are instantiated in the following way in the context of AFDX. Each node of the system corresponds to an AFDX switch output port, including the output link. Each link of the system corresponds to the switching fabric. Each flow corresponds to a VL path.

The switching fabric delay is upper bounded by a constant value (16  $\mu$ s), thus  $L = L_{min} = L_{max} = 16 \mu$ s. VL parameters match the definition of sporadic flows in the following manner:

$$T_i = BAG, J_i = 0, \text{ and } C_i^h = C_i = s_{max}/R \text{ since all the links have the same rate } R.$$

### 49.5.2 Illustration on a Sample AFDX Configuration

Let us consider the sample AFDX configuration depicted in Figure 49.4. Figure 49.8 shows an arbitrary scheduling of the frames, which are identified by their VL numbers (e.g., frame 3 is a frame from VL v3). The scheduling in Figure 49.8 focuses on frame 3.

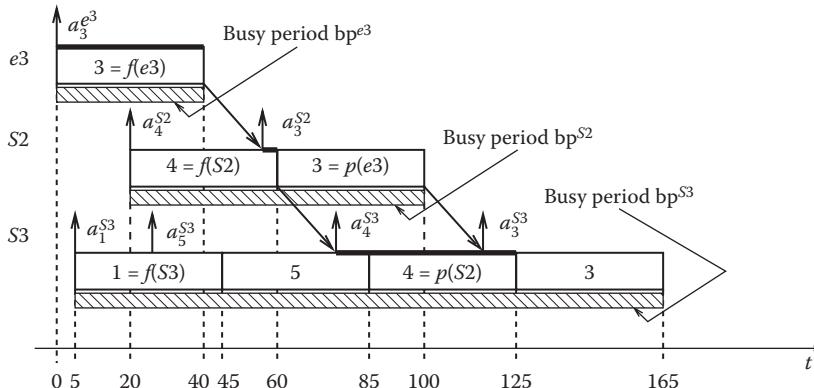

FIGURE 49.8 An arbitrary scheduling of frames.

The arrival time of a frame  $m$  in a node  $N_h$  is denoted  $a_m^{N_h}$ . Time origin is arbitrarily chosen as the arrival time of frame 3 in node  $e3$ . The processing time of a packet in a node is  $40 \mu\text{s}$ . It corresponds to the transmission time of the frame on a link. The delay between the end of the processing of a frame by a node and its arrival in the next node corresponds to the  $16 \mu\text{s}$  switch factory delay. Due to the FIFO policy, frame 3 is delayed by frame 4 in S2. In node S3, frame 5 is delayed by frame 1 and delays frame 4, which delays frame 3.

Frame 3 from  $v3$  crosses three busy periods  $bp^{e3}$ ,  $bp^{S2}$ , and  $bp^{S3}$  on its trajectory, corresponding to the three nodes  $N_1 = e3$ ,  $N_2 = S2$ , and  $N_3 = S3$ . Let  $f(N_i)$  be the first frame that is processed in the busy period  $bp^{N_i}$  during which frame 3 is processed. Considering the scheduling in Figure 49.8, we have  $f(e3) = 3$ ,  $f(S2) = 4$ , and  $f(S3) = 1$ . As flows do not necessarily follow the same path in the network, it is possible that frame  $f(N_i)$  does not come from the same previous node  $N_{i-1}$  as frame 3. This case occurs in node S2, where frame 4 comes from node  $e4$ . It also occurs in node S3, where frame 1 comes from node S1. Therefore,  $p(N_{i-1})$  is defined as the first frame, which is processed in  $bp^{N_i}$  and comes from node  $N_{i-1}$ . Considering the scheduling in Figure 49.8, we have  $p(e3) = 3$  and  $p(S2) = 4$ .

The starting time of frame 3 in node S3 is obtained by adding parts of the three busy periods  $bp^{e3}$ ,  $bp^{S2}$ , and  $bp^{S3}$  to the delays between the nodes, that is,  $2 * 16 \mu\text{s}$ . From [MM06a], the part of the busy period  $bp^{N_i}$  that has to be added is the processing time of frames between  $f(N_i)$  and  $p(N_i)$  minus the time elapsed between the arrivals of  $f(N_i)$  and  $p(N_{i-1})$ , that is,  $(a_{p(N_{i-1})}^{N_i} - a_{f(N_i)}^{N_i})$ .

In the example in Figure 49.8, the parts that have to be considered are the transmission of frame 3 in node  $e3$ , the time elapsed between the arrival of frame 3 and the end of processing of frame 4 in node S2, and the time elapsed between the arrival of frame 4 and the end of processing of frame 5 in node S3. These parts are shown by thick lines on top of the frames in Figure 49.8. The starting time of frame 3 in node S3 in the example in Figure 49.8 is  $125 \mu\text{s}$ .

It has been shown [MM06a] that the latest starting time of a frame  $m$  in its last node is reached when

$$(a_{p(N_{i-1})}^{N_i} - a_{f(N_i)}^{N_i}) = 0$$

for every node  $N_i$  on the path of  $m$ . It comes to postpone the arrival time of every frame joining the path of  $m$  in the node  $N_i$  in order to maximize the waiting time of  $m$  in  $N_i$ .

The result of this postponing in the example in Figure 49.8 is illustrated in Figure 49.9. The arrival time of frame 4 at node S2 is postponed to the arrival time of frame 3 at node S2. In node S3, frames 1 and 5 have been postponed in order to arrive between frames 4 and 3.

Then, the worst-case end-to-end delay of a frame is obtained by adding its latest starting time on its last visited node and its processing time in this last node. For frame 3 in Figure 49.9, this worst-case end-to-end delay is

$$232 + 40 = 272 \mu\text{s}$$

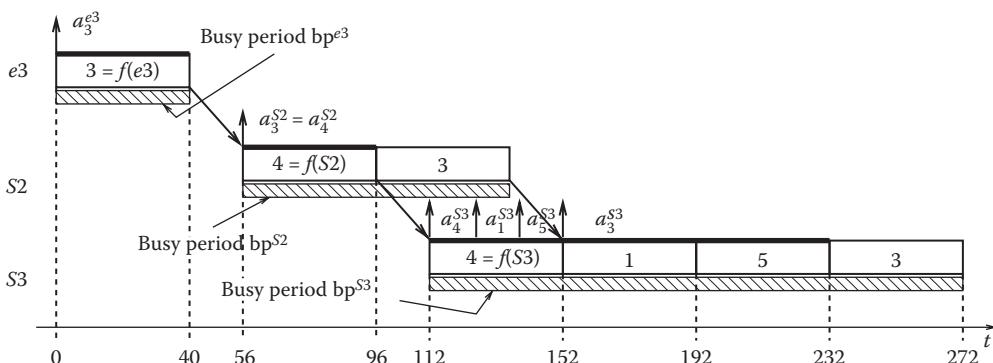

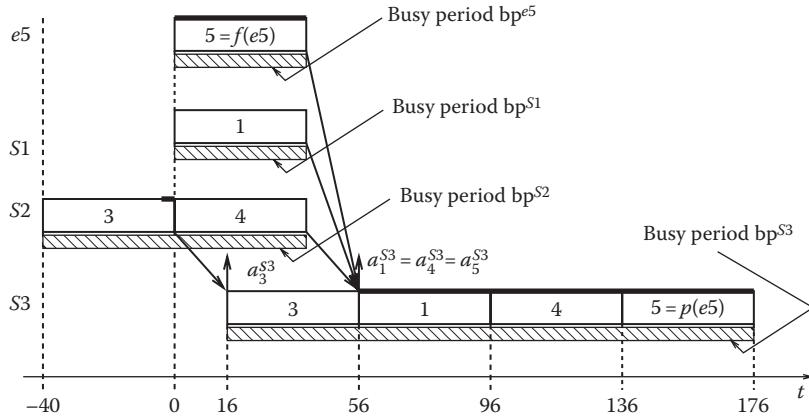

FIGURE 49.9 Latest starting time of frame 3.

**FIGURE 49.10** Latest starting time of 5.

More precisely, this delay includes the transmission times of frame 3 on node  $e3$ , frame 4 on node  $S2$ , and frames 4, 1, 5, and 3 on node  $S3$ . In this example, it can be seen that frames 3 and 4 are counted twice. Actually, it has been shown [MM06b] that exactly one frame has to be counted twice in each node, except the slowest one. In the context of the AFDX, all the nodes work at the same speed. Thus, the slowest node is arbitrarily chosen as the last one. In the example in Figure 49.9, frames 3 and 4 are, respectively, counted twice in nodes  $e3$  and  $S2$ . Frame 3 is the longest one transmitted in nodes  $e3$  and  $S2$ , while frame 4 is the longest one transmitted in nodes  $S2$  and  $S3$ .

In the context of an AFDX network, it is not always possible to find a scheduling that cancels the term  $(a_{p(N_{i-1})}^{N_i} - a_{f(N_i)}^{N_i})$  for every node  $N_p$ , as proposed in [MM06b]. Let us consider VL v5 of the example depicted in Figure 49.4.  $bp^{S3}$  is the busy period corresponding to frame 5. In order to maximize the delay of frame 5 in  $bp^{S3}$ , the arrival time of frames 3 and 4 in  $S3$  has to be as large as possible, but not larger than the arrival time of frame 5 in node  $S3$ , because of the FIFO scheduling policy:

$$a_3^{S3} \leq a_5^{S3} \text{ and } a_4^{S3} \leq a_5^{S3}$$

Since both frames come from the same link, they are already serialized:

$$|a_3^{S3} - a_4^{S3}| \geq 40 \mu\text{s}$$

Without loss of generality, let us consider that frame 3 arrives before frame 4. Then, we have

$$a_4^{S3} = a_5^{S3} \text{ and } a_3^{S3} = a_5^{S3} - 40 \mu\text{s}$$

The resulting worst-case scheduling is depicted in Figure 49.10. We have

$$(a_{p(e5)}^{S3} - a_{f(S3)}^{S3}) \geq 40 \mu\text{s}$$

for any possible scheduling.

### 49.5.3 Trajectory Approach Computation

The computation of the worst-case end-to-end delay of a frame of a flow  $\tau_i$  has been formalized in [MM06a]. In our context, all the nodes work at the same rate, and the jitter in each emitting node is null. Thus, the worst-case end-to-end response time of any flow  $\tau_i$  is bounded by

$$R_i = \max_{t \geq 0} (W_{i,t}^{last_i} + C_i - t)$$

$last_i$  is the last visited node of flow  $\tau_i$

$W_{i,t}^{last_i}$  is a bound on the latest starting time of a frame  $m$  generated at time  $t$  on its last visited node  
 $W_{i,t}^{last_i}$  is the sum of the following terms:

- $\sum_{j \in [1,n], j \neq i, P_j \cap P_i \neq \emptyset} (1 + \lfloor (t + A_{ij}) / T_j \rfloor) * C_j$ : It corresponds to the processing time of frames from every flow  $\tau_j$  crossing the flow  $\tau_i$  and transmitted in the same busy period as  $m$ .  $A_{ij}$  integrates the maximum jitter of frames from  $\tau_i$  and  $\tau_j$  on their first shared output port.
- $(1 + \lfloor t/T_i \rfloor) * C_i$ : It is the processing time, on one node, of the frames of the flow  $\tau_i$  that are transmitted in the same busy period as  $m$ .
- $\sum_{N_h \in P_i, N_h \neq last_i} (max_{j \in [1,n], N_h \in P_j} (C_j))$ : It is the processing time of the longest frame for each node of path  $P_i$ , except the last one. It represents the frames that have to be counted twice, as explained before.
- $(|P_i| - 1) * L_{max}$ : It corresponds to the sum of switching delays.
- $-\sum_{N_h \in P_i, N_h \neq first_i} (\Delta_{N_h})$ : It subtracts for each node  $N_h$  in  $P_i$  the duration between the beginning of the busy period and the arrival of the first frame coming from the preceding node in  $P_i$ , that is,  $N_{h-1}$ . This term is null in the context of [M06a]. A lower bound of  $\Delta_{N_h}$  for each node  $N_h$  in  $P_i$  has been established in the context of AFDX [BSF10]. At a given node  $N_h$ , frames are grouped by input links, and one frame is removed from each group: the smallest one for the input link of the frame under study and the largest one for the other input links. It leads to a set of sequences of frames. If the sequence of the input link of the frame under study is the largest one,  $\Delta_{N_h}$  is null. Otherwise,  $\Delta_{N_h}$  is the difference between the largest sequence and the sequence of the input link of the frame under study.
- $-C_i$ : It is subtracted, because  $W_{i,t}^{last_i}$  is the latest starting time and not the ending time of the frame from  $\tau_i$  on its last node.

Solving  $R_i = max_{t \geq 0} (W_{i,t}^{last_i} + C_i - t)$  comes to find the maximum vertical deviation between the function  $t \alpha W_{i,t}^{last_i} + C_i$  and the identity function ( $t \alpha t$ ).

The following table gives the upper bounds computed for the configuration in Figure 49.4. For this configuration, the trajectory approach always gives tighter bounds than the ones obtained by the network calculus approach.

	Traj (μs)
v1	272
v2	192
v3	272
v4	272
v5	176

## 49.6 Exact Worst-Case Delays with Model Checking

The approach is based on a modeling in timed automata.

### 49.6.1 Overview of Timed Automata

Timed automata have been first proposed in [AD94] in order to describe systems behavior with time. A timed automaton is a finite automaton with a set of clocks, that is, real and positive variables increasing uniformly with time. Transition labels can be a condition on clock values (a guard), actions, or updates, which assign new value to clocks.

The composition of timed automata is obtained by a synchronous product. Each action  $a$  executed by a first timed automaton corresponds to an action with the same name  $a$  executed in parallel by a second

timed automaton. In other words, a transition that executes the action  $a$  can be fired only if another transition labeled  $a$  is possible. The two transitions are performed simultaneously. Thus, communication uses the rendezvous mechanism.

Performing transitions requires no time. Conversely, time can run in nodes. Each node is labeled by an invariant, that is, a Boolean condition on clocks. The node is occupied if the invariant is true.

Several extensions of timed automata have been proposed. One of these extensions is timed automata with shared integer variables. The principle consists in defining a set of integer variables that are shared by different timed automata. The values of these variables can be consulted and updated by the different timed automata [LPY97].

A system modeled with timed automata can be verified using a reachability analysis that is performed by model checking. It consists in encoding each property in terms of the reachability of a given node of one of the automata.

In the general case, reachability analysis is undecidable on timed automata with shared integer variables. In the particular case where the shared variables are represented by nodes of a timed automaton, the reachability analysis is decidable.

The approach considered for the AFDX is based on timed automata with shared integer variables that are represented by nodes of a timed automaton.

## 49.6.2 Modeling of an AFDX Network

The modeling of an AFDX network considers an automaton for each VL and an automaton for each output port of a switch [CSEF06]. Figure 49.11 depicts the timed automaton of a VL with a BAG equal to  $period$ . This automaton sends a first message  $send_i$  ( $send_0$  in the example) delayed by an offset between 0 and  $period$  and then sends periodically a new message  $send_i$ .

Figure 49.12 shows an example of an output port of a switch. Each node of the automaton models a location in the FIFO queue associated with the port (3 in the example in Figure 49.12). Each transition

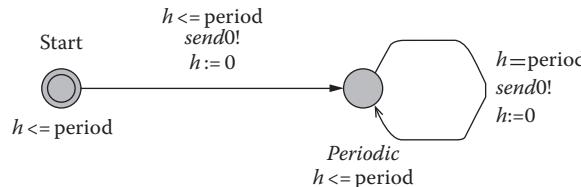

FIGURE 49.11 Automaton of a VL.

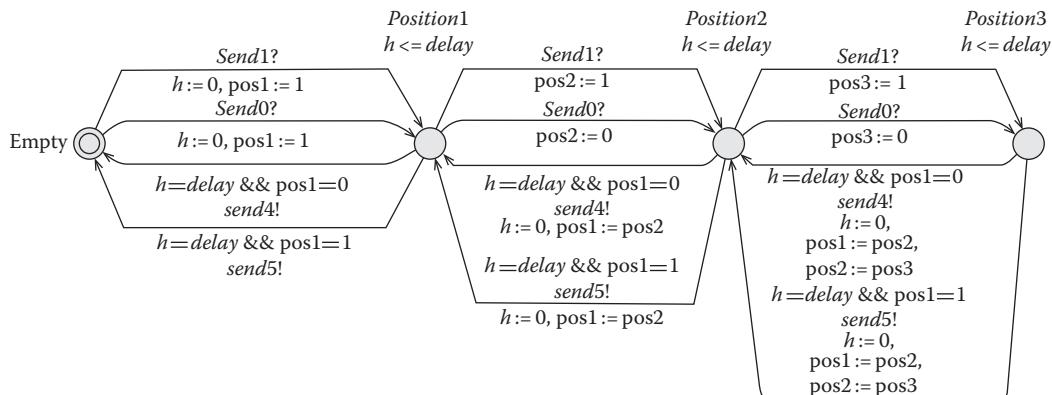

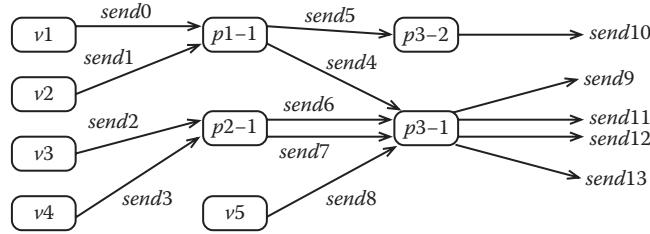

FIGURE 49.12 Automaton of an output port of a switch.

**FIGURE 49.13** Global modeled system.

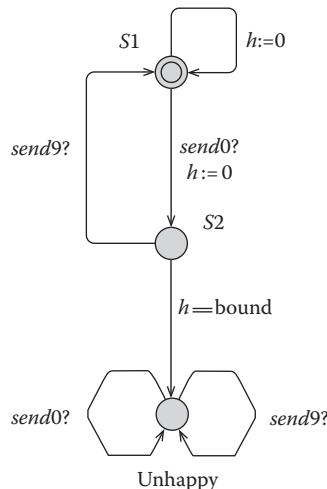

from a node  $Position_i$  to a node  $Position_{i+1}$  of the automaton models the arrival of one frame at the output port, while each transition from a node  $Position_{i+1}$  to a node  $Position_i$  models the end of the transmission from this port. The automaton of Figure 49.12 considers two VLs received using signals  $send0$  and  $send1$  and transmitted using signals  $send4$  and  $send5$ .  $delay$  is the transmission time of the frame (in the example, all the frames have the same length).  $pos1$ ,  $pos2$ , and  $pos3$  indicate the flows corresponding to the frames waiting in each position of the queue.

The global system is obtained by composing the timed automata of the VLs and the output ports of the switches. For instance, Figure 49.4 is composed of five VLs and four output ports, leading to nine timed automata, as depicted in Figure 49.13. As an example, VL  $v2$  is modeled by the timed automaton  $v2$ , which sends signal  $send1$ . It is received by timed automaton  $p1 - 1$ , which models the unique output port of switch  $s1$ .  $v2$  follows the path composed of signals  $send5$  and  $send10$ .

### 49.6.3 Computation of the Exact Worst-Case End-to-End Delay

Using the test automaton method [BBF+01], the worst-case end-to-end delay of each VL is obtained from the model previously described. The test automaton corresponding to  $v1$  is depicted in Figure 49.14.

This automaton models the property *delay of  $v1$  is less than bound*. By receiving signal  $send0$ , it evolves to node  $s2$  and waits for  $send9$ . If this signal is not received within delay  $bound$ , the automaton evolves to node  $reject$ . This behavior corresponds to a scenario for which the end-to-end delay of  $v1$  is at least  $bound$ . So, the goal is to find the lowest value of  $bound$  for which node  $reject$  is reached. This value is the maximum end-to-end delay.

**FIGURE 49.14** Test automaton of  $v1$ .

The approach is implemented in Uppaal. The calculation takes less than 1s on a Linux station with a Pentium 4 processor and 2GB of memory size. The exact worst-case end-to-end delays obtained for the VLs in Figure 49.4 are given in the following table. They are identical to the results obtained with the trajectory approach.

MC ( $\mu$ s)	
$v_1$	272
$v_2$	192
$v_3$	272
$v_4$	272
$v_5$	176

This approach exhibits the exact worst-case, and it is valuable since it helps understand the worst-case behavior of the network. However, it cannot be used for the certification of a realistic network (e.g., the AFDX of the A380), due to the well-known combinatorial explosion problem. Actually, it cannot cope with configurations including more than eight VLs.

## 49.7 Analysis of a Realistic Configuration

The realistic AFDX network considered in this chapter is composed of two redundant networks [CSEF06]. Each network includes 123 end systems, 8 switches, 964 VLs, and 6412 VL paths (due to VL multicast features). The following table gives the dispatching of VLs among BAGs. It can be seen that BAGs are harmonic between 2 and 128.

BAG (ms)	2	4	8	16	32	64	128
Nb of VLs	20	40	78	142	229	220	255

A second table gives the dispatching of VLs among frame lengths, considering the maximum length  $s_{max}$ . Most of the VLs consider short frames.

Frame length (bytes)	0–150	151–300	301–600	601–900	901–1200	1201–1500	>1500
Nb of VLs	561	202	114	57	12	35	3

A third table shows the number of VL paths per length (i.e., the number of crossed switches). Most of the VLs have short paths.

Nb of crossed switches	1	2	3	4
Nb of paths	1797	2787	1537	291

The temporal analysis of this realistic configuration has been conducted. As previously mentioned, the model-checking approach cannot cope with such large-scale configurations. Both the network calculus and the trajectory approaches have been implemented using Python programming language. Upper bounds of the end-to-end delays for each VL path of the realistic configuration have been computed with this tool. This computation takes less than 2 minutes for any approach on a Pentium 4 processor running at 2.8 GHz. The following table gives for both approaches the average upper bounds among all

the VLs of the configuration, as well as the minimum and the maximum upper bounds. The obtained upper bounds are slightly tighter with the trajectory approach.

	Network Calculus (ms)	Trajectories (ms)
Minimum upper bound	0.386	0.293
Average upper bound	4.532	4.247
Maximum upper bound	13.194	12.949

Both network calculus and trajectory approaches lead to pessimistic results. Indeed, network calculus is based on arrival curves and service curves that are pessimistic. It has been shown in [Li2011] that the trajectory approach computation can also be pessimistic. Then, the issue is to upper-bound the pessimism of both approaches. This issue has been addressed in [BSF10]. The idea is to build, for each VL, an unfavorable scenario, that is, a scenario that leads to an as-high-as-possible end-to-end delay for the VL. This high end-to-end delay gives an underestimation of the worst-case delay. Thus, the difference between this high end-to-end delay and the computed upper bound gives an overestimation of the pessimism of the computed upper bound.

The overestimation of the pessimism of upper bounds has been conducted on the industrial configuration analyzed in this section [BSF10]. The following table summarizes the obtained results:

	Network Calculus (%)	Trajectories (%)
Minimum pessimism	0.8	0
Average pessimism	13.5	6.5
Maximum pessimism	63	33

The pessimism depends on the flow. The trajectory approach computes the exact worst-case for around 12% of the flows (the minimum pessimism is 0%). This approach is on average at least two times less pessimistic than the network calculus approach. Thus, the trajectory approach significantly reduces the pessimism of the computed upper bounds and the remaining pessimism is very small.

## 49.8 Trends for the Dimensioning of AFDX Network

Measurements on real AFDX networks show that the end-to-end delays are always much smaller than the computed upper bounds. Thus, the network is overdimensioned. However, it has been shown in the previous section that both worst-case approaches (network calculus and trajectories) provide tight upper bounds on typical industrial configurations. These two observations seem contradictory. Actually, they are not. Indeed, the worst-case delay for a given VL corresponds to very rare scenarios. Moreover, the worst-case approaches consider that all the VLs are independent. This is true for VLs generated by different end systems. This is not true for VLs generated by the same end system. Indeed, each end system implements a scheduling that can generate constraints on the generation times of the VL frames. Some work has been conducted in order to integrate these constraints in the worst-case delay analysis. It is summarized in Section 49.8.1.

A second trend for a better utilization of available resources is to integrate Quality of Service (QoS) mechanisms in the network. Indeed, for future aircraft, the addition of other type of flows (audio, video, best-effort, etc.) on the AFDX network is envisioned. These different flows have different timing constraints and criticality levels. Thus, they have to be differentiated, and the FIFO policy on switch output ports is not suitable. Therefore, it is necessary to design a QoS-aware AFDX switch that implements other service disciplines, such as static priority queueing or weighted fair queueing [PG93]. The issue is to integrate efficiently these QoS mechanisms in the worst-case delay analysis. Work done on this point is summarized in Section 49.8.2.

A third trend concerns the model-checking approach. One valuable feature of this approach is to be able to exhibit a worst-case scenario. Obtaining such a scenario on a medium-sized configuration can bring interesting information on worst-case scenario features. Thus, work has been done in order to mitigate the combinatorial explosion problem. It is summarized in Section 49.8.3.

### 49.8.1 More Precise Modeling of Input Flows

Input flows generated by a given end system are scheduled. This scheduling leads to minimum duration between frames of different VLs generated by this end system. This fact is illustrated in Figure 49.15.

Two strictly periodic VLs  $v1$  and  $v2$  (resp.  $v3$  and  $v4$ ) with the same BAG are generated by an end system  $e1$  (resp.  $e2$ ). Due to the scheduling implemented by  $e1$  (resp.  $e2$ ), there is a minimum duration from any frame of  $v1$  (resp.  $v3$ ) to any frame of  $v2$  (resp.  $v4$ ). Similarly, there is a minimum duration from any frame of  $v2$  (resp.  $v4$ ) to any frame of  $v1$  (resp.  $v3$ ).

The integration of these minimum duration constraints in the network calculus approach has been proposed in [LSF10]. The idea is to build, for each end system, one arrival curve per group of VLs with minimum duration constraints between them. In the example in Figure 49.15, there is one arrival curve for the group  $\{v1, v2\}$  and one arrival curve for the group  $\{v3, v4\}$ . It brings a reduction of the burst generated by each end system. The same principle is also applied at the switch output port level.

Obtained results are promising. Indeed, the integration of these minimum duration constraints on the industrial configuration studied in Section 49.7 can decrease the worst-case upper bounds by 50%, assuming that all the VLs are strictly periodic.

### 49.8.2 Integration of QoS Mechanisms in the Worst-Case Analysis

The integration of fixed priority (FP) scheduling in the trajectory approach has been proposed in [BSF12]. A priority is associated to each VL. At each output port, the pending frame with the highest priority is transmitted. If two frames have the same priority, the first arrived one is transmitted.

The differences with the trajectory approach for FIFO scheduling are the following:

- One frame  $m$  can be delayed by a frame with higher priority till their last shared output port, as soon as this higher-priority frame arrives at the output port before  $m$  leaves. This is taken into account in the computation of competing flow workload, as well as in the computation of the serialization effect factor.
- At each output port, one frame  $m$  can be delayed by at most one lower-priority frame with maximum size. Thus, a new term is added to take into account this delay.

The trajectory approach for FP has been applied to the industrial configuration of Section 49.7. An overestimation of the pessimism of the obtained upper bounds has been conducted. The average pessimism is 8.2% (it is 6.5% for the trajectory approach for FIFO). It means that an FP scheduling can be efficiently integrated in the worst-case delay analysis.

### 49.8.3 Pushing the Limits of Model Checking

In order to mitigate the combinatorial explosion problem, the idea is to drastically reduce the number of scenarios to be tested. Therefore, properties have been established in [ASF11, ASEF12]. Any scenario that does not verify these properties cannot lead to the worst case. Thus, it does not have to be tested.

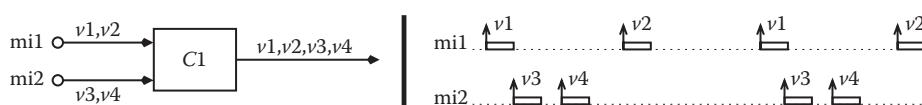

FIGURE 49.15 Minimum duration constraints.

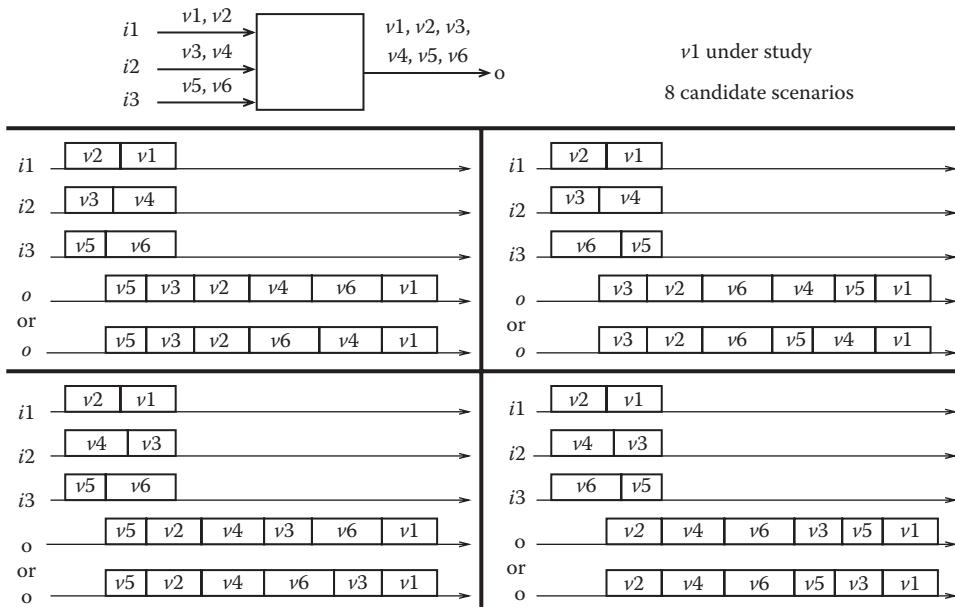

FIGURE 49.16 Worst-case candidate scenarios.

These properties are based on the critical instant concept. Let us consider a frame  $m$  of a VL  $v$ . A scenario can lead to the worst case for  $m$  if it verifies the following properties in each output port crossed by  $m$ :

- $m$  arrives in the output port of a switch at the same instant as one frame from each input port of the switch that has traffic for this output port
- All the frames that can delay  $m$  arrive at the switch output port as late as possible
- $m$  is transmitted last among the frames that have arrived in the output port at the same instant

These properties are illustrated in Figure 49.16.  $v_1$  is under study. A scenario can lead to the worst-case for  $v_1$  if

- One frame from  $v_3$  or  $v_4$  arrives at the output port at the same time as the frame from  $v_1$
- One frame from  $v_5$  or  $v_6$  arrives at the output port at the same time as the frame from  $v_1$
- The other frames arrive at the output port as late as possible
- The frame from  $v_1$  is transmitted last on the output link

It leads to eight candidate scenarios for the worst case for  $v_1$ .

Two approaches taking into account these properties have been proposed. The first one is based on timed automata and Uppaal [ASEF12]. It can analyze configurations with up to 30 VLs. The limitation is mainly due to the fact that the modeling uses arrays that are memory consuming in Uppaal. The second approach is based on a home-made tool in Java [ASF11]. It can cope with configurations including up to 60 VLs.

Such results are promising. The analysis of a medium-sized configuration becomes possible with a model-checking approach. However, further work is needed in order to cope with an industrial size configuration.

## 49.9 Conclusion

This chapter gives an overview of the temporal analysis of switched Ethernet avionic network (AFDX). Today, three approaches exist for the computation of a safe upper bound of the end-to-end delay of each flow transmitted on the avionic network.

The first approach is based on network calculus. It is optimized for AFDX, since it integrates the serialization of frames on links. It has been used for the certification of the A380. It gives safe upper bounds on the end-to-end delays of flows. These bounds are pessimistic, due to network calculus assumptions. Moreover, the worst-case delay for a flow corresponds to very rare scenarios. Consequently, the network is overdimensioned. Recently, the integration of the scheduling of flows by source nodes has been proposed. It can significantly reduce the delay upper bounds. Thus, it is a promising direction in order to limit the overdimensioning of the network.

The second approach is based on trajectories. It computes the maximum workload faced by any frame of a given flow on its trajectory. It gives tighter upper bounds, compared with the network calculus approach. A pessimism analysis has been conducted on the obtained upper bounds. It shows that these bounds are tight (less than 6.5% pessimism).

The third approach is based on model checking and allows the computation of the exact worst-case delay of each flow, but it is limited by the combinatorial explosion problem. This problem can be mitigated by considering only the scenarios that can lead to the worst case. Thus, it becomes possible to analyze medium-size networks. However, the analysis of an industrial-size configuration is still an open issue.

For future aircraft, the addition of other type of flows on the AFDX network is envisioned. These different flows have different timing constraints and criticity levels. Thus, it is necessary to differentiate them, and the FIFO policy on switch output ports is not suitable. The integration of FP mechanism in the trajectory approach has been proposed, and it has been shown that obtained upper bounds are tight. Further studies are needed in order to allocate these priorities efficiently and to extend the approach to other scheduling policies.

Finally, the sporadic characteristic of avionics flows could be taken into account with the help of a probabilistic modeling, as it has been proposed for the aperiodic traffic in the automotive context [Khan2009]. This leads to a probabilistic analysis of the worst-case delay of flows. Such a preliminary analysis has been proposed in the context of AFDX [SRF09]. It is based on a stochastic network calculus approach [VLB01,VLB02].

### 50.1 Automotive Communication Systems: Characteristics and Constraints

---

#### 50.1.1 From Point-to-Point to Multiplexed Communications

Since the 1970s, one observes an exponential increase in the number of electronic systems that have gradually replaced those that are purely mechanical or hydraulic. The growing performance and reliability of hardware components and the possibilities brought by software technologies enabled implementing complex functions that improve the comfort of the vehicle's occupants as well as their safety. In particular, one of the main purposes of electronic systems is to assist the driver to control the vehicle through functions related to the steering, traction (i.e., control of the driving torque), or braking such as the antilock braking system (ABS), electronic stability program (ESP), electric power steering (EPS), active suspensions, or engine control. Another reason for using electronic systems is to control devices in the body of a vehicle such as lights, wipers, doors, windows, as well as entertainment and communication equipment (e.g., radio, DVD, hand-free phones, navigation systems). More recently appeared a large set of advanced driver assistance systems (ADAS), often camera based, such as brake and park assistance,

lane departure detection, night vision assistance with pedestrian recognition or suspension proactively scanning the road surface [55]. In the future, vehicles will become entities of large intelligent transportation systems [51], involving cooperation mechanisms [50] through car-to-car and car-to-infrastructure communications.

In the early days of automotive electronics, each new function was implemented as a stand-alone electronic control unit (ECU), which is a subsystem composed of a microcontroller and a set of sensors and actuators. This approach quickly proved to be insufficient with the need for functions to be distributed over several ECUs and the need for information exchanges among functions. For example, the vehicle speed estimated by the engine controller or by wheel rotation sensors has to be known in order to adapt the steering effort, to control the suspension, or simply to choose the right wiping speed. In today's luxury cars, several thousands of signals (i.e., elementary information such as the speed of the vehicle) are exchanged by up to 100 ECUs [1]. Until the beginning of the 1990s, data were exchanged through point-to-point links between ECUs. However, this strategy, which required an amount of communication channels of the order of  $n^2$ , where  $n$  is the number of ECUs (i.e., if each node is interconnected with all the others, the number of links grows in the square of  $n$ ), was unable to cope with the increasing use of ECUs due to the problems of weight, cost, complexity, and reliability induced by the wires and the connectors. These issues motivated the use of networks where the communications are multiplexed over a shared medium, which consequently required defining rules—protocols—for managing communications and, in particular, for granting bus access. It was mentioned in a 1998 press release (quoted in Ref. [45]) that the replacement of a “wiring harness with LANs in the four doors of a BMW reduced the weight by 15 kg.” In the mid-1980s, the third part supplier Bosch developed controller area network (CAN), which was first integrated in Mercedes production cars in the early 1990s. CAN has become today the most widely used network in automotive systems, and already in 2004, the number of CAN nodes sold per year was estimated [38] to be around 400 millions (all application fields). Other communication networks, providing different services, are now being integrated in automotive applications. A description of the major networks is given in Section 50.2.

### 50.1.2 Car Domains and Their Evolution

As all the functions embedded in cars do not have the same performance or safety needs, different quality of services (QoS) (e.g., response time, jitter, bandwidth, redundant communication channels for tolerating transmission errors, and efficiency of the error detection mechanisms) are expected from the communication systems. Typically, an in-car embedded system is divided into several functional domains that correspond to different features and constraints. Two of them are concerned specifically with real-time control and safety of the vehicle's behavior: the *powertrain* (i.e., control of engine and transmission) and the *chassis* (i.e., control of suspension, steering, and braking) domains. The third, the *body*, mostly implements comfort functions. The *telematics* (i.e., integration of wireless communications, vehicle monitoring systems, and location devices), *multimedia*, and *human-machine interface* (HMI) domains take advantage of the continuous progress in the field of multimedia and mobile communications. Finally, an emerging domain is concerned with the safety of the occupant and with functions providing driver assistance.

The main function of the powertrain domain is controlling the engine. This domain is increasingly constrained by stringent regulations, such as EURO 5 in force at the time of writing in Europe, for the protection of environment (e.g., emissions of particulate matter) and energy efficiency. The powertrain function is realized through several complex control laws with sampling periods of a magnitude of some milliseconds (due to the rotation speed of the engine) and implemented in microcontrollers with high computing power. In order to cope with the diversity of critical tasks to be treated, multitasking is required and stringent time constraints are imposed on the scheduling of the tasks (see Ref. [58] for typical automotive scheduling solutions). Furthermore, frequent data exchanges with other car domains, such as the chassis (e.g., ESP, ABS) and the body (e.g., dashboard, climate control), are required.

The chassis domain gathers functions such as ABS, ESP, automatic stability control (ASC), and four-wheel drive (4WD), which control the chassis components according to steering/braking solicitations and driving conditions (ground surface, wind, etc.). Communication requirements for this domain are quite similar to those for the powertrain, but because they have a stronger impact on the vehicle's stability, agility, and dynamics, the chassis functions are more critical from a safety standpoint. Furthermore, the *x-by-wire* technology, currently used for avionic systems, is now slowly being introduced to execute steering or braking functions. X-by-wire is a generic term referring to the replacement of mechanical or hydraulic systems by fully electrical and electronic (EE) ones, which led and still leads to new design methods for developing them safely [98] and, in particular, for mastering the interferences between functions [4]. Chassis and powertrain functions operate mainly as closed-loop control systems, and their implementation is moving toward a time-triggered (TT) approach [44,70,74,80], which facilitates composability (i.e., ability to integrate individually developed components) and deterministic real-time behavior of the system.

Dashboard, wipers, lights, doors, windows, seats, mirrors, and climate control are increasingly controlled by software-based systems that make up the *body* domain. This domain is characterized by numerous functions that necessitate many exchanges of small pieces of information among themselves. Not all nodes require a large bandwidth, such as the one offered by CAN; this leads to the design of low-cost networks, such as local interconnect network (LIN; see Section 50.2) or, more recently, Peripheral Sensor Interface 5 (PSI5) and Single-Edge Nibble Transmission (SENT). On LIN, only one node, termed the master, possesses an accurate clock and drives the communication by polling the other nodes—the slaves—periodically. The mixture of different communication needs inside the body domain leads to a hierarchical network architecture where integrated mechatronic subsystems based on low-cost networks are interconnected through a CAN backbone. The activation of body functions is mainly triggered by the driver and passengers' solicitations (e.g., opening a window and locking doors).

Telematics functions are becoming more and more numerous: hand-free phones, car radio, CD, DVD, in-car navigation systems, rear-seat entertainment, remote vehicle diagnostic, stolen vehicle tracking, etc. These functions require a lot of data to be exchanged within the vehicle but also with the external world through the use of wireless technology (see, for instance, Ref. [79]). Here, the emphasis shifts from messages and tasks subject to stringent deadline constraints to multimedia data streams, bandwidth sharing, multimedia QoS where preserving the integrity (i.e., ensuring that information will not be accidentally or maliciously altered) and confidentiality of information is crucial. HMI aims to provide human-machine interfaces that are easy to use and that limit the risk of driver inattention [19].

Electronic-based systems for ensuring the safety of the occupants are increasingly embedded in vehicles. Examples of such systems are impact and roll-over sensors, deployment of air-bags and belt pretensioners, tire pressure monitoring, adaptive cruise control (ACC—the car's speed is adjusted to maintain a safe distance with the car ahead), lane departure warning system, collision avoidance, driver intent and driver drowsiness detection, and night vision assistance. These functions form an emerging domain usually referred to as *active and passive safety*.

### 50.1.3 Event Triggered versus Time Triggered

One of the main objectives of the design step of an in-vehicle embedded system is to ensure a proper execution of the vehicle functions, with a predefined level of safety, in the normal functioning mode but also when some components fail (e.g., reboot of an ECU) or when the environment of the vehicle creates perturbations (e.g., EMI causing frames to be corrupted). Networks play a central role in maintaining the embedded systems in a *safe* state since most critical functions are now distributed and need to communicate. Thus, the different communication systems have to be analyzed in regard to this objective; in particular, messages transmitted on the bus must meet their real-time constraints, which mainly consist of bounded response times and bounded jitters.

There are two main paradigms for communications in automotive systems: TT and event triggered. Event triggered means that messages are transmitted to signal the occurrence of significant events (e.g., a door has been closed). In this case, the system possesses the ability to take into account, as quickly as possible, any asynchronous events such as an alarm. The communication protocol must define a policy to grant access to the bus in order to avoid collisions; for instance, the strategy used in CAN (see Section 50.2.1.1) is to assign a priority to each frame and to give the bus access to the highest-priority frame. Event-triggered communication is very efficient in terms of bandwidth usage since only necessary messages are transmitted. Furthermore, the evolution of the system without redesigning existing nodes is generally possible, which is important in the automotive industry where incremental design is a usual practice. However, verifying that temporal constraints are met is not obvious, and the detection of node failures is problematic.

When communications are TT, frames are transmitted at predetermined points in time, which is well suited for the periodic transmission of messages as it is required in distributed control loops. Each frame is scheduled for transmission during one predefined interval of time, usually termed a slot, and the schedule repeats itself indefinitely. This medium access strategy is referred to as time division multiple access (TDMA). As the frame scheduling is statically defined, the temporal behavior is fully predictable; thus, it is easy to check whether the timing constraints expressed on data exchanges are met. Another interesting property of TT protocols is that missing messages are immediately identified; this can serve to detect, in a short and bounded amount of time, nodes that are presumably no longer operational. The first downside is the inefficiency in terms of network utilization and response times by comparison with the transmission of aperiodic messages (i.e., messages that are not transmitted in a periodic manner). A second drawback of TT protocols is the lack of flexibility even if different schedules (corresponding to different functioning modes of the application) can be defined and switching from one mode to another is possible at run-time. Finally, the unplanned addition of a new transmitting node on the network induces changes in the message schedule and, thus, may necessitate the update of all other nodes. The Time-Triggered Protocol (TTP, formerly known as TTP/c [95]) is a purely time-triggered network, but there are networks, such as time-triggered CAN (TTCAN) [37], Flexible Time-Triggered CAN FTT-CAN [18], FlexRay [11], or TTEthernet [94], that can support a combination of both time-triggered and event-triggered transmissions. This capability to convey both types of traffic fits in well with the automotive context since data for control loops as well as alarms and events have to be transmitted.

Several comparisons have been done between event-triggered and TT approaches; the reader can refer to [1,18,42] for good starting points.

#### 50.1.4 Different Networks for Different Requirements

The steadily increasing need for bandwidth\* and the diversification of performance, costs, and dependability† requirements lead to a diversification of the networks used throughout the car. In 1994, the Society for Automotive Engineers (SAE) defined a classification for automotive communication protocols [13,85,86] based on data transmission speed and functions that are distributed over the network. *Class A* networks have a data rate lower than 10 kbit/s and are used to transmit simple control data with low-cost technology. They are mainly integrated in the *body* domain (seat control, door lock, lighting, trunk release, rain sensor, etc.). Examples of class A networks are LIN [48,77] and TTP/A [27]. *Class B* networks are dedicated to supporting data exchanges between ECUs in order to reduce the number of sensors by sharing information. They operate from 10 to 125 kbit/s. The J1850 [87] and low-speed CAN [33] are the main representatives of this class. Applications that need high-speed real-time communications require *class C* networks (speed of 125 kbit/s to 1 Mbit/s) or *class D* networks‡

\* For instance, in [4], the average bandwidth needed for the engine and the chassis control was estimated to reach 1500 kbit/s in 2008, while it was 765 kbit/s in 2004 and 122 kbit/s in 1994.

† Dependability is usually defined as the ability to deliver a service that can justifiably be trusted (see Ref. [3] for more details).

‡ Class D is not formally defined, but it is generally considered that networks over 1 Mb/s belong to class D. This SAE classification is outdated today but was often referred to in the past.

(speed over 1 Mb/s). Class C networks, such as high-speed CAN [35], are used for the powertrain and currently for the chassis domains, while class D networks are devoted to multimedia data (e.g., Media Oriented Systems Transport [MOST] [59]) and safety-critical applications that need predictability and fault tolerance (e.g., TTP/C [93] or FlexRay [11] networks) or serve as gateways between subsystems (see the use of FlexRay at BMW in [83] and [39]).

It is common, in today's vehicles, that the electronic architecture includes four, five, or more different types of networks interconnected by gateways. For example, the first-generation Volvo XC90 [38] embeds up to 40 ECUs interconnected by a LIN bus, a MOST bus, a low-speed CAN, and a high-speed CAN. More recent high-end cars have much more complex architectures, such as the BMW 7 series launched in 2008 (see Ref. [39]), which implements four CAN buses, a FlexRay bus, a MOST bus, several LIN buses, an Ethernet bus, and wireless interfaces. The architecture is organized around a central gateway connecting most of the data buses and providing external connections for diagnostic and large data transfer (code upload, navigational maps, etc.).

### 50.1.5 New Challenges for In-Vehicle Communication Systems

We discuss here three main evolutions that will probably profoundly shape future automotive communication networks and architectures.

#### 50.1.5.1 Real-Time Processing of Large Data Quantities

The first trend is the requirement for an increasing number of functions to *process, at a high rate, large quantities of data*, for instance, produced by video and infrared cameras. A good example of such functions is a pedestrian detection system with autobrake, which relies on image recognition and machine-learning algorithms, and has to work at the highest possible vehicle speed. In the case of the pedestrian detection system introduced in 2010 in Volvo S60, a collision with a pedestrian can be avoided at up to 35 km/h [96]. This system has to analyze the flow of images and provide, on time, a deterministic verdict about whether there is a pedestrian in front of the car, and then possibly activate braking if the driver fails to respond in time. Such systems, often belonging to the active and passive safety car domain, require powerful computational resources. This is one of the rationales for the introduction of multicore architectures in automotive embedded systems [58]. Furthermore, these functions are often implemented on a distributed architecture and usually require sensor fusion, so that the underlying communication architecture has to provide a strong and guaranteed temporal QoS. Another driver for increasing data streams is of course infotainment systems, consider, for example, a rear-seat video system in HD quality.

#### 50.1.5.2 Reducing Electrical Energy Consumption

*Energy efficiency* is now a major concern when designing new embedded electronic architectures, while it was for the last 10 years a concern for actuators mainly. A reason is that, by regulation, the average CO<sub>2</sub> emission per passenger car sold in the EU must fall below the 95 g/km threshold from 2020 onward. Similar regulations will come into force in many countries outside EU, for instance, in China or in the United States [100]. At the same time, it is estimated in Ref. [8] that, between 2002 and 2012, the average power requirement for the automotive electronics was multiplied by 4 and reaches now 3 kW.

This leads to the introduction of two main strategies to achieve better energy efficiency: ECU degradation and partial networking. ECU degradation is the ability to switch off or reduce the execution rate of software modules, shut-down some I/O ports, or even put a complete CPU into idle mode. These low-power features are already supported in AUTOSAR. Partial networking means putting temporarily into sleep mode a group of nodes, or some entire network, when they do not need to be operational. For example, a parking assistance system that cannot be used above 20 km/h can be deactivated at higher speeds. Many control modules in the body of the vehicle (seats, mirror, door, etc.) can remain in sleep mode most of the time [8]. Then, the nodes are waken up when needed through specific messages. Audi estimates, for instance, that the potential savings of partial networking would be around 2.6 g CO<sub>2</sub>/km [8,95].

Partial networking has been an ongoing work in the automotive industry since 2008 [47], already fully supported in AUTOSAR for CAN. A working group of carmakers and semiconductor manufacturers was set up in 2010 to develop a specification for CAN transceivers with wake-up capability [8,95]. The outcomes of this working group have been submitted for standardization as ISO 11898-6, an extension to the existing CAN standard (ISO 11898). Several components supporting partial networking are commercially available [100], and the first implementation in a car has been announced for 2013 or 2014 [47].

### 50.1.5.3 Security Issues

The last issue to be dealt with is the security of communication and more generally security of the embedded systems. If safety has always been a matter of concern for automotive embedded systems, security issues have been in our view largely overlooked. The need for more security is driven by the ever-increasing connectivity between the car and the external world, which includes not only telematics services and Internet access but also upcoming vehicle-to-vehicle or vehicle-to-infrastructure communication.

As demonstrated in [43], some existing security mechanisms, for instance, to control ECU reprogramming, are weak, and many current automotive systems usually do not resist to attacks, sometimes even relatively unsophisticated ones according to [43]. With a physical access to the vehicle, through a connection to the standard OBD-II port, the authors were, for instance, able to reflash ECUs, even critical ones controlling the engine and the brakes. The authors were also able to remotely compromise the security of the car, by injecting malicious code, and “ultimately monitor and control the car remotely over the Internet” [43]. Obviously, such security breaches could have catastrophic consequences, especially with ADAS systems and future intelligent transportation systems requiring cooperation between vehicles. One may even imagine a scenario where an infected vehicle would contaminate other vehicles.

The technical answer to this security challenge will probably encompass a spectrum of solutions [43], ranging from cryptography (support for embedding a cryptographic module is available in AUTOSAR since release 4.0 [7]), to message authentication mechanisms, to security breach detection systems, etc. These functionalities will require additional bandwidth, and, for instance, CAN FD (CAN with Flexible Data-Rate, see Section 50.2.1.4) would probably be better suited than normal CAN to fulfill these needs. The use of virtualization technologies [62] will also increase security because it enables to isolate functions or subsystems running on the same ECUs having different security requirements, while enabling them to share information in a controlled manner. Typically, virtualization would help to prevent infotainment applications that are connected to the external world through wireless connections, from accessing the internal communication buses.

## 50.2 In-Car Embedded Networks

---

The different performance requirements throughout a vehicle, as well as the competition among companies, have led to the design of a large number of communication networks. The aim of this section is to give a description of the most representative networks for each main domain of utilization.

### 50.2.1 CAN Network

To ensure at run-time the *freshness*\* of the exchanged data and the timely delivery of commands to actuators, it is crucial that the medium access control (MAC) protocol is able to ensure bounded response times for frames. An efficient and conceptually simple MAC scheme that possesses this capability is the granting of bus access according to the priority of the messages (the reader can refer to Refs. [14,56,65,91] for how to compute bound on response times for priority buses). To this end, each message is assigned

---

\* The freshness property is verified if data have been produced recently enough to be safely consumed: the difference between the time when the data are used and its production time must be always smaller than a specified value. The delay experienced by a data is made up of the network latency, plus the latencies on the sending and receiving ends, which can be large especially if the application tasks are not synchronized with the transmissions on the network (see Ref. [25]).

an identifier, unique to the whole system. This serves two purposes: giving priority for transmission (the lower the numerical value, the greater the priority) and allowing message filtering upon reception. Besides CAN, two other representatives of such *priority buses* are vehicle area network (VAN) and J1850; they will be briefly presented in Section 50.2.1.3.

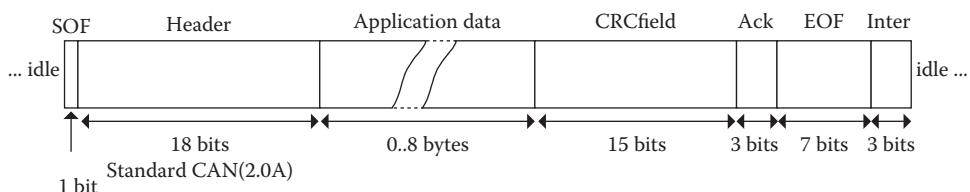

### 50.2.1.1 CAN Protocol

CAN is without a doubt the most widely used in-vehicle network. It was designed by Bosch in the mid-1980s for multiplexing communication between ECUs in vehicles and thus for decreasing the overall wire harness: length of wires and number of dedicated wires (e.g., the number of wires has been reduced by 40%, from 635 to 370, in the Peugeot 307 that embeds two CAN buses with regard to the nonmultiplexed Peugeot 306 [52]). Furthermore, it allows to share sensors among ECUs.

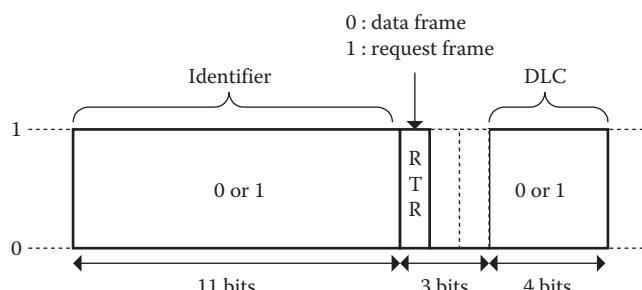

CAN on a twisted pair of copper wires became an ISO standard in 1994 [33,35] and is now a de facto standard in Europe for data transmission in automotive applications, due to its low cost, its robustness, and the bounded communication delays (see Ref. [38]). In today's car, CAN is used as an SAE class C network for real-time control in the powertrain and chassis domains (at 250 or 500 kbit/s), but it also serves as an SAE class B network for the electronics in the body domain, usually at a data rate of 125 kbit/s.

On CAN, data, possibly segmented in several frames, may be transmitted periodically, aperiodically, or on demand (i.e., client–server paradigm). A CAN frame is labeled by an identifier, transmitted within the frame (see Figures 50.1 and 50.2), whose numerical value determines the frame priority. There are two versions of the CAN protocol differing in the size of the identifier: CAN 2.0A (or *standard CAN*) with an 11-bit identifier and CAN 2.0B (or *extended CAN*) with a 29-bit identifier. For in-vehicle communications, only CAN 2.0A is used since it provides a sufficient number of identifiers (i.e., the number of distinct frames exchanged over one CAN network is lower than  $2^{11}$ ).

CAN uses non-return-to-zero (NRZ) bit representation with a bit stuffing of length 5. In order not to lose the bit time (i.e., the time between the emission of two successive bits of the same frame), stations need to resynchronize periodically, and this procedure requires edges on the signal. Bit stuffing is an encoding method that enables resynchronization when using NRZ bit representation where the signal level on the bus can remain constant over a longer period of time (e.g., transmission of “000000...”). Edges are inserted

**FIGURE 50.1** Format of the CAN 2.0A data frame. SOF, start of frame; EOF, end of frame; Ack, acknowledgment; Inter, intermission.

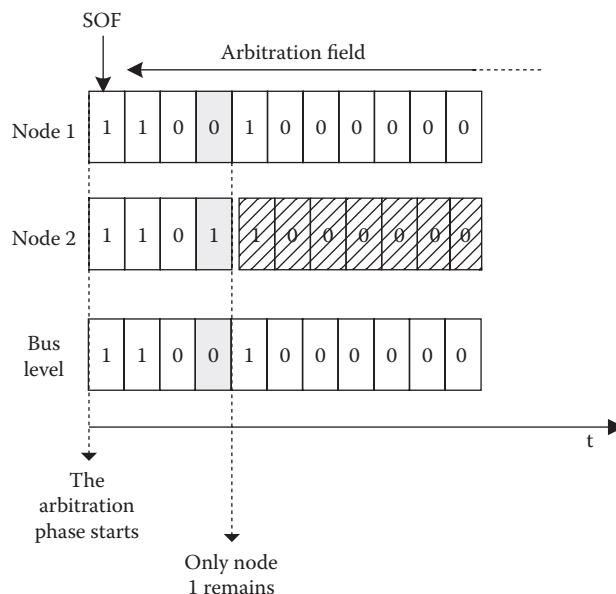

**FIGURE 50.2** Format of the header field of the CAN 2.0A data frame.

into the outgoing bit stream in such a way to avoid the transmission of more than a maximum number of consecutive equal-level bits (5 for CAN). The receiver will apply the inverse procedure and destuff the frame. CAN requires the physical layer to implement the logical “and” operator: if at least one node is transmitting the “0”-bit level on the bus, then the bus is in that state regardless if other nodes have transmitted the “1”-bit level. For this reason, “0” is termed the dominant bit value, while “1” is the recessive bit value.

The standard CAN data frame (CAN 2.0A; see Figure 50.1) can contain up to 8 bytes of data for an overall size of, at most, 135 bits, including all the protocol overheads such as the stuff bits. The sections of the frames are as follows:

- The header field (see Figure 50.2), which contains the identifier of the frame, the remote transmission request (RTR) bit that distinguishes between data frame (RTR set to 0) and data request frame (RTR set to 1) and the data length code (DLC) used to inform of the number of bytes of the data field.
- The data field having a maximum length of 8 bytes.
- The 15-bit cyclic redundancy check (CRC) field, which ensures the integrity of the data transmitted.
- The acknowledgment field (ACK). On CAN, the acknowledgment scheme solely enables the sender to know that at least one station, but not necessarily the intended recipient, has received the frame correctly.
- The end-of-frame (EOF) field and the intermission frame space, which is the minimum number of bits separating consecutive messages.

Any CAN node may start a transmission when the bus is idle. Possible conflicts are resolved by a priority-based arbitration process, which is said nondestructive in the sense that, in case of simultaneous transmissions, the highest-priority frame will be sent despite the contention with lower-priority frames. The arbitration is determined by the arbitration fields (identifier plus RTR bit) of the contending nodes. An example illustrating CAN arbitration is shown on Figure 50.3. If one node transmits a recessive bit on the bus while another transmits a dominant bit, the resulting bus level is dominant due to the “and” operator

**FIGURE 50.3** CAN arbitration phase with two nodes starting transmission simultaneously. Node 2 detects that a frame with a higher priority than its own is being transmitted when it monitors a level 0 (i.e., dominant level) on the bus while it has sent a bit with a level 1 (i.e., recessive level). Afterward, node 2 immediately stops transmitting.

realized by the physical layer. Therefore, the node transmitting a recessive bit will observe a dominant bit on the bus and then will immediately stop transmitting. Since the identifier is transmitted *most significant bit first*, the node with the numerically lowest identifier field will gain access to the bus. A node that has lost the arbitration will wait until the bus becomes free again before trying to retransmit its frame.

CAN arbitration procedure relies on the fact that a sending node monitors the bus while transmitting. The signal must be able to propagate to the most remote node and return back before the bit value is decided. This requires the bit time to be at least twice as long as the propagation delay, which limits the data rate: for instance, 1 Mbit/s is feasible on a 40 m bus at maximum, while 250 kbit/s can be achieved over 250 m. To alleviate the data rate limit and extend the life-span of CAN further, car manufacturers are starting to optimize the bandwidth usage by implementing *traffic shaping* strategies that are very beneficial in terms of response times (see, for instance, Ref. [24]).

CAN has several mechanisms for error detection. For instance, it is checked that the CRC transmitted in the frame is identical to the CRC computed at the receiver end, that the structure of the frame is valid, and that no bit-stuffing error occurred. Each station that detects an error sends an *error flag*, which is a particular type of frame composed of six consecutive dominant bits that allows all the stations on the bus to be aware of the transmission error. The corrupted frame automatically reenters into the next arbitration phase, which might lead it to miss its deadline due to the additional delay. The error recovery time, defined as the time from detecting an error until the possible start of a new frame, is 17–31-bit times. CAN possesses some fault-confinement mechanisms aimed at identifying permanent failures due to hardware dysfunctioning at the level of the microcontroller, communication controller, or physical layer. The scheme is based on error counters that are increased and decreased according to particular events (e.g., successful reception of a frame, reception of a corrupted frame). The relevance of the algorithms involved is questionable (see Ref. [22]), but the main limitation is that a node has to diagnose itself, which can lead to the nondetection of some critical errors. For instance, a faulty oscillator can cause a node to transmit continuously a dominant bit, which is one manifestation of the *babbling-idiot* fault (see Ref. [72]). Furthermore, other faults such as the partitioning of the network into several subnetworks may prevent all nodes from communicating due to bad signal reflection at the extremities. Without additional fault-tolerance facilities, CAN is not well suited for safety-critical applications. For instance, a single node can perturb the functioning of the whole network by sending messages outside their specification (i.e., length and period of the frames). Many mechanisms were proposed for increasing the dependability of CAN-based networks (see Ref. [72] for an excellent survey), but if each proposal solves a particular problem, they have not necessarily been conceived to be combined. Furthermore, the fault hypotheses used in the design of these mechanisms are not necessarily the same, and the interactions between them remain to be studied in a formal way.

The CAN standard only defines the physical layer and data link layer (DLL). Several higher-level protocols have been proposed, for instance, for standardizing start-up procedures, implementing data segmentation, or sending periodic messages (see OSEK/VDX and AUTOSAR in Section 50.3). Other higher-level protocols standardize the content of messages in order to ease the interoperability between ECUs. This is the case for J1939, which is widely used, for instance, in Scania's trucks and buses [97].

### 50.2.1.2 CAN's Use in Today's Automobiles

There is now more than 20 years of experience in automotive CAN applications, and CAN has certainly proven very successful as a robust, cost-effective, and all-around network technology. But the use of CAN in vehicles is evolving, in particular, because of more complex and heterogeneous architectures with FlexRay or Ethernet networks and because of recent needs like hybrid, electric propulsion, or driver assistance that involve more stringent real-time constraints. Besides, there are other new requirements on CAN: more fine-grained ECU mode management for energy savings [8,100], multi-ECU splitted functions, and huge software downloads. In parallel, safety issues request more and more mechanisms to protect against potential failures and provide end-to-end (E2E) integrity (see Section 50.3.3 and Ref. [2]).

### **50.2.1.2.1 Increased Bandwidth Requirements**

The robustness and performance of the CAN technology, as well as the new possibilities brought by distributed software functions, have led engineers to use more and more bandwidth in order to improve existing EE functions and introduce new ones. This trend has never ceased and, along with topology and functional domain constraints, has led to the use of several CAN clusters within a car, sometimes more than four or five [39,63]. Also, the data rates of the CAN buses are now higher (e.g., 250 kbit/s for a body network when it used to be 125 kbit/s), and the bus load level has increased (e.g., >50%).

### **50.2.1.2.2 More Complex Architectures**

At the beginning of CAN, just a few ECUs were connected, while today, there are thousands of signals exchanged by several tens of ECUs, with some signals having timing constraints below 5 ms. Besides, the architectures are becoming complex because of gateways between the CAN buses or between a CAN bus and another networking technology (typically FlexRay). The use of several CAN clusters raises also technical issues regarding, for instance, fault handling, diagnosis timing response, and wake-up and sleep synchronization. And, whatever is done, there is an overlap between the data sent on the buses connected to a gateway, which induces a significant waste of bandwidth. To face the EE architecture complexity and be able to push the limits of CAN, carmakers have established rigorous development processes. Besides, there are now several well-suited COTS tool sets available on the market to help them with the optimization and verification using simulation, schedulability analysis, and trace analysis (see Ref. [63] for how they are used).

### **50.2.1.2.3 Optimizing CAN Networks**

When CAN was introduced, the bus load levels were limited, typically much less than 30% (see Ref. [64] for a typical set of messages of the years 1995–2000). Optimizing CAN networks, which includes reaching higher load levels, has now become an industrial requirement for several reasons:

- It helps to master the complexity of the architectures.
- It reduces the hardware costs, weight, space, consumption, etc.
- It facilitates an incremental design process.
- It may avoid the industrial risk, the costs, and the time to master new technologies such as FlexRay.
- It leads to better communication performances and helps to match the bandwidth needs. Sometimes, a 60%-loaded CAN network can be more efficient than two 40% CAN networks interconnected by a gateway causing delays and high jitters.

The first obvious way to optimize a CAN network is to keep the amount of data transmitted to a minimum, specifically limit the transmission frequency of the frames. This requires a rigorous identification and traceability of the temporal constraints. Given a set of signals or frames, and their associated temporal constraints (freshness, jitters, etc.), they are in addition a few configuration strategies than can be used:

1. Desynchronize the stream of frames by using offsets. The reader may refer to Ref. [26] for comprehensive experiments on the large gains achieved using offsets.
2. Reassign the priorities of the frames, so that the priority order better reflects the timing constraints.
3. Reconsider the frame packing, that is, the allocation of the signals to the frames and choice of the frame periods, so as to minimize the bandwidth usage while meeting timing constraints (see Ref. [81]).
4. Optimize the ECU communication stacks so as to remove all implementation choices that cause a departure from the ideal CAN behavior (see Ref. [63]).

However, because there is less margin for error, using complex CAN-based architectures at high-load levels involves more detailed supplier specifications on the one hand and, on the other hand, spends more time and effort in the integration/validation phase.

### 50.2.1.3 Other Priority Buses: VAN and J1850

The J1850 [87] is an SAE class B priority bus that was adopted in the United States for communications with nonstringent real-time requirements, such as the control of body electronics or diagnostics. Two variants of the J1850 are defined: a 10.4 kbit/s single-wire version and 41.6 kbit/s two-wire version. For quite a long time, the trend in new designs seems to be the replacement of J1850 by CAN or a low-cost network such as LIN (see Section 50.2.3.1).

In the 1990s, another competing technology was the French VAN (see Ref. [34]) which is very similar to CAN (e.g., frame format, data rate) but possesses some additional or different features that are advantageous from a technical point of view (e.g., no need for bit-stuffing, in-frame response: a node being asked for data answers in the same frame that contained the request). VAN was used for years in production cars by the French carmaker PSA Peugeot Citroen in the body domain (e.g., for the 206 model), but as it was not adopted by the market, it was abandoned in favor of CAN.

### 50.2.1.4 CAN FD: A High-Speed CAN Network

CAN FD is a new protocol that was presented for the first time by Robert Bosch GmbH at the International CAN Conference in 2012 [30] that combines CAN's core features with a higher data rate and larger data payloads. The data field length can be up to 64 bytes long: from 0 to 8 bytes, then above 8 bytes, the possible values are 12, 16, 20, 24, 32, 48, and 64 bytes. Technically, two bit rates are used successively in the transmission of a CAN FD frame: one lower for the arbitration phase, as required by the CAN bit-wise arbitration (see Section 50.2.2.2), and a higher one used immediately after the arbitration for the transfer of the data payload and related fields (e.g., DLC, CRC). The bit rate for this data part of the frame transmission can be freely chosen (e.g., 10 Mbit/s is mentioned in Ref. [30]), but in practice, it will depend much on the topology of the network and the efficiency of the transceivers. It is not clear at the time of writing what is the kind of data rate and thus the speedup with regard to standard CAN that can be achieved in typical automotive applications, and this will largely determine the acceptance of CAN FD. The target mentioned in Ref. [30] is an average data rate of 2.5 Mbit/s with existing CAN transceivers.

Four main use cases are identified for CAN FD in Ref. [49]: faster software download (end-of-production line or maintenance), avoiding segmentation of long messages (and possibly securing normal CAN messages with message authentication information), offering higher bandwidth to car domains requiring it (e.g., powertrain [49]), and enabling faster communication on long CAN buses (e.g., in trucks and buses). An important advantage of CAN FD is that there is an easy migration path from CAN systems to CAN FD systems since existing CAN application software can basically remain unchanged, the changes taking place in the communication layers and their configuration. Following FPGAs' implementations, microcontrollers with CAN FD are already available (e.g., [20]), and the protocol has been submitted as ISO 11898-7 for international standardization.

## 50.2.2 Time-Triggered Networks

Among communication networks, as discussed previously, one distinguishes TT networks where activities are driven by the progress of time and event triggered once where activities are driven by the occurrence of events. Both types of communication have advantages, but one considers that, in general, dependability is much easier to ensure using a TT bus (refer, for instance, to Ref. [80] for a discussion on this topic). This explains that mainly TT communication systems are being considered for use in the most critical applications such as x-by-wire systems. In this category, multiaccess protocols based on TDMA are particularly well suited; they provide deterministic access to the medium (the order of the transmissions is defined statically at the design time) and thus bounded response times. Moreover, their regular message transmissions can be used as *heartbeats* for detecting station failures. The three TDMA-based networks that could serve as gateways or for supporting safety-critical applications are TTP/C (see Ref. [93]), FlexRay (see Section 50.2.2.1), and TTEthernet (see Section 50.2.5.4). FlexRay, which was backed by the world's

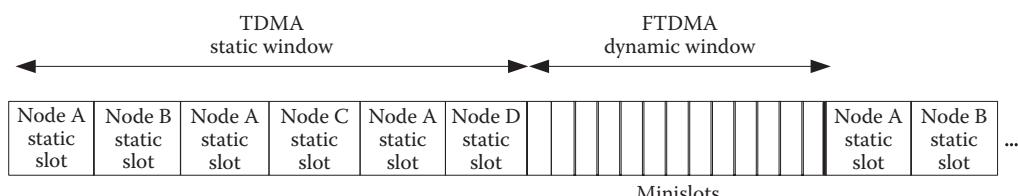

automotive industry, is becoming a standard technology in the industry, though without gaining broad acceptance, and is already in use in production cars since 2006 (see Refs. [28,83]). TTCAN (see Section 50.2.2.2) was, before the advent of FlexRay, considered for use and is briefly discussed in this section. In the following, we choose not to discuss further TTP/C, which, to the best of our knowledge, is no more considered for vehicles but is used in aircraft. However, the important experience and know-how gained over the years with TTP/C, in particular regarding its fault-tolerance features (see Ref. [23]) and their formal validation (see Ref. [71]), is certainly beneficial to FlexRay and any Ethernet-based protocols such as TTEthernet (see Section 50.2.5.4) or even Audio/Video Bridging (AVB; see Section 50.2.5.3).

### 50.2.2.1 FlexRay Protocol

A consortium of major companies from the automotive field developed the FlexRay protocol. The core members of the consortium, now disbanded, were BMW, Bosch, Daimler, General Motors, NXP Semiconductors, Freescale Semiconductor, and Volkswagen. The first publicly available specification of the FlexRay Protocol was released in 2004; the current version of the specification is now available as a set of ISO standards issued in 2013 (ISO 17458 Part 1–5), based on the 3.0.1 release from the FlexRay consortium [11]. FlexRay did not gain very wide acceptance yet, since most car manufacturers still rely on CAN-based architectures, but it has been used since 2006 in some production cars by BMW and Audi. For instance, the latest series 5 from BMW implements up to 17 FlexRay nodes [28].

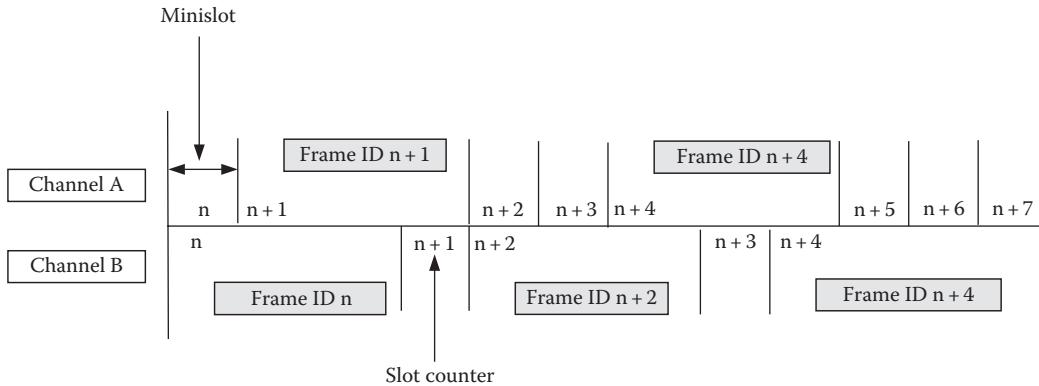

The FlexRay network is very flexible with regard to topology and transmission support redundancy. It can be configured as a bus, a star, or multistar. It is not mandatory that each station possesses replicated channels nor a bus guardian. At the MAC level, FlexRay defines a communication cycle as the concatenation of a TT (or static) window and an event-triggered (or dynamic) window. In each communication window, size of which is set statically at design time, two distinct protocols are applied. The communication cycles are executed periodically. The TT window uses a TDMA MAC protocol; the main difference with TTP/C is that a station in FlexRay might possess several slots in the TT window, but the size of all the slots is identical (see Figure 50.4). In the event-triggered part of the communication cycle, the protocol is flexible TDMA (FTDMA): the time is divided into so-called minislots, each station possesses\* a given number of minislots (not necessarily consecutive), and it can start the transmission of a frame inside each of its own minislots. A minislot remains idle if the station has nothing to transmit, which actually induces a loss of bandwidth (see Ref. [10] for a discussion on that topic). An example of a dynamic window is shown in Figure 50.5: on channel B, frames have been transmitted in minislots  $n$  and  $n + 2$ , while minislot  $n + 1$  has not been used. It is noteworthy that frame  $n + 4$  is not received simultaneously on channels A and B since, in the dynamic window, transmissions are independent in both channels.

The FlexRay MAC protocol is more flexible than the TTP/C MAC since in the static window nodes are assigned as many slots as necessary (up to 2047 overall) and since the frames are only transmitted if necessary in the dynamic part of the communication cycle. In a similar way as with TTP/C, the structure of the communication cycle is statically stored in the nodes; however, unlike TTP/C, mode changes with a different communication schedule for each mode are not possible.

**FIGURE 50.4** Example of a FlexRay communication cycle with four nodes: A, B, C, and D.

\* Different nodes can send frames in the same slot but in different cycles; this is called *slot multiplexing*, and it is only possible only in the dynamic segment.

**FIGURE 50.5** Example of message scheduling in the dynamic segment of the FlexRay communication cycle.

The FlexRay frame consists of three parts: the header, the payload segment containing up to 254 bytes of data, and the CRC of 24 bits. The header of 5 bytes includes the identifier of the frame and the length of the data payload. The use of identifiers allows to move a software component, which sends a frame X, from one ECU to another ECU without changing anything in the nodes that consume frame X. It has to be noted that this is no more possible when signals produced by distinct components are packed into the same frame for the purpose of saving bandwidth (i.e., which is referred to as frame packing or protocol data unit [PDU] multiplexing—see Ref. [81] for this problem addressed on CAN).

From the dependability point of view, the FlexRay standard solely specifies a bus guardian (optional), passive and active star coupler (optional), and the clock synchronization algorithms. Other features, such as mode management facilities or a membership service, will have to be implemented in software or hardware layers on top of FlexRay (see, for instance, Ref. [5] for a membership service protocol that could be used along with FlexRay). This will allow to conceive and implement exactly the services that are needed with the drawback that correct and efficient implementations might be more difficult to achieve in a layer above the communication controller.

In the FlexRay specification, it is argued that the protocol provides scalable dependability, that is, the *ability to operate in configurations that provide various degrees of fault tolerance*. Indeed, the protocol allows for mixing links with single- and dual-transmission supports on the same network, subnetworks of nodes without bus guardians or with different fault-tolerance capability with regard to clock synchronization, etc. In the automotive context where critical and noncritical functions coexist and interoperate, this flexibility can prove to be efficient in terms of cost and reuse of existing components. The reader interested in more information about FlexRay can refer to [11,84] and to [25,75,101] for how to configure the communication cycle.

### 50.2.2.2 TTCAN Protocol

TTCAN (see Ref. [37]) is a communication protocol developed by Robert Bosch GmbH on top of the CAN physical and DLLs. TTCAN uses the CAN standard but, in addition, requires that the controllers have the possibility to disable automatic retransmission of frames upon transmission errors and to provide the upper layers with the point in time at which the first bit of a frame was sent or received. The bus topology of the network, the characteristics of the transmission support, the frame format, as well as the maximum data rate—1 Mbits/s—are imposed by the CAN protocol. Channel redundancy is possible (see Ref. [57] for a proposal) but not standardized, and no bus guardian is implemented in the node. The key idea was to propose, as with FlexRay, a flexible TT/event-triggered protocol. As illustrated in Figure 50.6, TTCAN defines a basic cycle (the equivalent of the FlexRay communication cycle) as the concatenation of one or several TT (or *exclusive*) windows and one event-triggered (or *arbitrating*) window. Exclusive windows are devoted to TT transmissions (i.e., periodic messages), while the arbitrating window is ruled by the standard CAN protocol: transmissions are dynamic and bus access is granted

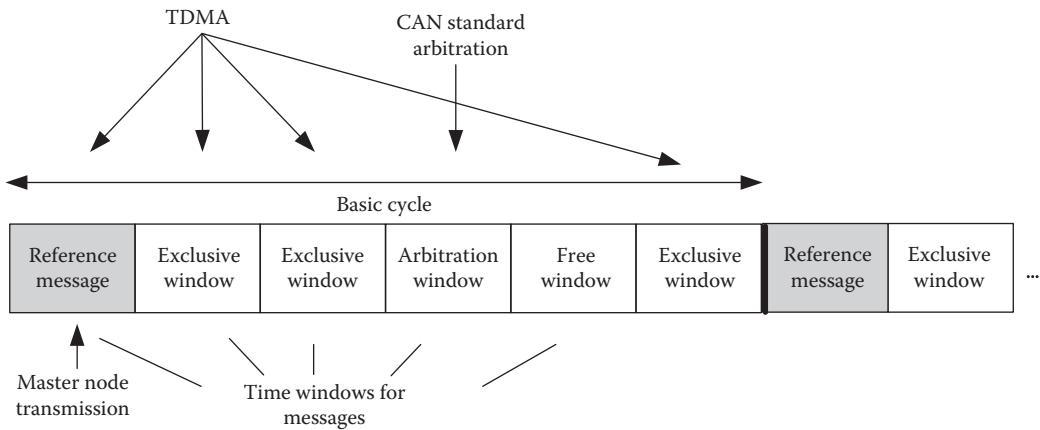

FIGURE 50.6 Example of a TTCAN basic cycle.

according to the priority of the frames. Several basic cycles that differ by their organization in exclusive and arbitrating windows and by the messages sent inside exclusive windows can be defined. The list of successive basic cycles is called the system matrix, which is executed in loops. Interestingly, the protocol enables the master node (i.e., the node that initiates the basic cycle through the transmission of the *reference message*) to stop functioning in TTCAN mode and to resume in standard CAN mode. Later, the master node can switch back to TTCAN mode by sending a reference message.

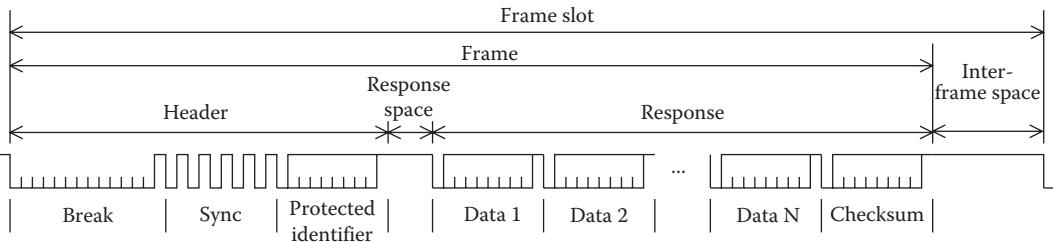

TTCAN is built on a well-mastered and low-cost technology, CAN, but, as defined by the standard, does not provide important dependability services such as the bus guardian, membership service, and reliable acknowledgment (see Ref. [72]). It is, of course, possible to implement some of these mechanisms at the application or middleware (MW) level but with reduced efficiency. About 10 years ago, it was thought that carmakers could be interested in using TTCAN during a transition period until FlexRay technology is fully mature, but this was not really the case, and TTCAN has not been used in production cars to the best of our knowledge.

### 50.2.3 Low-Cost Automotive Networks

Several fieldbus networks have been developed to fulfill the need for low-speed/low-cost communication inside mechatronic-based subsystems generally made of an ECU and its set of sensors and actuators. Two representatives of such networks are LIN and TTP/A. The low-cost objective is achieved not only because of the simplicity of the communication controllers but also because the requirements set on the microcontrollers driving the communication are reduced (i.e., low computational power, small amount of memory, low-cost oscillator). Typical applications involving these networks include controlling doors (e.g., door locks, opening/closing windows) or controlling seats (e.g., seat position motors, occupancy control). Besides cost considerations, a hierarchical communication architecture, including a backbone such as CAN and several subnetworks such as LIN, enables reducing the total traffic load on the backbone.

Both LIN and TTP/A are master/slave networks where a single master node, the only node that has to possess a precise and stable time base, coordinates the communication on the bus: a slave is only allowed to send a message when it is polled. More precisely, the dialogue begins with the transmission by the master of a *command frame* that contains the identifier of the message whose transmission is requested. The command frame is then followed by a *data frame* that contains the requested message sent by one of the slaves or by the master itself (i.e., the message can be produced by the master).

This paragraph also presents the SENT and PSI5 networks, which are other more recent low-cost alternatives to CAN.

**FIGURE 50.7** Format of the LIN frame. A frame is transmitted during its *frame slot*, which corresponds to an entry of the schedule table.

### 50.2.3.1 LIN Network

LIN (see Refs. [48,77]) is a low-cost serial communication system used as SAE class A network, where the needs in terms of communication do not require the implementation of higher-bandwidth multiplexing networks such as CAN. LIN is developed by a set of major companies from the automotive industry (e.g., Daimler, Volkswagen, BMW, and Volvo) and is widely used in production cars.

The LIN specification package (LIN version 2.2A [48]) includes not only the specification of the transmission protocol (physical layer and DLLs) for master-slave communications but also the specification of a diagnostic protocol on top of the DLL. A language for describing the capability of a node (e.g., bit rates that can be used, characteristics of the frames published and subscribed by the node) and for describing the whole network is provided (e.g., nodes on the network, table of the transmissions' schedule). This description language facilitates the automatic generation of the network configuration by software tools.

A LIN cluster consists of one *master* node and several *slave* nodes connected to a common bus. For achieving a low-cost implementation, the physical layer is defined as a single wire with a data rate limited to 20 kbit/s due to EMI limitations. The master node decides when and which frame shall be transmitted according to the schedule table. The schedule table is a key element in LIN; it contains the list of frames that are to be sent and their associated frame slots, thus ensuring determinism in the transmission order. At the moment a frame is scheduled for transmission, the master sends a header (a kind of transmission request or command frame) inviting a slave node to send its data in response. Any node interested can read a data frame transmitted on the bus. As in CAN, each message has to be identified: 64 distinct message identifiers are available. Figure 50.7 depicts the LIN frame format and the time period, termed a *frame slot*, during which a frame is transmitted.

The header of the frame that contains an identifier is broadcast by the master node, and the slave node that possesses this identifier inserts the data in the response field. The *break* symbol is used to signal the beginning of a frame. It contains at least 13 dominant bits (logical value 0) followed by one recessive bit (logical value 1) as a break delimiter. The rest of the frame is made of byte fields delimited by one start bit (value 0) and one stop bit (value 1), thus resulting in a 10-bit stream per byte. The *sync* byte has a fixed value (which corresponds to a bit stream of alternatively 0 and 1); it allows slave nodes to detect the beginning of a new frame and be synchronized at the start of the identifier field. The so-called protected identifier is composed of two subfields: the first 6 bits is used to encode the identifier, and the last 2 bits, the identifier parity. The data field can contain up to 8 bytes of data. A checksum is calculated over the protected identifier and the data field. Parity bits and checksum enable the receiver of a frame to detect bits that have been inverted during transmission.

LIN defines five different frame types: unconditional, event triggered, sporadic, diagnostic, and user defined. Frames of the latter type are assigned a specific identifier value and are intended to be used in an application-specific way that is not described in the specification. The first three types of frames are used to convey signals. Unconditional frames are the usual type of frames used in the master-slave dialogue

and are always sent in their frame slots. Sporadic frames are frames sent by the master, only if at least one signal composing the frame has been updated. Usually, multiple sporadic frames are assigned to the same frame slot, and the higher-priority frame that has an updated signal is transmitted. An event-triggered frame is used by the master willing to obtain a list of several signals from different nodes. A slave will only answer the master if the signals it produces have been updated, thus resulting in bandwidth savings if updates do not take place very often. If more than one slave answers, a collision will occur. The master resolves the collision by requesting all signals in the list one by one. A typical example of the use of the event-triggered transfer given in Ref. [48] is the door knob monitoring in a central locking system. As it is rare that multiple passengers simultaneously press a knob, instead of polling each of the four doors, a single event-triggered frame can be used. Of course, in the rare event when more than one slave responds, a collision will occur. The master will then resolve the collision by sending one by one the individual identifiers of the list during the successive frame slots reserved for polling the list. Finally, diagnostic frames have a fixed size of 8 bytes, fixed value identifiers for both the master's request and the slave answers, and always contain diagnostic or configuration data whose interpretation is defined in the specification.

It is also worth noting that LIN offers services to send nodes into a sleep mode (through a special diagnostic frame termed *go-to-sleep command*) and to wake them up, which is convenient since optimizing energy consumption, especially when the engine is not running, is a real matter of concern in the automotive context.

### 50.2.3.2 TTP/A Network

As TTP/C, TTP/A [27] was initially invented at the Vienna University of Technology. TTP/A pursues the same aims and shares the main design principles as LIN, and it offers, at the communication controller level, some similar functionalities, in particular, in the areas of plug-and-play capabilities and online diagnostic services. TTP/A implements the classic master-slave dialogue, termed *master-slave round*, where the slave answers the master's request with a data frame having a fixed length data payload of 4 bytes. The *multipartner* rounds enable several slaves to send up to an overall amount of 62 bytes of data after a single command frame. A *broadcast round* is a special master-slave round in which the slaves do not send data; it is, for instance, used to implement sleep/wake-up services. The data rate on a single-wire transmission support is, as for LIN, equal to 20 kbit/s, but other transmission supports enabling higher data rates are possible. To our best knowledge, TTP/A is not currently in use in production cars.

### 50.2.3.3 PSI5 and SENT Networks

PSI5 (see <http://www.psi5.org>) is another low-cost bus that was originally developed for communication between ECUs and air-bags but is now considered for use with any kinds of sensors. It provides 125 kbit/s communication and needs only two wires for both data communication and sensor power supply. When used in bus mode with several sensors on the bus, as opposed to the point-to-point mode, the communication is organized in a TT manner according to a TDMA-based MAC protocol, each sensor sending in a predefined time slot.

Another competing technology is SENT, normalized as SAE J2716, which provides one-way communication, but it can be complemented by the SPC protocol (short PWM code, see Ref. [6]), which adds functionalities such as bidirectional communication.

### 50.2.4 Multimedia and Infotainment Networks

Several protocols have been adapted or specifically conceived for transmitting the large amount of data needed by multimedia and infotainment applications increasingly available in cars. Two prominent protocols in this category are MOST and 1394 Automotive (formerly known as IDB-1394) that are discussed in the following. Another technology, not specifically developed for the automotive domain though that is currently broadly used for infotainment and automotive cameras, is low-voltage differential signaling (LVDS), which enables communication at 655 Mbit/s and above [54] over twisted pair copper cables.

In the near future, it is very likely that Ethernet-based networks, probably compliant with the IEEE 802.1 AVB QoS standard (see Section 50.2.5.3), will be used to transport the high data volumes needed by multimedia and infotainment applications [28,89].

#### 50.2.4.1 MOST Network

MOST (see Ref. [59]) is a multimedia network, development of which was initiated in 1998 by the MOST Cooperation (a consortium of carmakers and component suppliers). MOST provides point-to-point audio and video data transfer with different possible data rates. MOST supports end-user applications like radios, GPS navigation, video displays, and entertainment systems. MOST's physical layer has been so far a polymer optical fiber (POF) transmission support, which provides a better resilience to EMI and higher transmission rates than classical cooper wires, but a new coaxial standard has been introduced recently [41]. It was estimated in 2008 [53] that around 50 model series, for example, from BMW and Daimler, implement a MOST network (e.g., MOST25 at 25 Mbit/s at Daimler, see Ref. [46]). MOST has now become a de facto standard for transporting audio and video streams within vehicles (see Refs. [60,61]).

The third revision of MOST [59] has introduced the support of a channel that can transport standard Ethernet frames and is thus well suited to transmit IP traffic. These features, along with the higher bandwidth provided by MOST150 introduced in 2007, are already taken advantage of in some new vehicle projects [46] to provide access to Internet services and web browsing and independent access to audio and video sources from all seats with a single bus. In Ref. [41], the MOST consortium announces its intention to develop a next generation of the protocol, with a target bandwidth of 5 Gbit/s, that would be suited as well for ADAS requiring the transmission of uncompressed video streams, competing thus with automotive Ethernet solutions.

#### 50.2.4.2 1394 Automotive Network

The 1394 Automotive is an automotive version of IEEE 1394 (FireWire) for in-vehicle multimedia and telematics applications that is developed by the 1394 Trade Association (see <http://www.1394ta.org>). The system architecture of 1394 Automotive permits existing IEEE 1394 consumer electronics devices to interoperate with embedded automotive grade devices. The 1394 Automotive is advertised to support a data rate of 800 Mbps [82,90] over several physical layers including twisted pair or POF. Thanks to its large bandwidth and the interoperability with existing IEEE 1394 consumer electronic devices, 1394 Automotive was at some time considered a serious competitor for MOST technology, but despite a few early implementations at Renault and Nissan, as far as we know, the protocol did not reach wide acceptance in the automotive market.

### 50.2.5 Automotive Ethernet

At the time of writing, the question is not if, but when switched Ethernet will become a standard technology in cars [28,94,99]. For instance, Continental expects to start series production of Ethernet-capable control units as soon as 2015 [12]. The introduction of Ethernet will, however, be gradual, and Ethernet is probably going to fulfill different use cases over time. This paragraph discusses these use cases and the main Ethernet technologies that are considered for use.

#### 50.2.5.1 Motivation and Use Cases for Ethernet

The first motivation for Ethernet is that it is a low-cost and mature technology that offers much more bandwidth than what is available today, which is of interest for infotainment and active safety especially [29]. From the user perspective, as well as from an economic point of view, the reuse of nonautomotive-specific networking technologies such as Ethernet can be beneficial. However, automotive-specific requirements must be taken into account: for example, the need for partial networking and power over Ethernet to reduce the wiring, provision of specific QoS, and robustness to severe environmental conditions (e.g., EMI, heat).

In Ref. [29], the authors describe a plausible roadmap for the use of Ethernet. First-generation Ethernet network, based on 100BASE-TX physical layer, will be for diagnostics (using ISO 13400 standard) and code upload (as already done since 2008, see Ref. [39]). The second-generation Ethernet network, from 2015 onward, will support infotainment and camera-based ADAS using Ethernet AVB (see Section 50.2.5.3) and BroadR-Reach physical layer (see Section 50.2.5.2). At the third stage, from 2020 onward, gigabit Ethernet should become the backbone interconnecting most other networks and replacing thus today's gateways (see Section 50.4). This communication architecture will benefit from the ability of Ethernet switches to handle ports having different speeds. The backbone will have to support various kinds of traffic with different QoS requirements and thus require QoS policies that may be offered, according to the authors of Ref. [29], by a second generation of AVB protocols. A new Gb/s physical layer derived from today's 100 Mbit/s BroadR-Reach will be needed, and TT transmissions would be available.

### 50.2.5.2 BroadR-Reach Physical Layer

BroadR-Reach is a 100 Mbit/s physical layer over low-cost unshielded copper wires that is being developed by the OPEN Alliance SIG consortium (see <http://www.opensig.org/>). This consortium, which already counts 140 member companies with many of the carmakers along with Bosch and Continental, aims at establishing BroadR-Reach as the standard for the automotive Ethernet physical layer, with Gb/s speed in its roadmap [32]. For that purpose, BroadR-Reach was designed to meet the automotive requirements in terms of cost, power-saving modes, robustness to environmental conditions, etc. One clear advantage of BroadR-Reach over standard 100BASE-TX Fast Ethernet is that it only requires a single pair of copper cables. At the time of writing, the BroadR-Reach specification is close to being final [99].

### 50.2.5.3 Ethernet AVB

IEEE 802.1 AVB is a set of standards aimed at providing low-latency streaming services on 802.3 Ethernet. The development and adoption of AVB is promoted by the AVnu Alliance consortium (see <http://www.avnu.org/>), which counts several car manufacturers and automotive suppliers among its members.

IEEE 802.1AS is a synchronization protocol that builds on IEEE 1588 Precision Time Protocol to enable sub-microsecond time synchronization between nodes. IEEE 802.1Qav specifies a leaky-bucket credit-based traffic shaper (CBS) on the output ports of the switches. This shaping mechanism is aimed at enforcing some fairness among traffic streams. 802.1Qat is an E2E bandwidth reservation protocol. Finally, 802.1BA specifies default parameters and profiles that manufacturers of AVB equipment can use. AVB defines three classes of traffic: stream reservation (SR) class A with a guaranteed latency of 2 ms maximum, SR class B with a guaranteed 50 ms maximum latency, and best effort for the rest of the traffic. At most, 75% of the bandwidth can be reserved for both SR class A and SR class B streams.

Experiments in Ref. [89] suggest that AVB would be an excellent option for in-car multimedia streams, with the advantage that it enables to dynamically register data flows and can be used with higher-level protocols for handling audio/video streams such as IEEE 1733. To the best of our knowledge, there is no clear cut answer yet about the suitability of the current AVB standard for the transmission of critical control data. In October 2012, AVnu Alliance has announced the formation of the AVB Gen2 Council with the aims to improve AVB functionality in areas such as time-sensitive transmission and fault tolerance. This new specification is currently in development within the IEEE (AVB Task Group).

### 50.2.5.4 TTEthernet

TTEthernet [92] is a TT switched Ethernet protocol, promoted by the TTA Group (see <http://www.ttagroup.org/>), that was standardized as SAE AS6802 in 2011. TTEthernet natively supports mixed-criticality temporal requirements as it defines three types of traffic streams: TT (with off-line configured transmission schedule), rate constrained (i.e., the maximum workload is bounded), and best effort. Upper bounds on the jitters and latencies can be derived for both the TT and rate-constrained traffic.

The temporal QoS in terms of jitters is better for the TT traffic, but sending and receiving must be done at predefined points in time. Conceptually, the rate-constrained traffic model is similar to virtual links in AFDX and SR classes A and B in AVB.

TTEthernet is designed to be operational in cross-domain critical applications, up to highest criticality level such as DO178 DAL-A in aeronautics, and thus possesses a wide range of fault-tolerant mechanisms. Besides, the TT traffic offers a temporal QoS that cannot be matched by the current version of AVB. These features could be needed for some future automotive applications. Another idea currently investigated [89,99] is the integration of AVB and TTEthernet, which aims to come up with an efficient solution for all common automotive Ethernet use cases.

## 50.3 Automotive Middleware

---

### 50.3.1 Objectives of an Embedded Middleware

The design of automotive electronic systems has to take into account several constraints. First, nowadays, the performance, quality, and safety of a vehicle depend on functions that are mainly implemented in software (e.g., the engine control, body electronics, ADAS) and moreover depend on a tight cooperation between these functions. For example, the control of the engine is done according to requests from the driver (speeding up, slowing down as transmitted by the throttle position sensor or the brake pedal) and requirements from other embedded functions such as climate control, ESP, or brake assist. Second, in-vehicle embedded systems are produced through a complex cooperative multipartner development process shared between OEMs and suppliers. Therefore, in order to increase the efficiency of the production of components and their integration, two important problems have to be solved: (1) the portability of components from one ECU to another one enabling some flexibility in the architecture design and (2) the reuse of components between platforms, which is a key point for car manufacturers. Thus, the cooperative development process raises the problem of interoperability of components. A classic approach for easing the integration of software components is to implement an *MW layer* that provides application programs with common services and a common interface. In particular, the common interface allows the design of an application disregarding the hardware platform and the distribution and therefore enables the designer focusing on the development and the validation of the software components and the software architecture that realize a function.

Among the set of common services usually provided by an MW, those that relate to the communication between several application components are crucial. They have to meet several objectives:

- *Hide the distribution* through the availability of services and interfaces that are the same for intra-ECU, inter-ECU, interdomain communications whatever the underlying protocols.
- *Hide the heterogeneity* of the platform by providing an interface independent of the underlying protocols, of the CPU architecture (e.g., 8/16/32 bits, endianness), of the operating systems (OSs), etc.
- *Provide high-level services* in order to shorten the development time and increase quality through the reuse of validated services (e.g., periodic transmission, working mode management such as partial networking). A good example of such a function is the *frame packing* (sometimes also called *signal multiplexing*) that enables application components to exchange *signals* (e.g., the number of revolutions per minute, the speed of the vehicle, the state of a light) while, at run-time, *frames* are transmitted over the network, so the *frame-packing* service of an MW consists in packing the signals into frames and sending the frames at the right points in time for ensuring the deadline constraint on each signal it contains.
- *Ensure QoS properties required by the application*, in particular, it can be necessary to improve the QoS provided by the lower-level protocols, for example, by furnishing an additional CRC (cyclic redundancy code) if the data link layer CRC is not sufficient in regard to the dependency objectives (see for instance in Section 50.3.3 the end-to-end communication protection

library of AUTOSAR that protects from message alteration in the communication stacks too). Other examples are the correction of *bugs* in lower-level protocols such as the *inconsistent message duplicate* of CAN (see Ref. [73]), the provision of a reliable acknowledgment service or message authentication mechanism on CAN, the status information on the data consumed by the application components (e.g., data were refreshed since last reading, its freshness constraint was not respected), or filtering mechanisms (e.g., notify the application for each  $k$  reception or when the data value has changed in a significant way).

Note that a more advanced features would be to come up with adaptive communication services, thanks to algorithms that would modify at run-time the parameters of the communication protocols (e.g., priorities, transmission frequencies) according to the current requirements of the application (e.g., inner-city driving or highway driving) or changing environmental conditions (e.g., EMI level). For the time being, to the best of our knowledge, such features exist in series automotive embedded systems only for low-power modes (see Section 50.1.5 and see also Ref. [102] for a research work in the direction of more adaptive communication systems). By increasing the efficiency and the robustness of the application, such an adaptive strategy would certainly ease the reusability.

### 50.3.2 Former Propositions of Middleware

Some proprietary MWs were developed by several carmakers in order to support the integration of ECUs and software modules provided by their third-party suppliers. For instance, the TITUS/DBKOM communication stack was a proprietary MW of Daimler that standardizes the cooperation between components according to a client/server model. *Volcano* [9,78] is a commercial product of Mentor Graphics, initially developed in tight cooperation with Volvo. The Volcano Target Package (VTP) consists of a communication layer and a set of off-line configuration tools for application distributed on CAN and LIN. It is aimed at providing the mapping of signals into frames under network bandwidth optimization and ensures a predictable and deterministic real-time communication system, thanks to schedulability analysis techniques (see Refs. [9,91]). To the best of our knowledge, there are no publicly available technically precise descriptions of both TITUS and Volcano.

A first step to define a standard for in-car embedded MW was started by the OSEK/VDX consortium (<http://www.osek-vdx.org>). In particular, two specifications are of particular interest in the context of this chapter: the *OSEK/VDX communication layer* [68] and the *fault-tolerant communication layer* [66]. The first one specifies a communication layer [68] that defines common software interfaces and common behavior for internal and external communications between application components. How signals are packed into a frame is statically defined off-line, and the *OSEK/VDX communication layer* automatically realizes the packing/unpacking at run-time as well as the handling of queued or unqueued messages at the receiver side. *OSEK/VDX communication* runs on top of a transport layer (e.g., [36]) that takes care mainly of possible segmentation of frames, and it can operate on any OS compliant with *OSEK/VDX OS* services for tasks and events and interrupt management (see Ref. [69]).

*OSEK/VDX communication* is not intended to be used on top of a TT network, for example, TTP/C or FlexRay. For this purpose, there is *OSEK/VDX FT Communication* specification (fault-tolerant communication, see Ref. [66]) whose main role is to manage the redundancy of data needed to achieve fault tolerance (i.e., the same information can be produced by a set of replicated nodes) by presenting only one copy of data to the receiving application according to the strategy specified by the designer. Two other important services of *OSEK/VDX FT Communication*, already offered by *OSEK/VDX Communication*, are to manage the packing/unpacking of messages [81] and to provide message-filtering mechanisms for passing only *significant* data to the application. *OSEK/VDX FT Communication* was developed to run on top of a TT OS such as OSEK time [67]. *OSEK/VDX* is no more under active development and has been superseded by AUTOSAR.

### 50.3.3 AUTOSAR—A Standard for the Automotive Industry

From 2001 to 2004, the ITEA European project EAST-EEA aimed at the specification of an automotive MW for the automotive industry. To the best of our knowledge, this was the first important initiative targeting the specification of both the services to be ensured by the MW and the architecture of the MW itself in terms of components and architecture of components. Similar objectives are guiding the work done in the AUTOSAR consortium (see <http://www.autosar.org> and [17,21,40]) that gathers most the key players in the automotive industry. The specifications produced by the consortium became quickly de facto standards for the cooperative development of in-vehicle embedded systems (see, for instance, the migration to AUTOSAR at PSA Peugeot Citroen [16]).

#### 50.3.3.1 Reference Model

AUTOSAR specifies the software architecture embedded in an ECU. More precisely, it provides a reference model, which is comprised of three main parts:

1. The application layer
2. The basic software (MW software components)
3. The run-time environment (RTE) that provides standardized software interfaces to the application software

One of AUTOSAR's main objectives is to improve the quality and the reliability of embedded systems. By using a well-suited abstraction, the reference model supports the separation between software and hardware, eases the mastering of the complexity, and allows the portability of application software components and therefore the flexibility for product modification, upgrade and update, as well as the scalability of solutions within and across product lines. Besides, AUTOSAR ensures a smooth integration process of components provided by different companies while protecting the industrial properties of each actor involved. The AUTOSAR reference architecture is schematically illustrated in Figure 50.8. An important issue is the automatic generation of an AUTOSAR MW that has to be

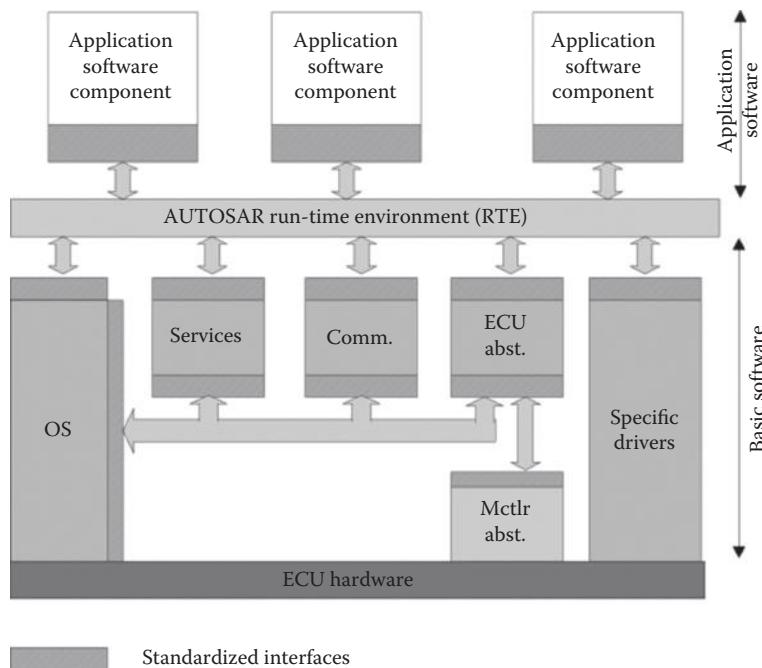

FIGURE 50.8 AUTOSAR reference architecture.

done from the basic software components, generally provided by suppliers, and the specification of the application itself (description of applicative-level tasks, signals sent or received, events, alarms, etc.). The challenge is to realize such a generation so that the deployment of the MW layer can be optimized for each ECU.

### 50.3.3.2 Communication Services

One of the main objectives of the AUTOSAR MW is to hide the characteristic of the hardware platform as well as the distribution of the application software components. Thus, the inter- or intra-ECU communication services are of major importance and are thoroughly described in the documents provided by the AUTOSAR consortium (see Figure 50.9 for an overview of the different modules). The role of these services is crucial for the behavioral and temporal properties of an embedded and distributed application. So their design, generation, and configuration have to be precisely mastered, and the verification of timing properties becomes an important activity. The problem is complex because, as for the formerly mentioned MW, the objects (e.g., signals, frames, interaction-layer PDU [I-PDU]) that are handled by services at one level are not the same objects that are handled by services at another level. Nevertheless, each object is strongly dependent on one or several objects handled by services belonging to neighboring levels. The AUTOSAR standard proposes two communication models:

1. *Sender-receiver* used for passing information between two application software components (belonging to the same task, to two distinct tasks on the same ECU or to two remote tasks)
2. *Client-server* that supports function invocation

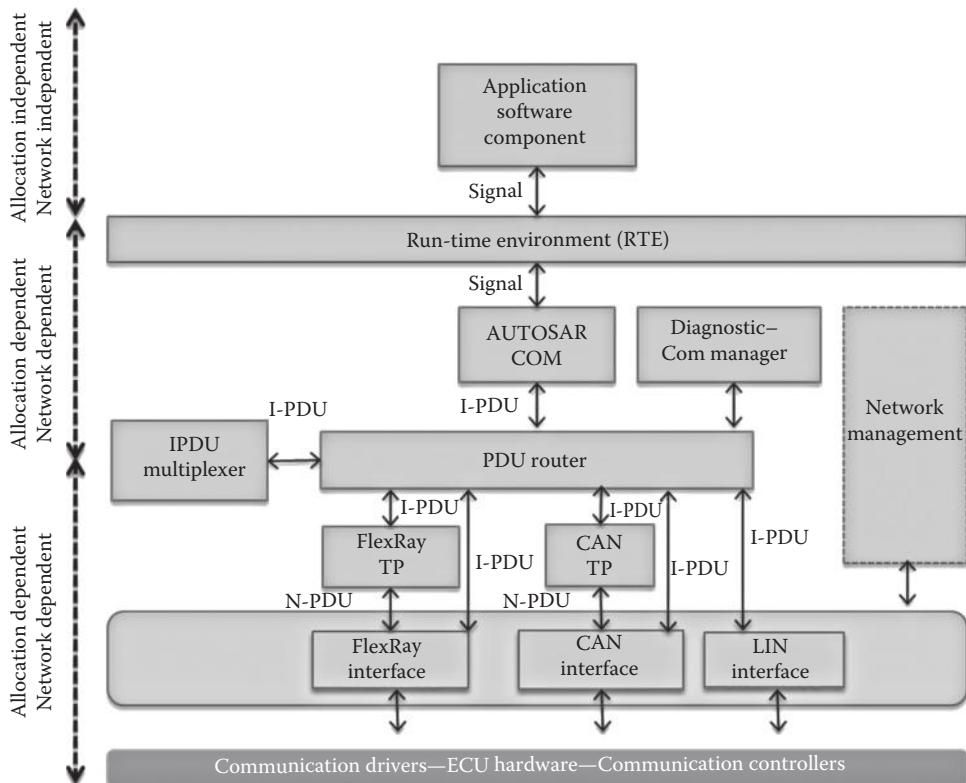

FIGURE 50.9 Communication software components and architecture.

Two communication modes are supported for the *sender-receiver* communication model:

1. The *explicit* mode is specified by a component that makes explicit calls to the AUTOSAR MW for sending or receiving data.
2. The *implicit* mode means that the reading (resp. writing) of data is automatically done by the MW before the invocation (resp. after the end of execution) of a component consuming (resp. producing) the data without any explicit call to AUTOSAR services; this is a way to protect effectively the data between application software components and MW services.

AUTOSAR identifies three main objects regarding the communication: signal exchanged between software components at application level, I-PDU that consists of a group of one or several signals, and the N-PDU (DLL PDU) that will actually be transmitted on the network. Precisely AUTOSAR defines the following:

- *Signals* at application level that are specified by a length and a type. Conceptually, a signal is exchanged between application software components through ports disregarding the distribution of this component. The application needs to indicate a *transfer property* parameter that will impact the behavior of the transmission and whose value can be *triggered* (each time the signal is provided to the MW by the application, it has to be transmitted on the network) or *pending* (the actual transmission of a signal on the network depends only on the emission rule of the frame that contains the signal). Furthermore, when specifying a signal, the designer has to indicate if it is a *data*, an *event*, or a *mode*. For *data* transmission, incoming data are not queued on the receiver side, while for *event* exchanges, signals are queued on the receiver side, and therefore, for each transmission of the signal, a new value will be made available to the application. The handling of buffers or queues is done by the RTE.
- I-PDUs are built by the AUTOSAR COM component. Each I-PDU is made of one or several signals and is passed via the PDU router to the communication interfaces. The maximum length of an I-PDU depends on the maximum length of the L-PDU (i.e., DLL PDU) of the underlying communication interface: for CAN and LIN, the maximum L-PDU length is 8 bytes, while for FlexRay, the maximum L-PDU length is 254 bytes. AUTOSAR COM ensures a local transmission when both components are located on the same ECU, or by building suited objects and triggering the appropriate services of the lower layers when the components are remote. This scheme enables the portability of components and hides their distribution. The transformation from signals to I-PDU and from I-PDU to signals is done according to an off-line generated configuration. Each I-PDU is characterized by a behavioral parameter, termed *Transmission Mode* whose possible value is *direct* (the sending of the I-PDU is done as soon as a *triggered* signal contained in this I-PDU is sent at application layer), *periodic* (the sending of the I-PDU is done only periodically), *mixed* (the rules imposed by the *triggered* signals contained in the I-PDU are taken into account, and additionally the I-PDU is sent periodically if it contains at least one *pending* signal), or *none* (for I-PDUs whose emission rules depend on the underlying network protocol, e.g., FlexRay; no transmission is initiated by AUTOSAR COM in this mode).
- An N-PDU is built by the basic components CAN transport protocol (TP) or FlexRay TP. It consists of the data payload of the frame that will be transmitted on the network and protocol control information. Note that the use of a transport layer is not mandatory and I-PDUs can be transmitted directly to the lower layers (see Figure 50.9).

The RTE implements the AUTOSAR MW interface and the corresponding services. In particular, when using the *sender/receiver* model, the RTE handles the *implicit/explicit* communication modes and the fact that the communication involves *events* (queued) or *data* (unqueued). The AUTOSAR COM component is responsible for several functions: on the sender side, it ensures the transmission and notifies the application about its outcome (success or error). In particular, AUTOSAR COM can inform the application if the transmission of an I-PDU did not take place before a specified deadline (i.e., deadline monitoring). On the receiver side, it also notifies the application (success or error of a reception) and supports

the filtering mechanism for signals (dispatching each signal of a received I-PDU to the application or to a gateway). Both at the sending and receiving end, the endianness conversion is taken in charge. An important role of the COM component is to pack/unpack *signals* into/from *I-PDUs*. Note that, as the maximal length of an I-PDU depends on the underlying networks, the design of a COM component has to take into account the networks, and therefore, it is not fully independent of the hardware architecture. The COM component has also to determine the points in time where to send the I-PDUs. This is based on the attributes *transmission mode* of an I-PDU and on the attribute *transfer property* of each signal that it contains.

The COM component is generated off-line on the basis of the knowledge of the signals, the I-PDUs, and the allocation of application software components on the ECUs. The *AUTOSAR PDU router* (see Figure 50.9), according to the configuration, dispatches each I-PDU to the right network communication stack. This basic component is statically generated off-line as soon as the allocation of software components and the operational architecture is known. Other basic software components of the communication stack are responsible for the segmenting/reassembling of I-PDU(s) when needed (FlexRay TP, CAN TP) or for providing an interface to the communication drivers (FlexRay interface, CAN interface, LIN interface).

### 50.3.3.3 End-to-End Communication Protection Library

In order to support safer communications between application software components, the AUTOSAR standard specifies the *E2E communication protection library* [2]. The specified E2E mechanisms aim to ensure that safety-critical data exchanges (up to ASIL D safety level) can be protected against faults that may occur at run-time during the transmission of the data: faults affecting the hardware (e.g., bit flipping due to EMI in the sending communication stack) or software faults due to the incorrect development of a component of the communication stack. In particular, the E2E protection mechanisms allow the following:

- To attach, on the sender side, specific control data to data that are to be sent to the RTE.
- To verify, on the receiver side, through the control data, the correction of the data received from the RTE.
- To report, when it occurs, that received data are faulty. In this case, the fault has to be handled by the receiver software components.

The E2E library is implemented as a set of functions that can be invoked at two levels: by application software components (thanks to a wrapping technique) or from the COM component. These functions are stateless and have to report synchronously a verdict (i.e., the success of the exchange or the detected errors) to their calling component. The E2E communication protection is based on a standardization of mechanisms under the concept of *E2E profile*. Each profile can have several variants. So the instantiation of one profile for a specific information exchange consists in the choice of a variant and therefore the setting of the corresponding configuration options. Each profile offers all or a subset of the following data protection mechanisms:

- Checking the integrity of an exchanged data. This is done by an additional CRC computed by a function belonging to the E2E library.
- Checking the systematic transmission of a data, thanks to a *sequence counter*. The *sequence counter* is incremented upon each transmission of the data, allowing thus the receiver to verify that no instance of the data has been lost.
- Checking, from the receiver side, if a sender is transmitting a data as expected. For this purpose, an *alive counter* is used, it is incremented upon each transmission of the data, and the receiver can verify that the counter has been incremented.
- To check if the received data are the one that are expected. This mechanism is based on the definition of a data ID that is not transmitted with the data but that is used in the computation of the CRC.
- Finally, to verify that the data are sent and/or received on time. Two mechanisms are provided for this purpose: receiver communication time-out and sender acknowledgment time-out.

The CRC and the counters are integrated into an E2E header, which is an additional control field transmitted along with the data payload. When a faulty transmission is detected, the error is then reported to the calling component.

## 50.4 Conclusions and Discussion

---

In our view, the development of in-vehicle embedded communications can be schematically subdivided into four main successive periods:

1. Communication through point-to-point links—until the beginning of the 1990s
2. CAN-based architectures as de facto standard—until 2006
3. The advent of AUTOSAR and FlexRay—until 2010
4. The emergence of automotive Ethernet and security concerns since then

One may imagine that the next stage will be when the *car will become an IP node in the World Wide Web* ([28], see also Ref. [31]), integrated into global data infrastructures enabling a more efficient type of *collaborative mobility* [76] relying on interactions between users and infrastructure operators.

Over the years, the technologies needed for the interoperability between applications located on different ECUs and subnetworks have been improved. With AUTOSAR, we are now close to the desirable characteristics listed in Section 50.3. However, if the traditional partitioning of automotive applications into several distinct functional domains with their own characteristics and requirements has proven useful in mastering the complexity, it leads to the development of several independent subsystems with their specific architectures, networks, and software technologies. Some difficulties arise from this partitioning since more and more cross-domain data exchanges are needed. The current practice is to transfer data between different domains through a central gateway (see, e.g., Ref. [39]). This subsystem is recognized as being critical in the vehicle: it constitutes a single point of failure, its design is overly complex, and ensuring a guaranteed QoS through gateways is difficult and requires a careful design (see, for instance, Refs. [15,88]). In the future, the interconnection between vehicle subdomains could be more efficiently ensured by an Ethernet backbone [29], instead of a gateway. This backbone will have to support various traffic with different QoS requirements on the same network, which will require to implement QoS policies such as bandwidth reservation.

A perhaps more difficult challenge ahead of us is security: automotive systems must be designed to be more resilient to security attacks. This entails finding the technical solutions but also the new cooperation schemes between all the automotive stakeholders that will permit to achieve the right trade-off for the automotive domain, between costs/overhead and security level.

These issues will certainly require more research and development work, but the current state of technological maturity in security, network hardware components, communication protocols, and MW engineering is such that in our view, everything is at hand to succeed in building safe, secure, and cost-optimized embedded communication architectures for the next car generations.

### 51.1 Introduction

---

In the last decade, the percentage of electronic components in today's cars has been ever increasing. Premium cars, for example, use up to 70 electronic control units (ECUs) that are connected via five system networks and realize over 800 different functions [1].

Since 1993, major automotive companies have been striving for the deployment of standard software modules in their applications as the potential benefits of using standard software modules are huge [2]. While the functional software heavily depends on the actual system and is a discriminating factor of competitive importance, this does not apply to the software infrastructure. Furthermore, with continuously shortened development cycles, especially in the electronics area, requirements arise concerning compatibility, reusability, and increased test coverage that can only be fulfilled by setting standards for the various system levels.

This trend has been a key motivation for the formation of several consortia like the OSEK/VDX (Offene Systeme und deren Schnittstellen für die Elektronik im Kraftfahrzeug—Vehicle Distributed Executive)\* consortium [3] in 1993/1994, the ASAM (Association for Standardization of Automation and Measuring Systems) initiative [4], the HIS (Herstellerinitiative Software)<sup>†</sup> group [5], the JasPar (Japan Automotive Software Platform Architecture) consortium [6] in 2004, the EASIS (Electronic Architecture and System Engineering for Integrated Safety Systems) project consortium [7] in 2003, the AUTOSAR (Automotive Open System Architecture) consortium [8] in 2003, and the GENIVI Alliance [9] in 2009.

\* Translated into English: *Open Systems and the Corresponding Interfaces for Automotive Electronics*

<sup>†</sup> Translated into English: *Manufacturers' Software Initiative*

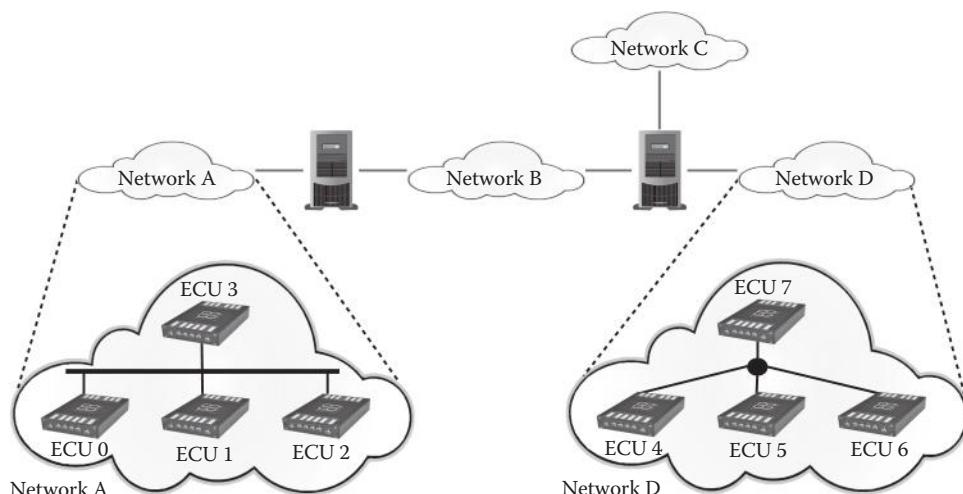

This chapter provides an overview of today's state of the art in the standardization of automotive software infrastructures. The chapter is structured as follows: Section 51.2 provides a short overview of the automotive hardware architecture. Section 51.3 provides information on the software modules specified by the German working groups OSEK/VDX. Section 51.4 illustrates the software modules standardized by the ISO. Section 51.5 targets the software modules defined by the ASAM. Section 51.6 deals with the AUTOSAR initiative. Section 51.7 provides a short summary, concluding the chapter.

## 51.2 Hardware Architecture

The hardware architecture of automotive systems can be viewed at different levels of abstraction. On the highest level of abstraction, the *system level*, an automotive system consists of a number of networks interconnected via gateways (see Figure 51.1). In general, these networks correspond to the different functional domains that can be found in today's cars (i.e., chassis domain, power train domain, body domain).

The networks themselves comprise a number of ECUs that are interconnected via a communication media (see zoom-in on network A and D in Figure 51.1). The physical topology used for the interconnection is basically arbitrary; however, bus, star, and ring topologies are the most common topologies in today's cars. This *network level* represents the medium level of abstraction.

On the lowest level of abstraction, the *ECU level* (Figure 51.2), the major parts of an ECU are of interest. An ECU comprises one or more microcontroller units (MCUs) as well as one or more communication controllers (CCs). In the past, in most cases, exactly one (single-core) MCU and one CC were used to build up an ECU. Today, however, there is a trend toward multicore MCUs and even ECUs consisting of multiple MCUs for performance and fault-tolerance reasons. In order to be able to control physical processes in the car (e.g., control the injection pump of an engine), the ECU's MCU is connected to actuators via the MCU's analog or digital output ports. To provide means to obtain environmental information, sensors are connected to the MCU's analog or digital input ports. We call this interface the ECU's environmental interface. The CC(s) facilitates the physical connectivity of the ECU to the respective network(s). We call this interface of an ECU the ECU's network interface.

**FIGURE 51.1** Hardware architecture—system and network level.

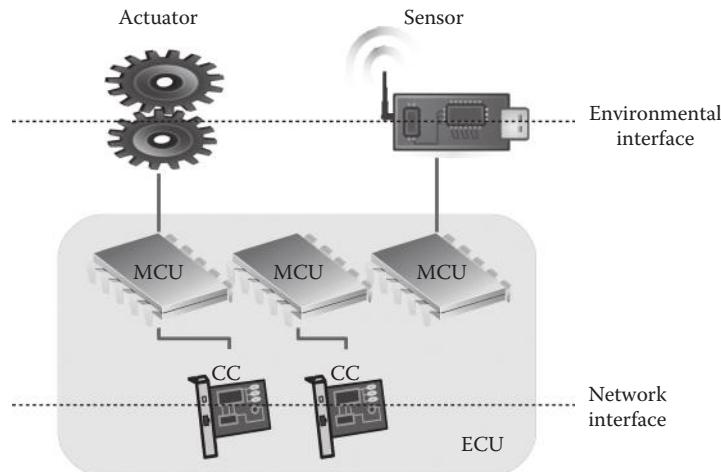

FIGURE 51.2 Hardware architecture—ECU level.

### 51.3 OSEK/VDX

The OSEK/VDX standard was the result of the endeavors of major German and French car manufacturers and their suppliers to create a standardized software infrastructure for automotive electronics. This standard was initially designed for applications in the area of automotive body electronics or for the power train where autonomous control units build up a loosely coupled network. It comprises the following standardized components:

**OSEK OS:** The OSEK operating system (OS) [10] is an event-driven OS intended for hard real-time applications. OSEK OS provides services for task management, task activation by means of events and alarms, intertask communication via messages, mutual exclusion by means of resources (implementing the *priority ceiling protocol* [11]), and interrupt handling. Hereby, OSEK OS distinguishes between *basic tasks* (which do not use any blocking interprocess communication [IPC] or synchronization constructs) and *extended tasks* (which are allowed to use blocking IPC or synchronization constructs).

**OSEK NM:** OSEK network management (NM) [12] provides network management facilities that take care of a *controlled coordinated shutdown of the communication* of multiple ECUs within a network. OSEK NM establishes a *logical ring* among all ECUs participating in OSEK NM. Along this ring, OSEK NM *ring messages* are passed between the participating ECUs. These ring messages contain information on whether the sending ECUs desire to perform a transition into a low-power sleep mode. In case all ECUs along the logical ring agree on this transition (i.e., no ECU objects), a coordinated transition into the sleep mode is performed. In case any ECU objects to this decision because it still requires network communication, a transition into the sleep mode is prevented.

**OSEK COM:** OSEK communication (CoM) [13] offers services to transfer data between different tasks and/or interrupt service routines (ISRs) residing on the same ECU (internal communication) or possibly being distributed over several ECUs (external communication). OSEK COM supports both *cyclic time-driven communication* and *on-demand event-driven communication*. In case of external communication, the *interaction sublayer* of OSEK COM takes care of the representational issues of signals like byte ordering and alignment. On the sender's side, this layer converts signals from the byte order of the sending ECU into the network byte order. Furthermore, the interaction layer packs multiple signals into a single communication frame in order to reduce

communication bandwidth consumption. On the receiver's side, this layer extracts multiple signals from a single communication frame and performs a byte order conversion from the network byte order to the byte order of the receiving ECU.

To support the detection of lost communication frames at the sender and the receiver side, OSEK COM provides mechanisms for transmission and reception time-out monitoring.

**OSEKtime OS:** OSEKtime OS [14] is a time-driven OS designed for minimal OS footprint and deployment in safety-related applications. Tasks are activated by a dispatcher based on predefined activation times stored in a *dispatcher table* before compile time. The processing of the dispatcher table during runtime is done in a cyclical fashion.

**OSEKtime FTCom:** OSEKtime FTCom [15] is the fault-tolerant communication layer accompanying OSEKtime OS that only supports *cyclic time-driven communication*. Similar to OSEK COM, OSEKtime FTCom can be used for both external and internal communication.

In case of external communication, the *fault-tolerance sublayer* of OSEKtime FTCom manages all fault-tolerance issues, namely, signal replication and signal reduction. On the sender's side, this layer replicates a single application signal and thus produces multiple signal instances. These signal instances are handed over to the interaction sublayer for byte order conversion and packing. Afterward, the packed signal instances are transmitted via redundant communication paths. Considering redundant transmission paths, temporal redundancy (multiple transmissions on a single communication channel) and spatial redundancy (transmission on multiple communication channels) can be distinguished. On the receiver's side, multiple signal instances are collected from the interaction sublayer and reduced to obtain a single application signal that is handed on to the application layer.

In order to minimize the memory footprint as well as the required execution time, each of these components is configured upon design time via a configuration file in OSEK implementation language (OIL) syntax [16]. Using a generation tool, the appropriate data structures in the used programming language are created based on this configuration file. Thus, none of the components provides services for dynamic resource allocation (like task creation, memory allocation, a.s.o.).

## 51.4 ISO

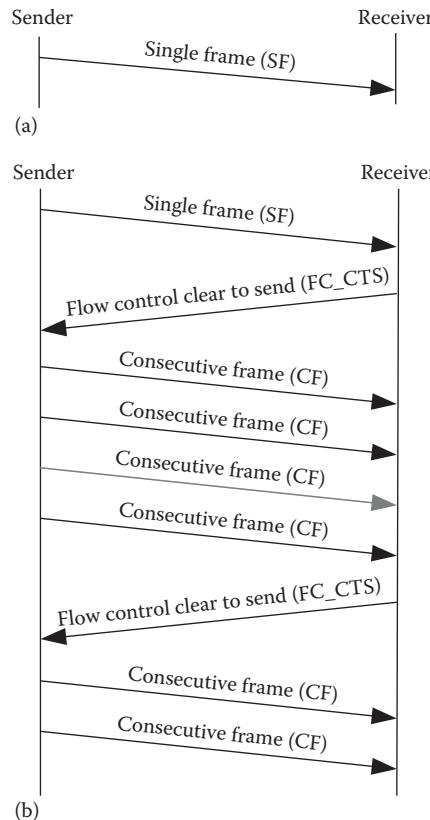

Some of the software layers used for automotive networks in today's cars have been standardized by the International Organization for Standardization (ISO). The most prominent of these software layers are the following:

**Transport Layer—Controller Area Network (CAN) and FlexRay:** This layer provides *segmented data transfer (SDT)* to all higher layers (e.g., the diagnostics layer) and thus facilitates exchange of data amounts larger than the maximum transfer unit (MTU) of the underlying communication system.

**Diagnostics Layer—Unified Diagnostic Services (UDS) and Onboard Diagnostics (OBD):** The UDS specifications define manufacturer-specific enhanced diagnostic services that *allow an external tester device to control diagnostic functions* in an ECU via a (serial) data link. The OBD specifications define a set of mandatory diagnostic services facilitating the *retrieval of emission-related diagnostic information* from an ECU by an *external tester device*.

### 51.4.1 Transport Layer: CAN and FlexRay

The ISO transport layer on CAN [17] provides services for *unacknowledged segmented data transfer (USDT) of known length* to higher software layers (e.g., the ISO diagnostics [see Section 51.4.2]) by facilitating the transmission of messages whose length is greater than the MTU of the underlying communication system. On the sender's side, the transport layer will split such long messages into multiple segments,

**FIGURE 51.3** ISO transport layer on CAN—transmission sequence for unsegmented transmission (a) and segmented transmission (b).

each small enough for the underlying communication system. On the receiver's side, the transport layer reassembles these segments again. As far as the frame format is concerned, the ISO transport layer distinguishes between single frames (SFs), first frames (FFs), consecutive frames (CFs), and flow control frames (FCs), for example, the clear-to-send FC (FC\_CTS) depicted in Figure 51.3b. Hereby, SFs are used for the reduction of protocol overhead in case the amount of data to be transmitted does not exceed the MTU. In that case, only an SF is used in order to exchange these data. Otherwise, an FF, which contains the total number of data bytes to be sent as well as the first few data bytes, is transmitted followed by one or more CFs, which then contain the remaining data bytes. For flow control reasons (i.e., to prevent the sender from outpacing the receiver), the receiver is allowed to send FCs at defined points in time. Figure 51.3 illustrates the frame exchange in an unsegmented (Figure 51.3a) and a segmented transmission (Figure 51.3b).

Hereby, the frame format depicted in Figure 51.4 is used by the ISO transport layer on CAN. The *source* and *destination address* fields are used to identify the sender and the receiver(s) of the TP frame. The *address type* field is used to define the semantics of the destination address. Here, the ISO transport protocol (TP) on CAN provides support for single ECU addresses (called *physical addresses* by the ISO TP on CAN specification) and multicast addresses (called *functional addresses* by the ISO TP on CAN specification). In case of multicast transmissions, only unsegmented data transfer is allowed in the ISO TP on CAN.

Src Addr	Dst Addr	Addr Type	PCI		Data
----------	----------	-----------	-----	--	------

**FIGURE 51.4** ISO transport layer on CAN—frame format.

The *protocol control information (PCI)* field is used to distinguish between the different frame types (i.e., SF, FF, CF, FC). Furthermore, the PCI field carries the *total number of data bytes* to be transmitted in case of an SF or an FF, a *sequence number* in case of a CF (in order to facilitate early detection of a loss of a CF), and more detailed information regarding the *type of flow control* in case of an FC.

In addition to the service of the ISO transport layer on CAN, the ISO transport layer on FlexRay [18] provides an *acknowledge and retry mechanism* facilitating a positive and a negative acknowledgment by the receiver to indicate successful reception or the request for (early) retransmission to the sender. To this end, a new FC for explicit acknowledgment (FC\_ACK) is introduced. Furthermore, the ISO transport layer on FlexRay supports the *transmission of messages with unknown but finite data length* by adding a dedicated last frame (LF) that marks the end of the transmission. By combining these two features, the ISO transport layer on FlexRay facilitates *acknowledged SDT of unknown length*.

### 51.4.2 Diagnostics: UDS and OBD

The unified diagnostic services (UDS) [19] define client/server diagnostic services that allow a tester device (client) to control diagnostic functions in an ECU (server) via a (serial) data link. Hereby, the provided services, the encoding of the SIDs, and the encoding of the parameters are standardized by the UDS specification. The services provided by the UDS can be grouped into the following six functional units:

*Diagnostic Management:* This functional unit covers all services realizing diagnostic management functions between the client and the server. Examples for these kinds of services are the services `startDiagnosticSession` for initiating a diagnostic session, `stopDiagnosticSession` for terminating a diagnostic session, `ecuReset` for resetting an ECU, and `readECUIdentification` for reading ECU identification information like the serial number or the programming date of the ECU.

*Data Transmission:* This functional unit covers all services dealing with data exchange between the client and the server. Prominent examples for these services are the services `readMemoryByAddress` and `writeMemoryByAddress`, which are used to read and write a memory range (defined by start address and the number of bytes to read/write) of the ECU, as well as `readDataByIdentifier` and `writeDataByIdentifier`, which read and write a data item that is uniquely identified via an ID.

*Stored Data Transmission:* This functional unit covers all services that are used to perform exchange of data that are stored within the ECU (in a nonvolatile [NV] way). Examples for these kinds of services are the service `readDiagnosticTroubleCodes`, which is used to retrieve stored trouble codes from the ECU's error log, as well as the service `clearDiagnosticInformation`, which is used to remove all entries from the ECU's error log.

*Input/Output Control:* This functional unit covers all services that deal with input and output control functions. An example for a service contained in this group is the service `inputOutputControlByLocalIdentifier`, which can be used by the client to substitute a value for an input signal of the server.

*Remote Activation of Routine:* This functional unit covers all services that provide remote activation of routines within an ECU. Examples for services in this functional unit are the services `startRoutineByAddress` and `stopRoutineByAddress`, which are used to remotely invoke a routine in the server (ECU) and to terminate an executing routine in the server (ECU). Hereby, the routine to invoke or stop is identified by the routine's address.

*Upload/Download:* This functional unit covers all services that realize upload/download functionality between the client and the server. Examples for services within this unit are the `requestDownload` service, which gives the client the possibility to request the negotiation of a data transfer from client to server; the `requestUpload` service, which gives the client the possibility to request the negotiation of a data transfer from server to client; and the `transferData` service, which actually takes care of the data transmission between client and server.

In UDS, services are identified by the so-called *service identifier (SID)* field that is the first byte in a diagnostic message.\* Based on this field, the layout of the remainder of the diagnostic message is completely different. The diagnostic server uses the SID to select the proper service requested by the client and interprets the remainder of the diagnostic message as parameters to the service request according to the SID.

The on board diagnostics (OBD) specifies a set of mandatory diagnostic services focusing on the *retrieval of emission-related information* from an ECU by an *external tester device*. For this purpose, the OBD defines services for the *retrieval of emission-related diagnostic trouble codes (DTCs)*, the *clearing/resetting of emission-related DTCs*, the *controlling of OBD monitoring functionality* like the invocation of defined tests (e.g., a test for leakage in the evaporative system of the vehicle), the *request of results of conducted OBD monitoring tests*, and the *retrieval of vehicle information* like the vehicle identification number (VIN).

Just like in UDS, the OBD encodes the diagnostic service requested by the client in an *SID* located in the first byte in a diagnostic message. Hereby, the SID ranges of ODB and UDS are disjunct to prevent interference between the two standards.

For the exchange of information between the client and the server (and vice versa), both diagnostic protocols use the transport layer described in Section 51.4.1.

### 51.4.3 Diagnostics over IP

In order to facilitate diagnostic communication between the external tester device and ECUs using the Internet protocol (IP) as well as the transmission control protocol (TCP) and the user datagram protocol (UDP), the diagnostics over IP (DoIP) specification [20] defines features that can be used to *detect a vehicle in a network* and to *enable communication with the vehicle's central diagnostic gateway* as well as with *other ECUs not directly connected to the tester device*.

ECUs that are capable of adhering to the DoIP protocol are termed *DoIP entities* by the DoIP specification. DoIP entities are further distinguished into *DoIP nodes*, which do not forward diagnostic communication requests toward a non-Ethernet in-vehicle network, and *DoIP gateways*, which perform this kind of forwarding and thus relay information between the external tester and non-DoIP-capable ECUs:

*Vehicle Identification Request and Vehicle Announcement:* These two types of messages are required to identify the DoIP entities in a network and to retrieve their IP and logical addresses.

The *vehicle identification request* contains either the *VIN* or a *unique hardware ID* (e.g., the medium access control (MAC) address) of the addressed DoIP entity and is broadcasted in the network. The DoIP entity with a matching VIN or hardware ID answers this request with a *vehicle announcement* containing its own IP address (as part of the IP header), its logical address (which is the ECU's physical ISO TP address [see Section 51.4.1]), and port numbers of TCP and UDP ports to be used for subsequent communication with the DoIP entity.

*Routing Activation Request and Response:* These two message types are required to activate routing in DoIP gateways between the vehicle's external network and the vehicle's internal network in order to facilitate subsequent diagnostic data exchange between the external tester device and non-DoIP-capable ECUs connected to the vehicle's internal network.

*Diagnostic Message and Diagnostic Message Acknowledgment:* After a successful routing activation, diagnostic message exchange between an external tester device and a non-DoIP-capable ECU connected to the vehicle internal network can take place. The diagnostic message used for the data exchange between the tester and the DoIP gateway hereby contains the ISO TP source address followed by the ISO TP destination address followed by the UDS/OBD message. If the DoIP gateway receives such a diagnostic message, it extracts the two ISO TP addresses and the UDS/OBD message and forwards the UDS/OBD message to the ISO TP of the target network

---

\* This diagnostic message is payload from ISO TP's point of view.

that is selected based on the destination address. Hereby, the ISO TP source address and the ISO TP destination address contained in the DoIP diagnostic message are used as respective source and destination addresses on the target network. A successful or a failed forwarding to the target network is signaled to the external tester device by means of positive or negative diagnostic message acknowledgment.

## 51.5 ASAM

The ASAM started as an initiative of German car manufacturers with the goal to define standards for data models, interfaces and syntax specifications for testing, evaluation, and simulation applications.

Apart from several data exchange formats like the open diagnostic data exchange format (ODX), the functional specification exchange format (FSX), the metadata exchange format for software module sharing (MDX), and the fieldbus exchange format (FIBEX), the ASAM defines the universal measurement and calibration protocol family (XCP) that is described in the next section.

### 51.5.1 XCP: The Universal Measurement and Calibration Protocol Family

The universal measurement and calibration protocol family XCP [21] is used for the following main purposes:

- Synchronous data transfer (acquisition and stimulation)
- Online calibration
- Flash programming for development purposes

Prior to describing these main operations of XCP though, we will focus on the protocol's internal structure. XCP itself consists of two main parts, namely, the *XCP protocol layer* and several *XCP transport layers*, one dedicated transport layer for each underlying communication protocol (currently, CAN, FlexRay, universal serial bus (USB) TCP/IP, UDP/IP, and serial peripheral interfaces (SPI) are supported). Figure 51.5 illustrates this XCP protocol stack.

#### 51.5.1.1 XCP Protocol Layer

The XCP protocol layer is the higher layer of the XCP protocol family. This layer implements the main operations of XCP that are described in detail in Sections 51.5.1.3 through 51.5.1.5. The XCP protocol layer itself is independent of a concrete communication protocol (e.g., CAN, FlexRay). Data exchange on the XCP protocol layer level is performed by data objects called *XCP packets*. Figure 51.6 illustrates the structure of an XCP packet.

FIGURE 51.5 XCP protocol stack.

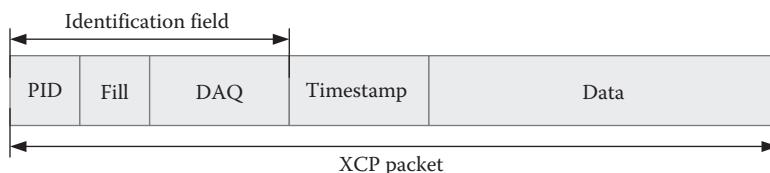

FIGURE 51.6 Structure of an XCP packet.

An XCP packet starts with an *identification field* containing a *packet identifier (PID)* that is used to establish a common understanding about the semantics of the packet's data between the XCP master and the XCP slave. The PID is thus used to uniquely identify each of the following two basic packet types and their respective subtypes:

*Command Transfer Object (CTO) Packets:* This packet type is used for the transfer of generic control commands from the XCP master to the XCP slave and vice versa. It is used for carrying out *protocol commands (CMD)*, transferring *command responses (RES)*, *errors (ERR)*, *events (EV)*, and for issuing *service requests (SERV)*.

*Data Transfer Object (DTO) Packets:* This packet type is used for transferring synchronous data between the XCP master and the XCP slave device. *Synchronous data acquisition (DAQ) data* are transferred from the XCP slave to the XCP master, whereas *synchronous data stimulation (STIM) data* are transported from the master to the slave.

The *DAQ field* is used to uniquely identify the DAQ list (see Section 51.5.1.3) to be used for data acquisition or stimulation if the XCP packet is of DTO packet type. In order to have the DAQ field aligned to 16-bit boundaries, a fill byte is introduced between the PID field and the DAQ field. In case the packet is a CTO packet, the DAQ field is omitted.

The *time-stamp field* is used in DTO packets to carry a time stamp provided by the XCP slave for the respective data acquisition. The length of the time-stamp field may vary between one to four bytes depending on the configuration. In case the packet is of CTO type, the time-stamp field is omitted.

Command packets (CMD) are explicitly acknowledged on the XCP protocol layer by sending either a command response packet (RES) or an error packet (ERR). Event (EV) packets (i.e., packets informing the XCP master that a specific event has occurred in the XCP slave [e.g., an overload situation has occurred during data acquisition]), service request (SERV) packets (i.e., packets used by the slave to request certain services from the master [e.g., a packet containing text that is to be printed by the master]), and data acquisition packets (DAQ, STIM) are sent asynchronously and unacknowledged at the XCP protocol layer. Therefore, it may not be guaranteed that the master device will receive these packets when using a nonacknowledged transportation link like UDP/IP.

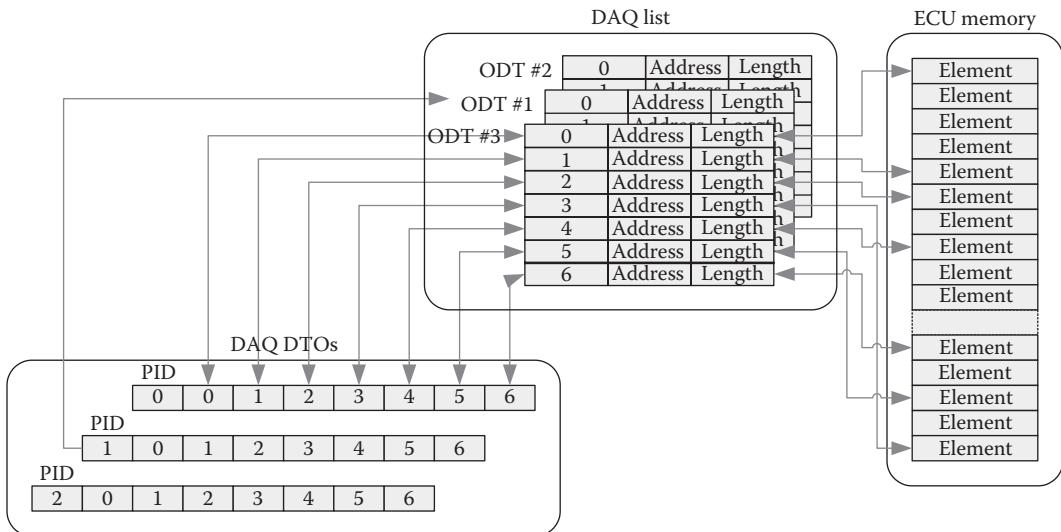

### 51.5.1.2 XCP Transport Layers

The protocol layer described in the previous sections is independent from the underlying communication protocol. In order to be able to use XCP on top of different communication protocols, the XCP specification defines multiple XCP transport layers that perform the packing of the protocol-independent XCP packets into frames of the respective communication protocol, by adding an XCP header containing a *node address field* used to identify the destination ECU, a *counter field* used for sequence numbering of the XCP packets and a *length field* defining the length of the XCP packet. Depending on the actual communication protocol used, some of these header fields might be missing (e.g., in case TCP/IP is used as communication protocol, the node address is omitted, since IP's addressing scheme is used).

### 51.5.1.3 Synchronous Data Transfer

The synchronous data transfer feature of XCP allows for a data exchange between the XCP master and the XCP slave that is performed synchronous to the XCP slave's execution. This exchange is carried out by using *DTOs* that are transferred via DTO packets. The memory regions of the XCP slave's memory that are the source or the destination of the transfer are linked to the DTO by so-called object description tables (ODTs). A sequence of one or more ODTs are grouped into a so-called DAQ list (see Figure 51.7).

Hereby, the DAQ-DTO contains a packet identification field (PID), which is used to link the DAQ-DTO to the respective ODT (PID field matches ODT number). For each element within a DAQ-DTO, a corresponding ODT entry is present in the ODT that references a specific part in the ECU's memory by the attribute's address and length. Upon processing of the ODT, the ODT entries are used to transfer

**FIGURE 51.7** Structure of a DAQ list.

an element from the ECU's memory into the corresponding element in the DAQ-DTO (in case of data acquisition) and vice versa (in case of data stimulation).

DAQ lists can either be statically stored in an XCP slave ECU's memory or dynamically allocated by the XCP master via special protocol command packets.

#### 51.5.1.4 Online Calibration

For the online calibration feature of XCP, the slave's physical memory is divided into so-called sectors that reflect the memory's size and limit constraints when reprogramming/erasing parts of the memory. This division into sectors thus describes the physical layout of the XCP slave's memory.

The logical layout is described by dividing the memory into *segments*. This division does not need to adhere to the physical limitations of the division into sectors. Each segment can further consist of one or multiple pages where at any given instance in time, only one page of a segment is accessible to the ECU. This page is called the active page for the ECU's application. The same holds true for XCP itself as well (active XCP page). XCP ensures that concurrent access to the same page by the ECU's application and XCP itself is prevented.

Via XCP CMD packets, the XCP master can instruct the XCP slave to switch active pages of the same segment (i.e., to make a page that has previously not been the active one the new active page) and to copy data between pages of the same or of different memory segments.

This way, the calibration data used for the slave ECU's control loops, for example, can be altered upon runtime under the control of the XCP master.

#### 51.5.1.5 Flash Programming

In order to facilitate the exchange of the current image of the application program in the slave ECU's NV memory, XCP defines special commands (exchanged via XCP command packets) for performing flash (re)programming. The following list contains a short description of the main commands used in flash programming:

**PROGRAM\_START:** This indicates the beginning of a programming sequence of the slave ECU's NV memory.

**PROGRAM\_CLEAR:** This clears a part of the slave ECU's NV memory (required before programming new data into this part of memory).

**PROGRAM\_FORMAT:** This is used to specify the format for the data that will be transferred to the slave ECU (e.g., used compression format, used encryption algorithm).

**PROGRAM:** This command, which is issued in a loop as long as there are still data available that need to be programmed, is used to program a given number of data bytes to a given address within the slave ECU's NV memory.

**PROGRAM\_VERIFY:** This verifies that the programming process has completed successfully by, for example, calculating a checksum over the programmed memory area.

**PROGRAM\_RESET:** This indicates the end of the programming sequence and optionally resets the slave ECU.

By means of these flash programming XCP commands, a flash download process for the ECU's development stage can be implemented. In-system flash programming in series cars, however, is usually performed via the diagnostic protocol (see Section 51.4.2).

## 51.6 AUTOSAR

---

The development partnership AUTOSAR is an alliance of car manufacturers, major supplier companies, and tool vendors working together to develop and establish an open industry standard for an automotive electronic architecture together with a development methodology and an XML-based data exchange format that is intended to serve as a basic infrastructure for the management of (soft and hard real-time) functions within automotive applications.

At the time being, AUTOSAR versions 1.0, 2.0, 2.1, 3.0, 3.1, 3.2, 4.0, and quite recently 4.1 as a major update of the standard, which, for example, for the first time included support for Ethernet as an in-vehicle communication network, have been released. Active development of the AUTOSAR standard is limited to the AUTOSAR 3.2 and 4.1 versions though. All other versions are in maintenance mode.

While series projects completed by today\* are based on AUTOSAR 2.1 and 3.1, the next-generation vehicles currently under development will mainly be based on AUTOSAR 4.0 [22].

The AUTOSAR software architecture makes a rather strict distinction between application software and basic or system software. While the *basic (or system) software* provides functionality like communication protocol stacks for automotive communication protocols (e.g., FlexRay [23,24]), a real-time OS, and diagnostic modules, the *application software* comprises all application-specific software items (i.e., control loops, interaction with sensor and actuators). This way, the basic or system software provides the foundation the application software is built upon.

The so-called runtime environment (Rte) acts as an interface between application software components (SWCs) and the system software modules as well as the infrastructure services that enables communication to occur between application SWCs.

### 51.6.1 Application Software Architecture

The application software in AUTOSAR is structured into SWCs that communicate via *ports* and are interconnected by means of *connectors*. In the following sections, these concepts will be explained in detail.

#### 51.6.1.1 Software Components

The application software in AUTOSAR is composed of reusable SWCs. For structuring reasons, AUTOSAR facilitates a hierarchical decomposition of the application software by distinguishing between *atomic SWCs*, which represent the bottom level of this decomposition and thus cannot be divided any further, and *composition SWCs*, which can be divided into multiple atomic SWCs and further composition SWCs.

---

\* The resulting vehicles are already on the road.

The following types of atomic SWCs are defined by AUTOSAR:

*Application SWCs:* An application SWC implements (part of) the application. Since the application SWC does not directly interact with any particular hardware resources, it is hardware and location independent.

*Parameter SWCs:* A parameter SWC provides read access to parameter values that can be based either on constant data or on variable data that can be modified by means of calibration (see Section 51.5.1.4). Like application SWCs, the parameter SWCs do not directly interact with any particular hardware resources and are thus hardware and location independent as well.

*Service SWCs:* The service SWC makes the services of a local (i.e., located on the same ECU) system software module (see Section 51.6.2) available to other SWCs.

*Service Proxy SWCs:* This type of SWC is responsible for the distribution of mode information throughout the system. Since AUTOSAR does not allow non-service proxy SWCs to directly access to mode information provided by other ECUs, each ECU requiring such remote mode information requires a service proxy SWC.

*Complex Driver SWCs:* The complex driver SWC facilitates direct access to the MCU's hardware in particular for resource critical applications performing complex sensor evaluation and actuator control.

*ECU-Abstraction SWCs:* The ECU-abstraction SWC is a specialization of a complex driver SWC that makes the ECU's specific I/O capabilities available to the other SWCs (especially to the sensor–actuator SWCs).

*Sensor–Actuator SWCs:* The sensor–actuator SWC handles the specifics of a particular sensor and/or actuator. To do so, the sensor–actuator SWC directly interacts with the ECU-abstraction SWCs.

*NV Block SWCs:* The NV block SWCs provide fine granular (i.e., smaller than the block-based access provided by the NV random access memory [RAM] Manager [NvM] [see Section 51.6.2.2]) read-and-write access to NV data to other SWCs by combining these fine granular accesses and mapping them to the blocks provided by the NvM.

While parameter SWCs and application SWCs can be relocated among ECUs (deployed on different ECUs), the other types of SWCs are bound to a specific ECU, since they require a particular piece of hardware (e.g., a particular sensor in case of sensor–actuator SWCs and ECU-abstraction SWCs), provide access to the ECU's local NV memory (in case of NV block SWCs), or provide access to the ECU's local system software or complex drivers (in case of service SWCs and complex driver SWCs). Since the sole purpose of service proxy SWCs is to act as a local proxy for the provision of remote mode information, service proxy SWCs are bound to the specific ECU as well.

### 51.6.1.2 Ports and Interfaces

All SWCs interact with their environment through *ports*. Depending on whether the SWC requires or provides specific services or particular data elements, a distinction between *require ports* (*R ports*) and *provide ports* (*P ports*) is made.

Ports are typed by a specific *interface*, where AUTOSAR defines the following types of interfaces:

*Sender–Receiver (S/R) Interfaces:* Via a sender–receiver interface, a single *sender* distributes information to one or more *receivers* (1:n communication), or one *receiver* gets information from one or several senders (n:1 communication). The sender–receiver interface consists of *data elements* that define the data that are exchanged. The type of a data element can either be a simple data type (e.g., an integral value) or a complex data type (e.g., an array or a structure). The transfer of a single data element is hereby performed in an atomic fashion.

*Client–Server (C/S) Interfaces:* Via a client–server interface, one or more *clients* can invoke a remote operation provided by a *server* (n:1 communication). The client–server interface consists of the

*operations* that are provided by the server and can be invoked by the client. This operation invocation can either be *synchronous* (i.e., the client is blocked until the result of the operation is available) or *asynchronous* (the client is not blocked but asynchronously notified as soon as the result is available).

*Mode-Switch (M/S) Interfaces:* Via a mode-switch interface, a *mode manager* publishes the current mode to one or more *mode users* (1:n communication) in order to have these mode users adjust their behavior according to the current mode or to synchronize activities to mode switches. The mode-switch interface consists of a so-called *mode declaration group* that is the aggregation of all distinct *mode declarations* (i.e., all different modes the mode manager can reside in).

*Parameter Interface:* Via a parameter interface, a parameter SWC *publishes constant data or calibration data*. Similar to the S/R interface, the parameter interface consists of *data elements* that define the data that are provided.

*NV Data Interface:* Via an NV data interface, an NV block SWC provides *access to NV data* on a fine-grained level. Similar to the S/R interface, the NV data interface consists of *data elements* that define the NV data that are provided.

*Trigger Interface:* By means of a trigger interface, an SWC is capable of *directly triggering* the execution of the *runnable entities* (see Section 51.6.1.4) of other SWCs in order to facilitate fast responses to certain events.

### 51.6.1.3 Connectors

The ports of different SWCs can be connected by means of *connectors*. Based on the type of interface of the ports, these connectors represent the exchange of data elements (in case of S/R interfaces), the invocation of a remote operation (in case of C/S interfaces), the information about a performed mode switch (in case of M/S interfaces), the retrieval of constant or calibration data (in case of parameter interfaces), the access to NV data (in case of NV data interfaces), and the direct triggering of the execution of a runnable entity (in case of trigger interfaces). Depending on whether a connector connects two P ports or two R ports or whether the connector connects a P port with an R port, AUTOSAR distinguishes between *delegation connectors* and *assembly connectors*. Whereas the former are used for connection of ports located on *different levels of the SWC hierarchy* (i.e., connection of a port of an SWC with the corresponding port of its enclosing composition SWC), the latter connect ports within the *same level of the SWC hierarchy* (i.e., connection of corresponding ports of SWCs within the same composition SWC).

### 51.6.1.4 Runnable Entities

The SWCs themselves are composed of one or more *runnable entities (REs)* that are executed in the context of OS tasks. Runnable entities are the basic unit of execution in AUTOSAR and basically correspond to a function in common programming languages. Depending on whether or not runnable entities have internal wait points (i.e., they use blocking ICP or synchronization constructs), AUTOSAR distinguishes between *category 1 runnable entities* (without wait points) and *category 2 runnable entities* (with wait points). The former can be assigned to basic tasks of the OS (which are not allowed to invoke any blocking system calls), whereas the latter have to be mapped to extended tasks (which are allowed to use blocking system calls).

Runnable entities are invoked by *Rte events*. The following list names the most important Rte events that are defined by AUTOSAR:

*Timing Event:* This kind of event facilitates the periodic activation a runnable entity in an SWC.

*Data Received Event:* This kind of event is used to activate a runnable entity in a receiver SWC upon the reception of a data element at an S/R port.

*Data Send Completed Event:* This kind of event is used to activate a runnable entity in a sender SWC upon the successful transmission of a data element at an S/R port.

*Operation Invoked Event:* This kind of event is used to activate the runnable entity implementing a C/S operation in a server SWC upon the request of the client SWC.

*Asynchronous Server Call Returns Event:* This kind of event is used to activate a runnable entity in a client SWC as a result of a notification that the server SWC has completed an asynchronous C/S operation.

*Mode Switch Event:* This kind of event is used to activate a runnable entity in a mode user SWC as a result of a mode switch performed by a mode manager SWC.

*Mode Switch Acknowledge Event:* This kind of event is used to activate a runnable entity in a mode manager SWC as a result of a notification that all mode users have reacted to the mode switch.

*(Internal/External) Trigger Occurred Event:* This kind of event is used to activate a runnable entity in an SWC as a result of an explicit trigger by a runnable entity of the same SWC (internal) or of some other SWC (external).

*Init Event:* This kind of event is used to activate a runnable entity in an SWC as a result of the initialization of the Rte.

### 51.6.1.5 Communication Scopes

When looking at the different possible scopes of communication, AUTOSAR distinguishes between the following scopes:

*Task:* Depending on whether or not the communicating runnables are allocated to the same task, a distinction between *intra-task communication* and *inter-task communication* is made.

*Partition:* Depending on whether or not the tasks of the communicating runnables are allocated to the same memory partition, a distinction between *intra-partition communication* and *inter-partition communication* is made.

*Core:* Depending on whether or not the tasks of the communicating runnables are allocated to the same MCU core, a distinction between *intra-core communication* and *inter-core communication* is made.

*ECU:* Finally, depending on whether or not the SWCs of the communicating runnables are deployed to the same ECU, a distinction between *intra-ECU communication* and *inter-ECU communication* is made.

### 51.6.2 System Software Architecture

In addition to the application SWCs, AUTOSAR also defines a layered architecture of system software modules [25] that provides the basic platform for the execution of the application SWCs. Figure 51.8 provides a coarse-grained overview of the major layers of these system software modules.

*Microcontroller Abstraction Layer:* This is the lowest software layer of the system software in AUTOSAR. This layer contains software modules that directly access the microcontroller's internal peripheral devices as well as memory-mapped external devices. The task of this layer is to make higher software layers independent of the microcontroller type.

*ECU-Abstraction Layer:* This layer interfaces with the software modules of the microcontroller abstraction layer and additionally contains drivers for external devices. The layer offers a standardized application programming interface (API) to access the peripheral devices of an ECU regardless of their location (i.e., whether the peripherals are internal or external with respect to the ECU's microcontroller) and their connection (e.g., via port pins, via a serial peripheral interface [SPI], a.s.o.). The task of this layer is to make higher software layers independent of the ECU's hardware layout.

*Services Layer:* This layer is mainly located on top of the ECU-abstraction layer and provides OS services, vehicle network communication and management services, memory services (e.g., NVRAM management), diagnostic services (e.g., error logger), and state management services of the whole ECU. The task of this layer is the provision of basic services to other

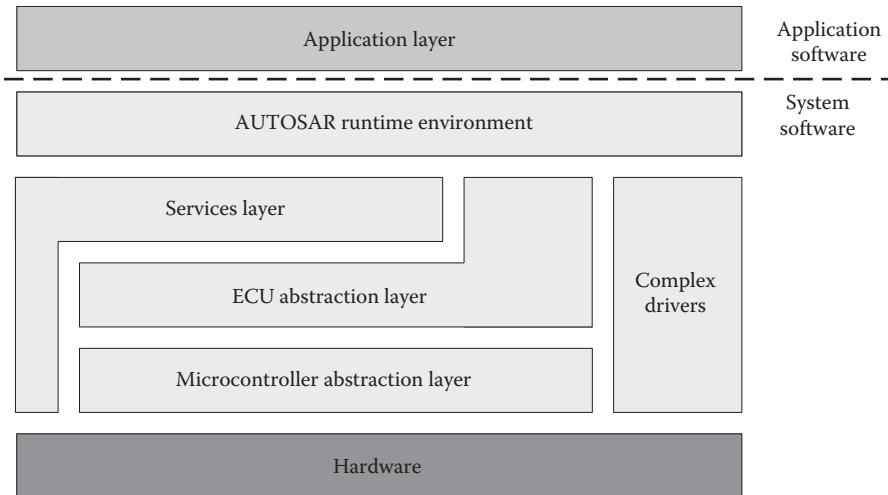

FIGURE 51.8 AUTOSAR—system software layered architecture.

system software modules and the application software. In the latter case, the respective service layer module acts as a service SWC toward the Rte.

**Complex Drivers:** The concept of complex drivers somehow intentionally violates the AUTOSAR layered architecture in order to provide the possibility to deploy legacy device drivers in an AUTOSAR system software module stack. Additionally, the complex device driver module concept has been introduced to facilitate the integration of highly application- and ECU-dependent drivers that require complex sensor evaluation and actuator control with direct access to the microcontroller itself and complex microcontroller peripherals for performance reasons. Complex drivers may provide an interface to (application) SWCs. In that case, the complex drivers act as complex driver SWCs toward the Rte.

**Rte:** The AUTOSAR Rte provides the interface between application SWCs and the system software modules as well as the infrastructure services that enable communication between application SWCs.

**Application Layer:** Actually, this layer is not part of the AUTOSAR system software module layered architecture, since this layer contains the AUTOSAR application SWCs described in Section 51.6.1.

**Libraries:** AUTOSAR libraries are *not* assigned to any particular software layer. Instead, *all* layers (including the SWCs of the application layer) are allowed to make use of these libraries.

In addition to this mainly vertical structuring, AUTOSAR further horizontally subdivides the system software modules into different substacks. This subdivision is depicted in Figure 51.9.

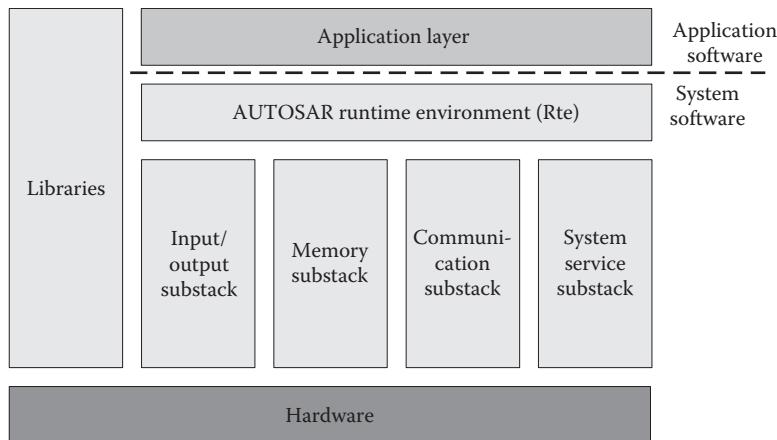

**Input/Output Substack:** The input/output substack comprises software modules that provide standardized access to sensors, actuators, and ECU onboard peripherals (e.g., D/A or A/D converters).

**Memory Substack:** The memory substack comprises software modules that facilitate the standardized access to internal and external NV memory for means of persistent data storage.

**Communication Substack:** The communication substack contains software modules that provide standardized access to vehicle networks (i.e., the local interconnect network [LIN] [26], the CAN [27,28], FlexRay [23,24], and Ethernet).

**System Service Substack:** Last but not least, the system service substack encompasses all software modules that provide standardized (e.g., OS, timer support, error loggers) and ECU-specific (ECU state management, watchdog management) system services and library functions.

**Libraries:** Since the libraries are not part of a particular substack, they are depicted separately in Figure 51.9.

**FIGURE 51.9** AUTOSAR—system software substacks overview.

Regardless of the vertical and horizontal structuring, the following classification can be applied to the AUTOSAR system software modules:

**Drivers:** A driver contains the functionality to *control and access an internal or an external device*. Hereby, internal devices, which are located within the microcontroller, are controlled by internal drivers, whereas external devices, which are located on ECU hardware outside the microcontroller, are controlled by external drivers. Internal drivers can usually be found within the microcontroller abstraction layer, whereas external drivers are situated in the ECU-abstraction layer. Drivers do not change the content of the data handed to them.

**Interfaces:** An interface contains the functionality to *abstract from the hardware realization of a specific device* and to provide a generic API to access a specific type of device independent of the number of existing devices of that type and independent of the hardware realization of the different devices. Interfaces are generally located within the ECU-abstraction layer. Interfaces do not change the content of the data handed to them.

**Handlers:** A handler *controls the concurrent, multiple, and asynchronous accesses of one or more clients* to one or more driver or interface modules. Thus, a handler performs buffering, queuing, arbitration, and multiplexing. Handlers do not change the content of the data handed to them.

**Managers:** A manager offers specific services for multiple clients. Managers are required whenever pure handler functionality is insufficient for accessing and using interface and driver modules. Managers furthermore are allowed to *evaluate and change or adapt the content of the data* handed to them. Managers are usually located in the services layer.

In the following sections, the different substacks of AUTOSAR system software modules are described in detail.

### 51.6.2.1 Communication Substack

The communication substack contains a group of modules that facilitate communication among the different ECUs in a vehicle via automotive communication protocols (CAN, LIN, FlexRay, and Ethernet). The structure of the communication substack is depicted in Figure 51.10.

Hereby, <Net> is used as a placeholder for the respective communication protocol (i.e., CAN, LIN, FlexRay, and Ethernet). Thus, the AUTOSAR communication substack contains communication

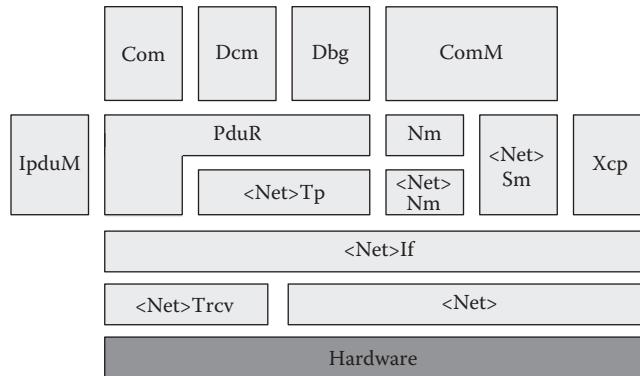

FIGURE 51.10 AUTOSAR—communication substack.

protocol-specific instances of the transport protocol ( $T_p$ ), network management (Nm), interface (If), state manager (Sm), transceiver driver (Trcv), and driver (no suffix) modules.

The structure of the communication substack for Ethernet networks and the communication substack for CAN networks for heavy-duty vehicles according to the SAE J1939 standard, however, slightly deviates from the structure depicted in Figure 51.10. For Ethernet networks, the transport protocol functionality is distributed among two modules, namely, the TcpIp modules and the SoAd module, and two additional modules, namely, the DoIp module and the Sd module, are introduced. The structure of the communication substack for Ethernet networks is depicted in Figure 51.11.

For CAN networks for heavy-duty vehicles according to the SAE J1939 standard, dedicated modules for transport protocol (J1939Tp) and network management (J1939Nm) replace the respective modules of the communication substack for standard CAN networks, and an additional Dcm module (J1939Dcm) and a request management module (J1939Rm) are introduced that implement J1939-specific functionality. The structure of the communication substack for CAN networks for heavy-duty vehicles according to the SAE J1939 standard is depicted in Figure 51.12.

In the following, the different modules of the communication substack are described in detail.

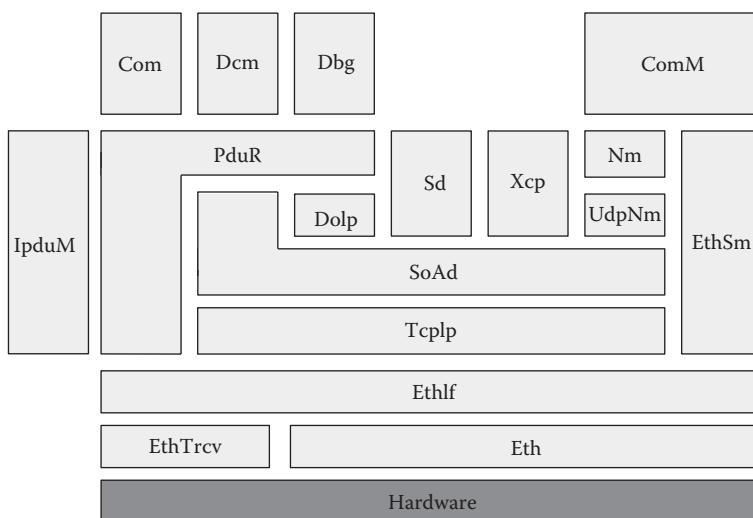

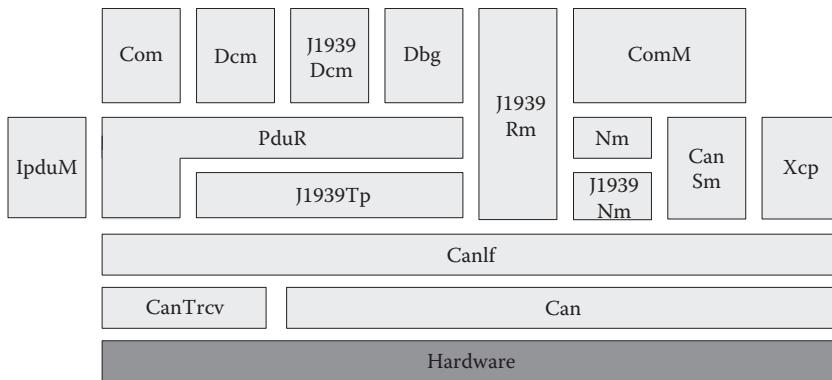

FIGURE 51.11 AUTOSAR—communication substack for Ethernet networks.

**FIGURE 51.12** AUTOSAR—communication substack for CAN networks for heavy-duty vehicles.

#### 51.6.2.1.1 Driver (<Net>)

The driver module (Fr, Can, Lin, and Eth) provides the basis for the respective interface module by facilitating the *transmission and the reception of frames* via the respective CC. Hereby, the driver is designed to handle multiple CCs of the same type. Thus, if an ECU contains, for example, FlexRay CCs of two different types, two different FlexRay driver modules are required.

In case of CAN, the driver module (Can) optionally provides the required support for TTCAN [29] and CAN FD [30] as well.

#### 51.6.2.1.2 Transceiver Driver (<Net>Trcv)

The transceiver driver module (i.e., FrTrcv, CanTrcv, LinTrcv, and EthTrcv) provides API functions for *controlling the transceiver hardware* (i.e., switching the transceivers into special modes [e.g., listen only or low-power mode]) and for obtaining diagnostic information from the transceiver hardware (e.g., information about short circuits of the different bus lines of CAN or information about wake-up events on the network).

#### 51.6.2.1.3 Interface (<Net>If)

Using the frame-based services provided by the driver module, the interface module (FrIf, CanIf, LinIf, and EthIf) facilitates *the sending and the reception of protocol data units (PDUs)*. Hereby, multiple PDUs can be packed into a single frame at the sending ECU and have to be extracted again at the receiving ECU.\* The point in time when this packing and extracting of PDUs takes place is governed by the temporal scheduling of so-called communication jobs of the FlexRay and the LIN interface. The instant when the frames containing the packed PDUs are handed over to the driver module for transmission or retrieved from the driver module upon reception is triggered by communication jobs of the interface module as well. In FlexRay, the schedule of these communication jobs is aligned with the communication schedule; in LIN, the schedule of the LIN interface module governs the communication schedule on the LIN bus. In contrast to this, in CAN, the temporal schedule of the PDU transmission is governed by the Com module (see following texts). In FlexRay, each communication job can consist of one or more *communication operations*, each of these communication operations handling exactly one communication frame (including the PDUs contained in this frame).

In case of CAN, the interface module (CanIf) optionally provides the required support for TTCAN [29] and CAN FD [30] as well.

\* Currently, only the FlexRay interface module supports the packing of multiple PDUs into a single frame. For the CAN, the LIN, and the Ethernet interface modules there is a 1:1 relationship between PDUs and frames.

In case of Ethernet, the interface module (`EthIf`) additionally provides support for virtual local area networks (VLANs) by taking care of the handling of the VLAN tags (i.e., tag protocol identifier [TPID] and tag control information [TCI]) and thus providing an abstraction from the distinction between VLAN and *normal* LANs to the upper layers.

All interface modules are designed to be able to deal with multiple different drivers for different types of CCs (e.g., freescale's MFR4300 or FlexRay CCs based on the Bosch E-Ray core in the FlexRay case). Furthermore, the interface module wraps the API provided by the transceiver driver module and provides support for multiple different transceiver driver modules (similar to the support for multiple different driver modules).

#### **51.6.2.1.4 Transport Protocol (<Net>Tp)**

The transport protocol is used to perform *segmentation and reassembly of large PDUs*. On CAN (`CanTp`) and FlexRay (`FrTp`), the used protocols are compatible (in certain configuration settings) to their respective ISO TP counterparts (see Section 51.4.1).

For FlexRay networks, AUTOSAR specifies an alternative transport protocol (`FrArTp`) that is backward compatible to the FlexRay transport protocol used in AUTOSAR 3.1 (but incompatible to the ISO TP for FlexRay).

In order to support the SAE J1939 standard and thus make AUTOSAR applicable for the use in heavy-duty vehicles, an alternative transport protocol for CAN (`J1939Tp`) is provided as well that adheres to the respective SAE J1939 specification [31].

A combination of `FrTp` and `FrArTp` or `CanTp` and `J1939Tp` on a single physical network is hereby not supported.

For the LIN communication network, AUTOSAR does not define a separate transport protocol module, but instead integrates the transport protocol functionality (which adheres to the LIN 2.1 specification [26]) into the LIN Interface (`LinIf`) module.

For the Ethernet communication network, AUTOSAR decided to reuse already well-proven protocols, namely, the IP, the Internet control message protocol (ICMP), the address resolution protocol (ARP) for IP address resolution, the UDP for unreliable connectionless communication, the TCP for reliable connection oriented communication, and the dynamic host configuration protocol (DHCP) for automated IP address assignment. The functionality of these protocols is implemented in the `TcpIp` module. The socket adapter (`SoAd`) module, which is located on top of the `TcpIp` module, maps AUTOSAR PDUs (which are identified by a unique PDU identifier) to the network endpoints of TCP connections and/or to the UDP datagrams (identified by a four-tuple of local/remote IP address and port number) by means of static configuration tables. Hereby, the `SoAd` abstracts from TCP specifics like the different methods for local IP address assignment (i.e., stateless address autoconfiguration according to RFC 3927, DHCP according to RFC 2131, or simply by means of static configuration) and details regarding the connection setup and teardown in order to provide an AUTOSAR PDU-based interface to the `PduR`. Similar to the packing of multiple PDUs into a single FlexRay frame in the `FrIf` for efficiency reasons, the `SoAd` allows for packing multiple PDUs into a single UDP datagram or TCP segment in order to achieve a decent header/payload ratio and to reduce the overhead for connection setup and teardown. Especially for the exchange and relaying of diagnostic data between an external tester device, the `DoIp` module that is located above the `SoAd` implements the services specified by the ISO DoIP standard (see Section 51.4.3) and presents itself as conventional AUTOSAR transport protocol (i.e., like `CanTp` or `FrTp`) toward the `PduR` by providing the respective API.

Just like with ISO TP, the user of the services provided by the various transport protocol modules is the diagnostic layer, called diagnostic communication manager in AUTOSAR (see following texts).

#### **51.6.2.1.5 Network Management (<Net>Nm, Nm)**

Similar to OSEK NM (see Section 51.3), the AUTOSAR NM modules provide means for the coordinated transition of the ECUs in a network into and out of a low-power (or even power-down) sleep mode. Hereby, the *network* can be the whole *physical* network with all its connected ECUs or only a *logical* network consisting of a statically defined subset of ECUs of the physical network, a so-called partial network.

The AUTOSAR NM functionality is divided into two modules: a communication protocol-independent module named generic NM (`Nm`) and communication protocol-dependent modules named FlexRay NM (`FrNm`), CAN NM (`CanNm`), LIN NM (`LinNm`), and UDP NM (`UdpNm`) for Ethernet networks.

In order to support the SAE J1939 standard and thus make AUTOSAR applicable for the use in heavy-duty vehicles, an alternative network management protocol for CAN (`J1939Nm`) is provided as well that adheres to the respective SAE J1939 specification [32]. `J1939Nm`, however, does not take care of a coordinated transition into and out of a low-power sleep mode, but handles the assignment of unique addresses to each ECU instead. A combination of `CanNm` and `J1939Nm` on a single physical network is hereby not supported.

#### **51.6.2.1.6 State Manager (<Net>SM)**

The state manager modules (`CanSM`, `LinSM`, `FrSM`, and `EthSM`) facilitate the *state management of the respective CCs* with respect to communication system-dependent start-up and shutdown features and provide a common state machine API to the upper layer (i.e., the communication manager [`ComM`]). This API consists of functions for requesting the communication modes `Full`, `Silent` (i.e., listen only), and `No Communication`.

#### **51.6.2.1.7 XCP**

For measurement and calibration purposes via CAN, FlexRay, and Ethernet networks, AUTOSAR includes an `Xcp` module in the communication stack, which implements the ASAM XCP specification (see Section 51.5.1).

#### **51.6.2.1.8 PDU Router**

The PDU router (`PduR`) module provides two major services. On the one hand, it *dispatches PDUs received via the underlying modules* (i.e., interface and transport layer modules) to the different higher layers (`Com`, `Dcm`). On the other hand, the `PduR` *performs gateway functionalities* between different communication networks by forwarding PDUs from one interface to another of either the same (e.g., FlexRay to FlexRay) or of different type (e.g., CAN to FlexRay). Routing decisions in the `PduR` are based on a static routing table and on the identifiers of the PDUs.

#### **51.6.2.1.9 PDU Multiplexer**

The PDU multiplexer (`IpduM`) module takes care of *multiplexing parts of a PDU*. Hereby, the value of a dedicated part of the PDU (the *multiplexer switch*) is used to define the semantic content of the remainder of the PDU (just like the tag element in a variant record or a union in programming languages). In the reception case, multiplexed PDUs are forwarded from the `PduR` to the `IpduM` for demultiplexing. Once demultiplexed, the `IpduM` hands the PDUs back to the `PduR`. In the sending case, the `PduR` obtains a PDU from `Com` and hands this PDU to the `IpduM` for multiplexing. The `IpduM` returns the multiplexed PDU to the `PduR`, which routes the multiplexed PDU to its final destination.

#### **51.6.2.1.10 Communication**

Similar to OSEK Com (see Section 51.3), the `Com` module in AUTOSAR provides *signal-based communication* to the upper layer (`Rte`). The signal-based communication service of `Com` can be used for intra-ECU communication as well as for inter-ECU communication. In the former case, `Com` mainly uses shared memory for this intra-ECU communication, whereas for the latter case at the sender side, `Com` packs multiple signals into a PDU and forwards this PDU to the `PduR` in order to issue the PDU's transmission via the respective interface module. On the receiver side, `Com` obtains a PDU from the `PduR`, extracts the signals contained in the PDU, and forwards the extracted signals to the upper software layer (`Rte`).

### 51.6.2.1.11 Diagnostic Communication Manager (Dcm)

The diagnostic communication manager module is a submodule of the AUTOSAR diagnostic module. The Dcm module provides *services that allow a tester device to control diagnostic functions* in an ECU via the communication network (i.e., CAN, LIN, FlexRay). Hereby, the Dcm supports the diagnostic protocols UDS and OBD (see Section 51.4.2 for details).

In order to support the SAE J1939 standard and thus make AUTOSAR applicable for the use in heavy-duty vehicles, an additional Dcm module (J1939Dcm) is provided that implements the diagnostic services mandated by the respective SAE J1939 specification [33]. Since the services provided by the J1939Dcm module are additions to the functionality provided by Dcm module, both modules can be used within a single ECU.

Both the Dcm and the J1939Dcm module act as *service SWCs* (see Section 51.6.1.1) toward the Rte and thus make their services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

### 51.6.2.1.12 Communication Manager (ComM)

The communication manager is a resource manager that *encapsulates the control of the underlying communication services*. The ComM collects network communication access requests from communication requesters (e.g., Dcm) and coordinates these requests by interacting with Nm and the respective state manager (<Net>SM) modules. This way the ComM provides a simplified API to the network management where a user of the API does not require any knowledge of the particular physical communication network (or partial network) to use. Via the ComM API, a user simply requests a specific communication mode (i.e., Full, Silent, or No Communication) and the ComM switches (based on a statically configured table mapping users to networks) the communication capability of the corresponding physical or partial networks to On, Silent, or Off.

The ComM module acts as a *service SWC* (see Section 51.6.1.1) toward the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

### 51.6.2.1.13 J1939 Request Manager (J1939Rm)

The J1939 request manager takes care of the SAE J1939-specific feature that the transmission of specific PDUs (termed parameter group number [PGN] in J1939) can explicitly be requested by dedicated request PDU [31]. The J1939Rm module receives this kind of request PDUs and, based on the contained information, triggers the transmission of the requested PDU.

The J1939Rm module acts as a *service SWC* (see Section 51.6.1.1) toward the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

### 51.6.2.1.14 Debugging (Dbg)

The AUTOSAR debugging module supports the remote debugging process of other AUTOSAR modules. For this purpose, the Dbg module collects information like function calls/returns and values/value changes of important variables of other modules during the runtime of the ECU without halting the processor. This, on the one hand, requires proper instrumentation of the debugged modules (e.g., the Dbg module must be notified upon function entry and exit) and, on the other hand, mandates that the relevant variables are accessible to the Dbg module. The collected data are then transmitted (either immediately or upon request) to an external debugging host system for further inspection.

### 51.6.2.1.15 Service Discovery (Sd)

The service discovery module provides means for a *service requester* (i.e., an ECU that requires a specific service) to detect available services that are offered by *service providers* within the vehicle network. Additionally, the Sd module facilitates to control the send behavior of event information in a way that an *event publisher* (i.e., an ECU sending the event information) only sends this information to the dynamically registered *event subscribers* (i.e., ECUs that want to receive this event information).

### 51.6.2.2 Memory Substack

The memory substack contains a group of modules that facilitate handling of the ECU's onboard NV memory (i.e., providing API functions to store data in and retrieve data from the ECU's NV memory [e.g., electrically erasable programmable read-only memory (EEPROM) or flash EEPROM]). The structure of the memory substack is depicted in Figure 51.13.

In the following, the different modules of the memory substack are described in detail:

**Flash Driver (Fls):** The flash driver provides services for *reading from, writing to, and erasing parts of the ECU's flash memory*. Furthermore, the flash driver facilitates the setting and resetting of the write/erase protection of the flash EEPROM if such protection is supported by the underlying hardware. In addition to these basic services, the flash driver provides a service for comparing a data block in the flash EEPROM with a data block in the memory (e.g., RAM).

**EEPROM Driver (Eep):** The EEPROM driver provides services for *reading from, writing to, and erasing parts of the ECU's EEPROM*. Additionally, similar to the flash driver, the EEPROM driver provides a service for comparing a data block in the EEPROM with a data block in the memory (e.g., RAM).

**Flash EEPROM Emulation (Fee):** The flash EEPROM emulation module *emulates EEPROM functionality* using the services provided by flash driver module. By making use of multiple flash sectors and smart copying of the data between these sectors, the Fee simulates an EEPROM-like behavior, that is, the possibility to perform program/erase operations on subsector granularity.

**EEPROM Abstraction (Ea):** The EEPROM abstraction module *provides uniform mechanisms to access the ECU's internal and external EEPROM devices*. It abstracts from the location of peripheral EEPROM devices (including their connection to the microcontroller), the ECU hardware layout, and the number of EEPROM devices.

**Memory Abstraction Interface (MemIf):** The memory abstraction interface module allows the NV RAM manager module (see following texts) to *access several memory abstraction modules (Fee or Ea modules) in a uniform way*. Hereby, the MemIf abstracts from the number of underlying Fee or Ea modules providing a runtime translation of each block access initiated by the NV RAM manager module to select the corresponding driver functions that are unique for all configured EEPROM or flash EEPROM storage devices.

**NV RAM Manager (NvM):** The NV RAM manager module provides services to *ensure the data storage and maintenance of NV data* according to their individual requirements in an automotive environment, namely, synchronous as well as asynchronous services for the initialization, the reading, the writing, and the control of NV data. The NvM operates on a block basis distinguishing the following types of blocks: For *native blocks*, the NvM provides a *RAM mirror* that contains a copy of the data stored in the NV memory block. This RAM mirror is initialized with the data from the NV block upon ECU power-up. Upon ECU shutdown, the data from the RAM mirror is flushed to the corresponding NV memory block. Additionally, the NvM provides API services that can force the transfer of a memory block from NV memory into

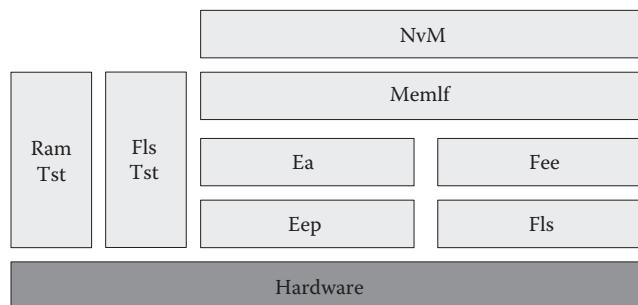

FIGURE 51.13 AUTOSAR—memory substack.

the corresponding RAM mirror and vice versa. In addition to the facilities of native blocks, *redundant blocks* provide enhanced fault tolerance, reliability, and availability. Due to replication of the redundant block in NV memory, the resilience against data corruption is increased.

The NvM module acts as a *service SWC* (see Section 51.6.1.1) toward the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

**RAM Test (RamTst):** The RAM test module provides means to perform *functional tests of the ECU's internal RAM cells*. *Complete* tests are performed upon ECU start-up and shutdown as well as on request by special diagnostic commands. During operation, *partial tests* are performed in a periodic manner (e.g., block by block or cell by cell). For both types of tests, several RAM test algorithms, which have been chosen according to the IEC 61508 standard, are available. Depending on the algorithms' diagnostic coverage rate, the algorithms are divided into the following categories: group 1 (low) with a diagnostic coverage rate smaller than 60%, group 2 (medium) exhibiting a diagnostic coverage rate of 60%–90%, and group 3 (high) with a diagnostic coverage rate of 90%–99%.

**Flash EEPROM Test (FlsTst):** The flash EEPROM test module provides means to perform *functional tests on the content of the ECU's nonmutable memory cells* (e.g., *program/data flash EEPROM content*). *Foreground tests* are performed on a per-block basis upon request via the module's API functions. *Background tests* are performed in a periodic manner for a set of configured blocks. Both kind of tests compute a configurable signature over the memory block (e.g., 8-, 16-, and 32-bit CRCs or hashes) and compare the computed signature value with a precomputed value stored in the FlsTst module's configuration.

### 51.6.2.3 Input/Output Substack

The input/output substack contains a group of modules that facilitate the handling of the ECU's input/output capabilities. The structure of the input/output substack is depicted in Figure 51.14.

In the following, the different modules of the input/output substack are described in detail:

**Port Driver (Port):** The port driver module provides the service for *initializing the whole port structure* of the microcontroller, allowing for the configuration of different functionalities for each port and port pin (e.g., analog–digital conversion [ADC], digital I/O [DIO]). Hereby, the port pin direction (input/output), the initial level of the port pin, and the fact whether the port pin direction is modifiable during runtime are part of this configuration. Other I/O drivers (e.g., Icu, Pwm) rely on the configuration performed by the port driver.

**Interrupt Capture Unit Driver (Icu):** The ICU driver is a *module using the ICU hardware* to implement services like signal edge notification, controlling of wake-up interrupts, periodic signal time measurement, edge time stamping (usable for the acquisition of nonperiodic signals), and edge counting. Hereby, the Icu module works on pins and ports that have been properly configured by the port driver for this purpose.

**Pulse Width Modulation Driver (Pwm):** The PWM driver module provides functions to *initialize and control the hardware PWM unit* of the microcontroller. The Pwm module allows for the generation of pulses with variable pulse width by facilitating the selection of the duty cycle and the signal period time. The Pwm module supports multiple PWM channels, where each channel is linked to a hardware PWM unit that belongs to the microcon-

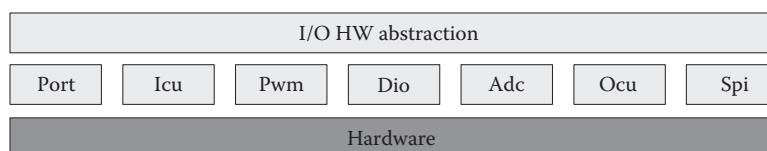

FIGURE 51.14 AUTOSAR—input/output substack.

troller. Similar to the `Icu` module, the `Pwm` module relies on pins and ports that have been properly configured by the port driver for this purpose.

*Digital I/O Driver (Dio):* The DIO driver provides services for *reading from and writing to DIO channels* (i.e., port pins), DIO ports, and groups of DIO channels. Hereby, the `Dio` module works on pins and ports that have been properly configured by the `Port` driver for this purpose.

*Analog/Digital Converter Driver (Adc):* The ADC driver module *initializes and controls the internal ADC unit(s)* of the microcontroller. The module provides services to start and stop an analog-digital conversion, respectively, to enable and disable the trigger source for a conversion. Furthermore, the module provides services to enable and disable a notification mechanism and routines to query status and result of a conversion. The `Adc` module works on so-called ADC channel groups. An ADC channel group combines an ADC channel (i.e., an analog input pin), the needed ADC circuitry itself, and a conversion result register into an entity that can be individually controlled and accessed via the `Adc` module. The `Adc` module operates on pins and ports that have been properly configured by the port driver for this purpose.

*Output Compare Unit Driver (Ocu):* The OCU driver module provides functions to *initialize and control the hardware OCU unit* of the microcontroller. The `Ocu` module allows comparing and acting automatically (e.g., by calling a notification function) when the value of a free-running counter matches a defined threshold. The module provides services to set the comparison threshold value, to start and stop a comparison, to enable and disable a notification mechanism, and to query the current counter value. The `Ocu` module works on so-called OCU channels. An OCU channel group combines a free-running counter and the corresponding threshold value into an entity that can be individually controlled and accessed via the `Ocu` module. The `Ocu` module relies on pins and ports that have been properly configured by the port driver for this purpose.

*Standard Peripheral Interface Handler/Driver (Spi):* The SPI handler/driver module provides services for reading from and writing to peripheral devices connected via SPI buses. These peripheral devices are explicitly addressed by means of a chip select (CS) line. For each peripheral device, a so-called SPI job consisting of multiple *SPI channels* can be configured in the `Spi` module's configuration. SPI channels hereby basically define the atomic units of data transferred between the microcontroller and a peripheral device. SPI jobs are grouped into *SPI sequences* to specify a defined order of data exchange.

Based on these SPI sequences, the `Spi` module provides services to synchronously and asynchronously conduct data transfers and to query the status of such a transfer on SPI sequence and SPI job granularity and notification services upon completion of a particular SPI sequence and/or a particular SPI job.

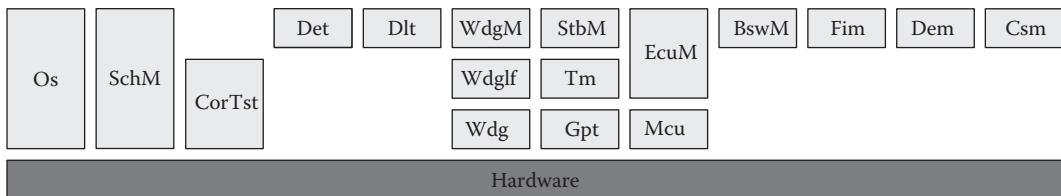

*I/O Hardware Abstraction:* The I/O hardware abstraction module provides a signal-based interface to internal and external I/O devices of an ECU. Hereby, the module abstracts from whether a certain I/O device is an MCU internal device or whether a device is externally connected to the MCU, by performing static normalization/inversion of values according to their physical representation at the inputs/outputs of the ECU hardware (i.e., static influences, like voltage division or hardware inversion, on the path between the I/O device and the MCU port pin are compensated).

The I/O hardware abstraction module acts as an *ECU-abstraction SWC* (see Section 51.6.1.1) toward the `Rte` and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### 51.6.2.4 System Services Substack

The system services substack contains a group of modules that can be used by modules of all AUTOSAR layers. Examples are real-time OS, error handler, and watchdog management. The structure of the system services substack is depicted in Figure 51.15.

In the following, the different modules of the system services substack are described in detail.

**FIGURE 51.15** AUTOSAR—system services substack.

#### 51.6.2.4.1 Operating System (**Os**)

The AUTOSAR OS provides *real-time OS services* to both the other system software modules and the application SWCs of AUTOSAR. The **Os** module is configured and scaled statically, provides a priority-based scheduling policy and protective functions with respect to memory and timing at runtime, and is designed to be hostable on low-end controllers.

Similar to the OSEKtime dispatcher tables (see Section 51.3), AUTOSAR **Os** provides so-called schedule tables consisting of one or more *expiry points*. Hereby, each expiry point is assigned an offset measured in **Os** ticks from the start of the schedule table. Once an expiry point is reached, the action corresponding to the expiry point (e.g., the activation of a task or the setting of an event) is processed. At runtime, the **Os** iterates over the schedule table, processing each expiry point in turn. The iteration is driven by an **Os** counter. In order to facilitate the execution of tasks synchronous to external events (e.g., synchronous to the FlexRay communication schedule), schedule tables can be synchronized to external time sources (e.g., FlexRay's global time).

As far as protection against timing violations is concerned, AUTOSAR **Os** does not provide deadline monitoring (as does OSEKtime **OS**) but provides the facility to track the execution time of each task and ISR and to raise an error in case either exceeds its statically assigned execution time budgets. Regarding memory protection, AUTOSAR **Os** uses the memory protection unit of the MCU to provide coarse-grained memory protection of so-called OS applications, which are a group of related tasks, against each other.

With AUTOSAR 4.0 onward, the AUTOSAR **Os** provides support for multicore MCUs by allowing different OS applications to be statically allocated to the different cores and by supporting data exchange among these cores by means of the inter-OS application communicator (**Ioc**) submodule.

The **Os** module acts as a *service SWC* (see Section 51.6.1.1) toward the **Rte**, thus making its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### 51.6.2.4.2 Basic Software Scheduler (**SchM**)

The basic software (BSW) scheduler module provides means to embed other AUTOSAR system software module implementations into the context of an AUTOSAR **Os** task or ISR, trigger main processing functions of the system software modules, and apply data consistency mechanisms for these modules. Just like the **Rte** provides the infrastructure for SWCs by embedding runnable entities in a task context, the **SchM** module *provides the infrastructure for the other system software modules* by embedding their main processing functions (termed schedulable entities) in a task context.\*

Due to the rather similar functionality between **Rte** and **SchM** and to allow for global scheduling and data consistency optimizations (e.g., automatic elision of data consistency mechanisms in case the involved runnable and schedulable entities cannot preempt one another), the **SchM** module's functionality is integrated into the **Rte** with AUTOSAR 4.0 onward.

#### 51.6.2.4.3 MCU Driver (**Mcu**)

The MCU driver module provides services for *basic microcontroller initialization, power-down functionality, microcontroller reset*, and microcontroller-specific functions required from other system

\* Usually, the main processing functions of multiple system software modules are embedded into a single task in order to keep the number of tasks required for execution of the whole AUTOSAR system software low.

software modules. The initialization services of the MCU driver module allow a flexible and application-related MCU initialization in addition to the start-up code.\* The services of the MCU driver include the initialization of the MCU's clock, initialization of the MCU's phase-locked loop (PLL), the initialization of clock prescalers, and the configuration of the MCU's clock distribution. Furthermore, the MCU driver takes care of the initialization of the MCU's RAM sections, facilitates the activation of the MCU's reduced power modes (i.e., putting the MCU into a low-power mode), and provides a service for enforcing a reset of the MCU and a service for obtaining the reset reason from the MCU hardware.

#### **51.6.2.4.4 ECU State Manager (EcUM)**

The ECU state manager module manages all aspects of the ECU related to the Off, Run, and Sleep states of that ECU and the transitions between these states like *start-up and shutdown*. In detail, the ECU state manager is responsible for the initialization and deinitialization of all system software modules including Os and Rte; cooperates with the ComM, and hence indirectly with Nm, to shut down the ECU (Off state) when needed; manages all wake-up events; and configures the ECU for Sleep state when requested. In order to fulfill all these tasks, the EcUM makes use of the services provided by the Mcu module and implements some important protocols: the *run request protocol*, which is needed to coordinate whether the ECU must be kept alive or is ready to shut down; the *wake-up validation protocol* to distinguish *real* wake-up events from *erratic* ones; and the *time-triggered increased inoperation protocol*, which allows to put the ECU into an increasingly energy-saving Sleep state depending on the duration of the ECU's inactivity.

With AUTOSAR 4.0, a distinction between an ECU state manager module with *fixed state machine* (EcUMfixed) and an ECU state manager module with *flexible state machine* (EcUMflex) has been made. While the former one implements all of the previously mentioned services by itself in a rather fixed way, the latter one focuses on the early start-up and late shutdown phases and initializes only a small number of other system software modules, delegating the rest of the functionality to the basic software mode manager (BswM) module.

The EcUM module (flex and fixed) acts as a *service SWC* (see Section 51.6.1.1) toward the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### **51.6.2.4.5 Basic Software Mode Manager (BswM)**

The basic software mode manager module arbitrates requests from application SWCs or other system software modules based on statically configurable rules and performs actions based on the arbitration result. Hereby, these configurable rules comprise one or more logical conditions that are combined into a logical expression and a list of actions that are executed in case the logical expression evaluates to true or to false, respectively. The logical conditions can be mode switches performed and announced by other modules and/or SWCs. The performed actions can be mode switches performed by the BswM itself that are announced towards other modules and/or SWCs. Thus, the BswM, on the one hand, acts as a mode user and, on the other hand, as a mode manager.

Additionally, the BswM is in charge of the part of initialization and shutdown process that is not covered by the EcUMflex module.

The BswM module acts as a *service SWC* (see Section 51.6.1.1) toward the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### **51.6.2.4.6 Diagnostic Event Manager (Dem)**

The diagnostic event manager module realizes part of the diagnostic functionality within AUTOSAR. The Dem is responsible for *processing and persistently storing diagnostic events/errors*<sup>†</sup> and associated data (so-called freeze frame data). To facilitate the persistent storage of these DTCs, the Dem makes use

---

\* The start-up code itself is not within the scope of AUTOSAR.

<sup>†</sup> These events can be mapped to UDS/OBD DTCs by means of the Dem's module configuration.

of the services provided by the NvM. Application SWCs as well as other system software modules can raise diagnostic events by means of Dem API calls.

The diagnostic events registered by the Dem serve as triggers for state updates of the Fim and thus might lead to the inhibition of certain runnables. Upon request of the Dcm, the Dem provides an up-to-date list of the currently stored DTCs that are then sent to a tester client by means of the Dcm services.

The Dem module acts as a *service SWC* (see Section 51.6.1.1) toward the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### 51.6.2.4.7 Function Inhibition Manager (Fim)

Like the Dem and the Dcm module, the function inhibition manager realizes part of the diagnostic functionality in AUTOSAR. The Fim is responsible for providing an *execution control mechanism for the runnables* of application SWCs and system software modules. By means of the Fim, these runnables can be inhibited (i.e., deactivated) according to the Fim's static configuration. The functionalities of the runnables are assigned to a unique function identifier (FID) along with an inhibit condition for that particular FID. The functionalities poll for the permission state of their respective FIDs before execution. If an inhibit condition is true for a particular FID, the corresponding functionality is not executed anymore.

The Fim is closely related to the Dem since diagnostic events and their status information can serve as possible inhibit conditions. Hence, functionality that needs to be stopped in case of a failure can be represented by a particular FID. If the failure is detected and the event is reported to the Dem, the Fim then inhibits the FID and therefore the corresponding functionality.

The Fim module acts as a *service SWC* (see Section 51.6.1.1) towards the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### 51.6.2.4.8 Watchdog Driver (Wdg)

This module provides services for initialization, changing of the operation mode (Fast, Slow, Off) and *triggering the ECU's watchdog device*. In case an ECU provides multiple different watchdog devices (e.g., internal and external devices), a dedicated Wdg module has to be present for each of the devices.

#### 51.6.2.4.9 Watchdog Interface (WdgIf)

In case of more than one watchdog device and corresponding watchdog driver (e.g., both an internal software watchdog and an external hardware watchdog) is being used on an ECU, the watchdog interface module allows the watchdog manager module (see following texts) to select the correct watchdog driver—and thus the watchdog device—via a device index while retaining the API and functionality of the underlying driver. Thus, the WdgIf module provides *uniform access to services of the underlying watchdog drivers* like mode switching and triggering.

#### 51.6.2.4.10 Watchdog Manager (WdgM)

The watchdog manager module is intended to *supervise the program execution* of application SWCs or other system software modules, so-called supervised entities. The WdgM provides services for *alive supervision* for periodic software, *deadline supervision* for aperiodic software, and *logical supervision* monitoring of the program flow of a supervised entity. Hereby, the WdgM monitors each supervised entity autonomously and derives a local status for this supervised entity. The aggregation of the local status of all supervised entities then yields a global status. Based on this global supervision status, the WdgM decides whether or not to trigger the hardware watchdog via the WdgIf's API. Hereby, the set of supervised clients, the desired degree of supervision, and the individual timing constraints are defined by configurable parameters of the WdgM.

The WdgM module acts as a *service SWC* (see Section 51.6.1.1) toward the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### 51.6.2.4.11 Development Error Tracer (Det)

The development error tracer module is the central instance where all other system software modules *report detected development errors* to. The API parameters handed to the Det allow for tracing the source and kind of error, namely, the module and the function in which the error has been detected and the type of the error. The functionality behind the API of the Det is not specified in AUTOSAR. Possible functionalities could be the setting of debugger breakpoints within the error reporting API, the counting of the number of reported errors, the logging of Det calls together with the passed parameters to a RAM buffer for later analysis, and the sending of reported errors via some communication interface (e.g., CanIf) to external logger devices.

The Det module acts as a *service SWC* (see Section 51.6.1.1) towards the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### 51.6.2.4.12 Diagnostic Log and Trace (Dlt)

The diagnostic log and trace module provides services for the logging of errors, warnings, and information messages to SWCs, as well as to the Det and the Dem module. Additionally, the Dlt modules provide trace functionality to the Rte to facilitate the tracing of relevant Rte events (see Section 51.6.1.4). The detail of both the logging and the tracing can hereby be controlled during runtime. The logged/traced data are then transmitted via the PduR or by means of the data transmission services of the Dcm.

The Dlt module acts as a *service SWC* (see Section 51.6.1.1) toward the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### 51.6.2.4.13 General-Purpose Timer Driver (Gpt)

The general-purpose timer (GPT) driver module provides services for starting and stopping a functional timer instance within the hardware GPT module and thus *provides exact and short-term timings* for use in the Os or within other system software modules where an Os alarm service causes too much overhead. Individual time-out periods (*single-shot mode*) as well as repeating time-out periods (*continuous mode*) can be generated via the Gpt module. The user can configure whether a notification shall be invoked when the requested time-out period has expired. These notifications can be enabled and disabled at runtime. Both, the relative time elapsed since the last notification occurred and the time remaining until the next notification will occur, can be queried via API functions of the Gpt module. Additionally, the Gpt module provides a set of free-running timers together with API functions to obtain the current time value of these free-running timers.

#### 51.6.2.4.14 Time Service (Tm)

The time service module builds on the free-running timers of the Gpt module and provides a set of *predefined timers with defined tick duration in physical time units* (e.g., microseconds) together with a set of API functions to reset these timers, to (busy) wait for a guaranteed minimum waiting time, to set the timers to a reference time, and to compute the time difference between the current time and this reference time. This way, compatibility of time-based functionality is ensured for all platforms that support the required predefined timers.

#### 51.6.2.4.15 Synchronized Time Base Manager (StbM)

The synchronized time base manager *provides a global time* to other system software modules or to the application SWCs (so-called time base users). Hereby, the StbM itself, however, does not provide any facility (e.g., synchronization protocols) for establishing a synchronized time base across multiple ECUs, but relies on the existence of such protocols at so-called time base providers (e.g., the FrIf that provides a synchronized time base for all ECUs connected to the specific FlexRay network). To facilitate a triggering of runnable entities of SWCs or schedulable entities of other system software modules that is synchronous to this global time base, the StbM is capable of synchronizing the schedule tables of the Os to this global time base.

The StbM module acts as a *service SWC* (see Section 51.6.1.1) towards the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### 51.6.2.4.16 Crypto Service Manager (Csm)

The crypto service manager module provides *cryptographic services* based on a software library or on a dedicated hardware module. These services include means to compute and verify checksums and hash values over a block of data elements; means to generate random numbers; means for symmetric and asymmetric en- and decryption of blocks of data; message authentication and integrity checks by means of digital signatures; derivation of one or more secret keys using a key derivation function; wrapping, serialization, and deserialization of keys for transportation purposes; and generation and secure exchange of shared keys.

The Csm module acts as a *service SWC* (see Section 51.6.1.1) towards the Rte and thus makes its services available to (application) SWCs via dedicated ports (see Section 51.6.1.2).

#### 51.6.2.4.17 Core Test (CorTst)

The core test module provides means to perform *functional tests related to basic functionality of the MCU's core(s)*, namely, tests verifying the correct functionality of the core's registers, the arithmetic logical unit (ALU), the interrupt controller and the exception handling, the memory interface, the memory protection unit (MPU) in case one is available, and the cache controller (w.r.t., cache coherency and consistency). Similar to the RamTst module, the CorTst module supports *foreground tests* that are performed upon request via the module's API functions and *background test* that are performed in a periodic manner.

### 51.6.2.5 Libraries

In addition to the previously described system software modules, AUTOSAR defines a set of libraries. These libraries are neither assigned to any particular software layer nor to a particular substack. Instead, *all layers* (including the SWCs of the application layer) as well as integration code are allowed to make use of these libraries. To facilitate this flexible use, AUTOSAR defines that the code of libraries

- Is executed synchronously in the context of the caller in the same protection environment
- Is only allowed to call other library code (i.e., library code must not call the code of system software modules or SWCs)
- Is reentrant and does not have any internal state
- Does not require any initialization

As far as the provided functionality is concerned, AUTOSAR specifies libraries for fixed point mathematics, floating point mathematics, interpolation routines for fixed point data, interpolation routines for floating point data, bit handling routines, end-to-end communication protection, CRC calculation, filtering routines, and cryptographical routines.

In the following, a subset of the libraries provided by AUTOSAR is discussed in more detail:

*Cyclic Redundancy Check (Crc):* The cyclic redundancy check (CRC) library provides bitwise, table-based, and (if available) hardware-assisted computation of CRCs using different 8-, 16-, and 32-bit generator polynomials, namely, the SAE-J1850 CRC8, the CCITT-FALSE CRC16, and the IEEE-802.3 CRC32 used for Ethernet.

*End-to-End Protection (E2e):* The end-to-end protection library provides means to protect safety-related data exchange at runtime against the effects of faults along the communication path, like random HW faults (e.g., corrupt registers of a CC), interference (e.g., due to EMC), and systematic faults within the communication substack. To this end, additional control fields like CRCs or sequence counters are added to the transmitted data at the sender side. At the receiver side, these control fields are evaluated and checked for correctness. In case this check fails, the received

data are marked as corrupt. In order to support the use with different fault hypotheses, multiple profiles that differ in the added control fields (e.g., the strength of the used CRC) are supported.

*Crypto Abstraction (Ca1):* From the functional point of view, the crypto abstraction library provides the same services as the Csm module. The only difference is the fact that the Ca1 is implemented as a library adhering to all the restrictions AUTOSAR imposes on the implementation of libraries (see earlier text).

## 51.7 Summary

---

Since 1993, the major automotive companies are striving for the deployment of standard software modules in their applications to achieve an increased test coverage and higher reliability, requirements that can only be met if standardized modules are used at various system levels.

This chapter provided an overview of today's industry practices in standardized automotive system software. Existing standards proposed by industry partnerships like OSEK/VDX, ASAM, and AUTOSAR and by standardization authorities like ISO have been presented. Of all presented approaches, the AUTOSAR partnership that started off in May 2003 and started putting software modules according to the AUTOSAR standard into production vehicles in 2008 (BMW being first to deploy AUTOSAR in its 7 Series car followed by Daimler, Audi, VW, PSA, and others) turns out to be the most promising one.

This is, on the one hand, due to the fact that several of already approved standards used today (like OSEK OS and COM, ASAM XCP, and ISO transport layer and diagnostics) heavily inspired the corresponding AUTOSAR standards, ensuring that the AUTOSAR standard is built on well-proven technology. On the other hand, the AUTOSAR open standard has massive industrial backup: all AUTOSAR core members including seven of the world's biggest vehicle manufacturers accounting for about 55% of all vehicles produced are strongly committed to the project and released the first revision of the AUTOSAR 4.1 specifications in March 2013, which will serve as a solid basis for future automotive software development.

### 52.1 Introduction

---

Controller area network (CAN) is one of the leading fieldbuses for networked control systems. Since the history of CAN goes back to 1986, some billion CAN nodes have been sold worldwide. At the beginning of the 1980s, most communication technologies, which were available at that time, were not adequate for in-car communications and unable to fulfill the requirements of a number of automotive applications. For these reasons, Bosch GmbH started a project to develop a new serial bus system suitable for use in passenger cars. The development of CAN also involved academic partners and was partially supported by Intel, which was interested as a potential semiconductor producer.

The new fieldbus called *automotive serial controller area network* (ASAN) appeared officially in 1986 at the Society of Automotive Engineers (SAE) congress in Detroit and included a number of features that were not present in competing fieldbus architectures. ASAN was a real multimaster network, and its access technique to the shared medium resembled the popular carrier sense multiple access (CSMA) approach. The peculiar aspect, however, was the adoption of a new distributed, nondestructive arbitration mechanism, which was able to solve contentions on the bus in real time, by leveraging priorities

implicitly assigned to the colliding messages. The robustness and fault tolerance of the whole system were also enhanced by the introduction of several error detection and management mechanisms.

In the following years, controller chips for CAN began to appear and spread on the market. Intel and Philips, in particular, were the main producers, even though they followed two significantly different approaches, whose consequences can be observed in components available off the shelf still today. Actually, the Intel solution (often referred to as FullCAN in the literature) required less host CPU power, since most of the communication and network management functions were carried out directly by the network controller. Philips, instead, relied on a simpler architecture (BasicCAN), which, by contrast, imposes a higher load on the microcontroller used to interface the CAN device.

In the last two decades, all main semiconductor vendors including Siemens, Motorola, and NEC have produced and shipped millions of CAN chips, mainly to car manufacturers such as Mercedes-Benz, Volvo, Saab, Volkswagen, BMW, Renault, and Fiat.

The Bosch specification (CAN version 2.0) was submitted for international standardization at the beginning of the 1990s. The proposal was approved and published as the ISO 11899 standard at the end of 1993 and contained the description of the medium access protocol and the physical layer architecture. In 1995, an addendum to ISO 11898 was approved to describe the extended format for message identifiers (IDs).

The CAN specification was then revised and reorganized, and it was split into several separate parts: Part 1 [ISO1] defines the CAN data link protocol, whereas part 2 [ISO2] and part 3 [ISO3] specify the high-speed (non-fault-tolerant) and low-speed (fault-tolerant) physical layers, respectively. Part 4 [ISO4] specifies the protocol for time-triggered communication (TTCAN). More recently, part 5 [ISO5] was added that deals with high-speed medium access units (MAUs) with low-power mode.

Recently, Bosch GmbH has introduced some significant changes to the architecture of CAN, to cope with some limitations of this technology that could not be tackled by simply improving the hardware and software. The new CAN with flexible data rate (CAN FD) specification introduces enhanced mechanisms based on some ideas first published in 1999 [CEN99] that should grant a high level of competitiveness to CAN for many years to come.

### 52.1.1 CAN in Automotive Applications

The main application area of CAN has been (and still is) the automotive industry. Here, CAN is adopted as an in-vehicle network for engine management and comfort electronics (e.g., doors control, air conditioning, lightning) as well as for some infotainment (information and entertainment) functions. Currently, it is also being used as on-vehicle network for special-purpose cars, such as police cars and taxis.

The different CANs in a vehicle are connected through gateways. In many cases, this functionality is implemented in the dashboard, which may be equipped with a local CAN for connecting displays and instruments.

High-speed CANs (e.g., 500 kbit/s) that comply with the ISO 11898-2 physical layer are used by a vast majority of carmakers in power engine systems. In addition, most passenger cars produced in Europe are equipped with CAN-based multiplex networks, which connect doors and roof control units as well as lighting and seat control units. These networks are often based on either the ISO 11898-3 fault-tolerant physical layer or the ISO 11898-5 high-speed physical layer with low-power functionality.

Sometimes, also infotainment devices are interconnected by means of CAN. Besides proprietary solutions, the SAE defined the Intelligent Transportation Systems (ITS) Data Bus on CAN (IDB-C) application profile in the ITS Data Bus series of specifications (SAE J2366), which is based on high-speed CAN (29-bit IDs) with a bit rate of 250 kbit/s. Finally, a CAN-based diagnostic interface is provided by several passenger cars for connecting diagnostic tools to in-vehicle networks. Several international standards are available in this case, namely, ISO 16765 (diagnostics on CAN including Keyword 2000 over CAN), ISO 14229-1 (Unified Diagnostic Services), and ISO 15031 (onboard diagnostic standard).

Electronic control units (ECUs) for vehicles (e.g., passenger cars, trucks, and buses) are in most cases OEM specific. This means they comply with the specifications dictated by the original equipment manufacturer (OEM) for what concerns both the physical (e.g., bit timing) and higher-layer protocols. While trucks and buses mostly rely on J1939-based specifications, proprietary higher-layer protocols and profiles are usually adopted in passenger cars. As an exception, CAN-based diagnostic interfaces to scanner tools usually comply with the ISO standards.

### 52.1.2 CAN in Automation and Networked Control Systems

Even though it was conceived explicitly for vehicle applications, at the beginning of the 1990s, CAN began to be adopted in different scenarios, too. Standard documents provided satisfactory specifications for the lower communication layers, but did not offer guidelines or recommendations for the upper part of the OSI protocol stack, in general, and for the application layer in particular. This is why the earlier applications of CAN outside the automotive scenario (i.e., textile machines, medical systems) adopted ad hoc monolithic solutions. The *CAN in Automation* (CiA) users' group, founded in 1992, was originally concerned with the specification of a *standard CAN application layer* (CAL). This effort led to the development of the general-purpose CAL specification. CAL was intended to fill the gap between the distributed application processes and the underlying communication support, but in practice, it was not successful, the main reason being that, as CAL is really application independent, each user had to develop suitable profiles for his or her specific application fields.

In the same years, Allen-Bradley and Honeywell started a joint distributed control project based on CAN. Although the project was abandoned a few years later, Allen-Bradley and Honeywell continued their works separately and focused on the higher protocol layers. The results of those activities were the Allen-Bradley *DeviceNet* solution and the Honeywell *Smart Distributed System* (SDS). For a number of reasons, SDS remained, in practice, a solution internal to Honeywell Microswitch, while the development and maintenance activities for DeviceNet were soon switched to the *Open DeviceNet Vendor Association* (ODVA). Thereafter, DeviceNet has been widely adopted in the United States in a number of factory automation areas, becoming a serious competitor to widespread solutions such as PROFIBUS-DP and INTERBUS.

Besides DeviceNet and SDS, other significant initiatives were focused on CAN and its application scenarios. *CANopen* was conceived in the framework of the European Esprit project automation and control systems for production units using an installation bus concept (ASPIC) by a consortium led once again by Bosch GmbH. The purpose of CANopen was to define a profile based on CAL, which could support communications inside production cells. The original CANopen specifications were further refined by CiA and released in 1995.

Later on, CANopen, DeviceNet, and SDS became European standards, CANopen as an embedded network for machine distributed control and the other two for factory and process automation. In particular, they are defined in standard EN 50325 [EN1], where part 2 is about DeviceNet [EN2], part 3 deals with SDS [EN3], and part 4 describes CANopen [EN4].

## 52.2 CAN Protocol Basics

The CAN communication architecture is structured according to the well-known layered approach foreseen by the ISO OSI reference model. However, as in most currently existing networks conceived for use at the field level in automated manufacturing environments, only few layers have been included in its protocol stack. This is to make implementations more efficient and inexpensive. Fewer protocol layers, in fact, imply reduced processing delays when receiving and transmitting messages, as well as simpler communication software (which has typically to run on embedded devices with low computational power). CAN specifications [ISO1,ISO2,ISO3], in particular, include only the *physical* and *data link* layers, as depicted in Figure 52.1.

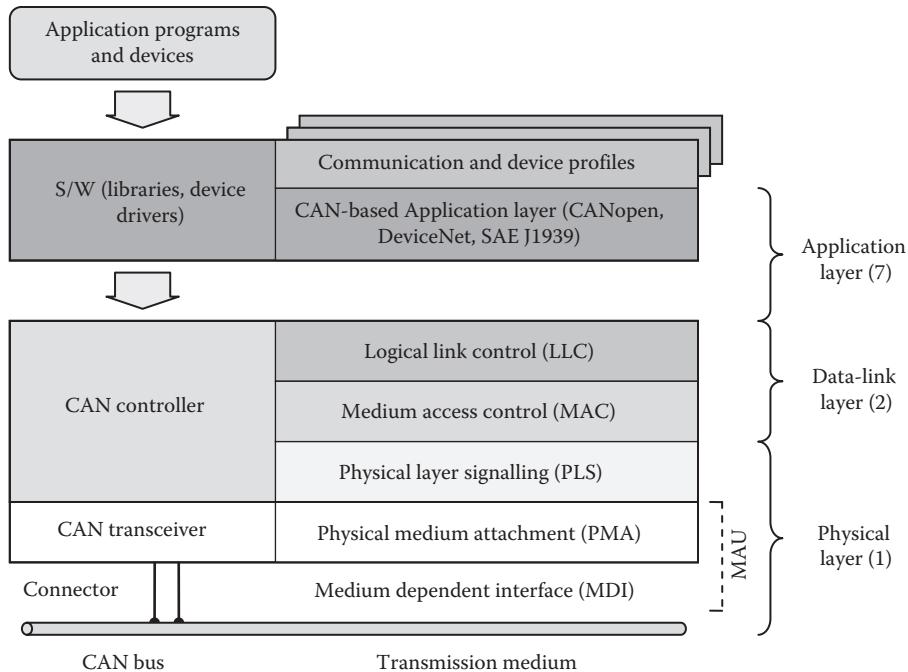

FIGURE 52.1 CAN protocol stack.

The physical layer is aimed at managing the actual transmission of information over the communication medium and is typically concerned with electrical aspects. Bit timing and synchronization, in particular, belong to this layer. The CAN physical layer is conceptually subdivided into three sublayers, namely, the *physical layer signaling* (PLS), the *physical medium attachment* (PMA), and the *medium dependent interface* (MDI). The PLS mostly defines aspects related to bit representation, timing, and synchronization. These features, which are valid for any CAN system, are described in the ISO 11898-1 document [ISO1]. Together, the PMA and the MDI make up the MAU, which is the part of the physical layer that actually couples the node to the transmission medium. The PMA covers functional circuitry to deal with transmission and reception over the bus and may also provide means for detecting bus failures. The MDI, instead, is about the mechanical and electrical interfaces between the MAU and the physical medium (i.e., the CAN bus).

The data link layer has to do with the (reliable) exchange of data between network nodes. It is located immediately above the physical layer and exploits the PLS services to carry out the transfer of frames (encoded as sequences of bits). The data link layer is conceptually split into two separate sublayers, namely, the *medium access control* (MAC) and the *logical link control* (LLC). Basically, the main purpose of the MAC is managing the access to the shared transmission support, by providing a mechanism aimed at coordinating the use of the bus, so as to avoid unmanageable collisions. MAC functions include frame encapsulation and decapsulation, arbitration, error checking and signaling. The LLC, instead, offers the user (either application programs or entities belonging to upper protocol layers) a proper interface, which is characterized by a well-defined set of communication services. In addition, it provides the ability to decide whether or not an incoming message is relevant to the node.

It is worth noting that CAN specifications are very flexible concerning both the actual implementation of LLC services and the choice of the physical support, whereas modifications to the behavior of the MAC sublayer are not admissible.

As mentioned before, and unlike most fieldbus networks, CAN specifications do not include any application layer natively. However, a number of such protocols exist that rely on CAN and ease the design and implementation of complex systems.

## 52.2.1 Physical Layer

PLS functions, as defined in [ISO1], are embedded directly into CAN controllers. Conversely, MAUs are mostly implemented in transceivers and are defined in separate documents. For instance, ISO 11898-2 [ISO2] and ISO 11898-3 [ISO3] deal with high- and low-speed communications, respectively, whereas ISO 11898-5 defines the power modes of high-speed MAUs (for systems requiring low-power consumption while no active communication is taking place on the bus). The definition of the actual interface to the medium (i.e., connectors) is usually covered in other documents: in fact, the ISO specifications mentioned earlier are aimed at standardizing the most important electrical parameters and not to define mechanical and material characteristics.

### 52.2.1.1 Network Topology and Cabling

CANs are based on a shared bus topology. Buses have to be terminated with resistors at each end (the recommended nominal impedance is  $120\ \Omega$ ), so as to suppress signal reflections. For the same reason, standard documents state that the topology of a CAN should be as close as possible to a single line. Stubs are permitted for connecting devices to the bus, but their length should be kept as short as possible. For example, at the transmission speed of 1 Mbit/s, the maximum allowed length of a stub is 30 cm.

Several kinds of transmission media can be used:

- A two-wire bus enables differential signal transmissions and ensures reliable communications [ISO2]. In this case, shielded twisted pair can be used to further enhance the immunity to electromagnetic interferences. A lower-speed, fault-tolerant version is defined in [ISO3].
- A single-wire bus is a simpler and cheaper solution that features lower immunity to interferences and is mainly suitable for use in comfort electronics in automotive applications [J2411].
- A point-to-point connection over unscreened twisted pair according to [ISO9] can be used, for instance, in the heavy-duty truck industry for communication between the tractor and one or more trailers.
- An optical transmission medium, which ensures complete immunity to electromagnetic noise, can be used in hazardous environments. Fiber optics can be adopted to interconnect different CAN subnetworks through repeaters. This is done to cover plants that spread over large areas.

Several bit rates can be selected for the network, the most commonly adopted being in the range from 50 kbit/s to 1 Mbit/s. Actually, CAN does not mandate any specific value for this parameter, nor does it suggest preferred transmission speeds (which, instead, are typically defined by CAN-based application protocols). One Mbit/s is the maximum allowable bit rate according to the CAN specifications. For reasons explained in the following, it was never increased and is still the same as in the very first version of the CAN specification.

The maximum extension of a CAN depends directly on the bit rate. The exact relation between extension and bit rate also involves parameters such as the latencies introduced by communication hardware and in particular transceivers and optocouplers. When the network speed is not too high, the rule of thumb is that the mathematical product between the length of the bus and the bit rate has to be approximately constant. For example, the maximum extension allowed for a 500 kbit/s network is about 100 m and increases up to about 500 m when the bit rate is 125 kbit/s.

Signal repeaters can be used to take care of signal attenuation, so as to increase the network extension, especially when large plants have to be covered and the bit rate is low to medium. However, since they introduce small additional delays on communication paths, the maximum distance between any two nodes is actually shortened at high bit rates. Using repeaters also enables network topologies different from the bus (e.g., trees or combs). In these cases, a good design may increase the effective area that is covered by the network, by minimizing the worst-case end-to-end delay between any two nodes.

It is worth noting that, unlike other networks conceived for the use in factory and process automation, such as PROFIBUS-PA, there is in general no cost-effective way in CAN to use the very same wire for carrying both signals and power. This is because signals sent over the CAN have a non-null DC component. However, power can be easily provided to devices by including an additional pair of wires in the CAN cable, as foreseen in several commercial solutions such as CANopen and DeviceNet.

Curiously enough, the use of standard connectors is not prescribed in CAN specifications. Instead, several companion or higher-level application standards exist that define their own connectors and pin assignments. CiA, for example, recommends the use of 9-pin D-SUB connectors for general-purpose applications [CiA102], while CANopen [CiA303] and DeviceNet also suggest other kinds of connectors (5-pin ministyle, microstyle, open-style, etc.). In addition, those documents include recommendations for bus lines, cables, and standardized bit rates, which were not included in the original CAN specifications.

### 52.2.1.2 Bit Encoding

The electrical interface of a node to the CAN bus is conceptually based on a scheme that resembles open-collector circuits. As a consequence, the signal level on the bus can assume two complementary values, which are denoted symbolically as *dominant* and *recessive*. Overall, the behavior of the CAN bus can be described as follows: If the output level of at least one node is dominant, then the level of the whole bus is dominant; conversely, if the output level of every node is recessive, the bus is recessive. The dominant level corresponds to the logical value 0, while the recessive level is the same as the logical value 1.

CAN relies on the *non-return-to-zero* (NRZ) bit encoding, which achieves very good efficiency, for example, noticeably higher than Manchester encoding. Clocking information is not encoded separately from data. Instead, bit synchronization in each node is achieved by means of a *digital phase locked loop* (DPLL), which extracts the timing information directly from the bit stream read on the bus. In particular, edges in the signal are used for synchronizing receiver clocks, so as to compensate unavoidable oscillator tolerances and drifts.

To provide a satisfactory level of synchronization between the sender and receivers, the transmitted bit stream must include a sufficient number of edges. To state it in better terms, the bus is not allowed to stay at the same level for long time intervals when transmission is taking place, so as to avoid clock misalignments and, possibly, bit slips. This is achieved in CAN by means of the so-called *bit stuffing* technique. In practice, whenever five consecutive bits at the same value (either dominant or recessive) appear in the transmitted bit stream (also including those bits that have possibly been added by the bit stuffing mechanism), the transmitting node inserts one additional *stuff bit* at the complementary value, as depicted in Figure 52.2. This is done transparently and automatically by CAN controllers. Stuff bits can be easily and safely removed by receiving nodes, so as to obtain the original stream of bits back.

From a theoretical point of view, the maximum number of stuff bits that may be added when transmitting a CAN message is one every 4 bits in the original frame. For example, in the rightmost part of Figure 52.2, the original bit stream alternates sequences of four consecutive bits at the dominant level followed by 4 bits at the recessive level (actually, the first stuff bit is triggered by a sequence consisting of 5 bits at the same level). This results in a domino effect that leads to the worst case for the number of added stuff bits. As a consequence, the encoding efficiency of the physical layer can be as low as 80%. However,

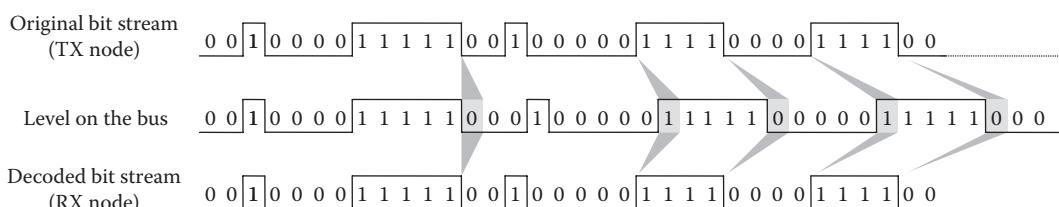

FIGURE 52.2 Bit stuffing technique.

the influence of bit stuffing in real operating conditions is noticeably lower than the theoretical value mentioned earlier. Simulations [CEN12] show that, on the average, only a few stuff bits are effectively added to each frame, depending on the size of the ID and data fields as well as on the generation law for signal values (traffic model).

Despite it is quite efficient, the bit stuffing technique has one main drawback, since the time taken to send a frame over the bus is not fixed. Instead, it depends on the content of the frame itself. This might cause annoying jitters on reception times, which affect the actuation and sampling on remote devices directly. Suitable techniques are available to cope with this undesired effect, which try to reduce the number of stuff bits inserted by the CAN controller by altering the content of the data field before transmission. Either scrambling techniques (which operate by carrying out the exclusive OR (XOR) between the payload and an alternating bit pattern) or true encoding schemes like 8B9B [CEN13] are worth mentioning to this purpose.

Not all the fields in a CAN frame are encoded according to the bit stuffing mechanism, which applies, in particular, only to the initial part of the frames, from the start of frame (SOF) up to the cyclic redundancy check (CRC) sequence (included). The remaining fields (up to the end of the frame) have a fixed form and are not stuffed.

### 52.2.1.3 DPLL Operation

Operations in the DPLL are timed by the so-called time quanta ( $T_q$ ). The time quantum is derived from the local oscillator period through a prescaler. As shown in Figure 52.3, the bit time in CAN is divided into four segments, namely, *synchronization segment* (SYNC\_SEG), *propagation time segment* (PROP\_SEG), and two *phase buffer segments* (PHASE\_SEG1 and PHASE\_SEG2). Each segment consists of an integral number of time quanta.

Receivers sample the level on the bus on every time quantum. By detecting the edges in the signal read from the bus, which can be inferred from such samples, the DPLL in each receiver is enabled to recover the clocking information of the transmitter. In this way, the actual reading of the current bit is carried out by the CAN controller at the moment in time that maximizes the likelihood of detecting the correct value, which is referred to as *sample point*.

The internal bit timing is adjusted by the DPLL using either the *hard synchronization* or *resynchronization* mechanisms. Whenever a recessive-to-dominant transition occurs while the bus is idle, a hard synchronization takes place that involves all nodes in the network. This transition corresponds to the leading edge of the SOF bit sent by the node that initiated transmission first, and it is located at the very beginning of the frame. The net effect is that, following a hard synchronization, the originating edge is forced to lie within the SYNC\_SEG of every node. In all other cases, edges cause a resynchronization. The main difference is that the effect of resynchronization depends on the offset (error) between the actual position of the edge and the point in time when it was expected.

The *phase error* ( $e$ ) of an edge is measured in time quanta and is defined as follows:

- $e = 0$  when the edge on the bus lies within the intended SYNC\_SEG in the receiver node (timely edge).
- $e > 0$  means that the edge on the bus is received late (but before the sample point of the current bit).
- $e < 0$  means that the edge on the bus is received early (but after the sample point of the previous bit).

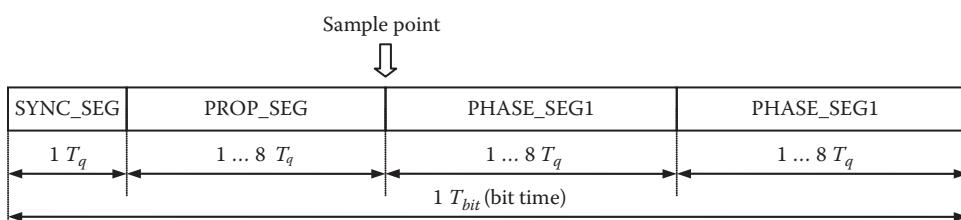

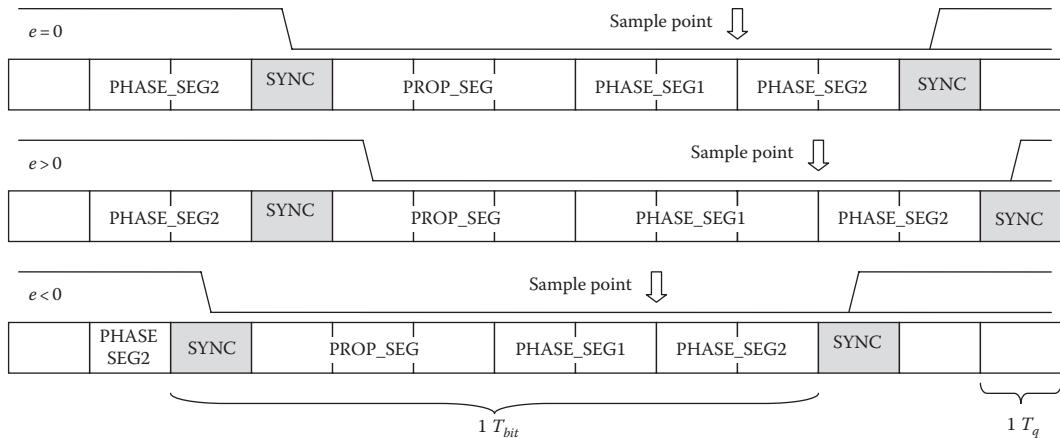

FIGURE 52.3 Segments in a bit time.

**FIGURE 52.4** DPLL synchronization rules.

When the absolute value of the phase error is less than or equal to the *resynchronization jump width* (SJW), a parameter that can be configured in the CAN controller, the effect of resynchronization is just the same as hard synchronization. Otherwise, the amount of correction is bounded by SJW. SJW is programmable in the range between 1 and the minimum between 4 and PHASE SEG1. Corrections take place by either lengthening PHASE SEG1 for the current bit when the edge is late or shortening PHASE SEG2 of the previous bit (during which the level transition was detected) when the edge is early. Such timing rules are sketched in Figure 52.4.

This approach can cope with differences between the actual frequencies of local clocks, as well as drifts, up to about 1.58%. Increasing the duration of the propagation delay segment permits enlarging the network size for any given bit rate. On the other hand, increasing the nominal width of the phase segments allows using cheaper oscillators, which are affected by worse tolerances. The choice on the actual DPLL parameter values in programming the CAN controller is typically a trade-off between system requirements and constraints.

A few additional rules help in reducing the likelihood that glitches on the bus—due, for instance, to short electromagnetic disturbances—may cause synchronization errors. They are basically as follows:

1. Synchronization can occur only once within every bit time; subsequent edges after the first one are ignored and do not restart the local timing.
2. An edge is used for synchronization only if the bus value immediately after the transition differs from the value read at the previous sampling point.

## 52.2.2 Frame Format

The CAN protocol foresees four kinds of frames only, namely, *data*, *remote*, *error*, and *overload* frames. Data and remote frames are quite similar, and the CAN specification [ISO1] defines both a *base* (or standard) and an *extended* format for them. These formats mainly differ for the size of the ID and for a few bits in the arbitration field. In particular, the base frame format (as defined in the CAN 2.0A specification) adopts 11-bit IDs, which means that up to 2048 different IDs are available to applications running in the same network (several older CAN controllers, however, only support IDs in the range 0–2031). The extended frame format (introduced with CAN 2.0B), instead, assigns 29 bits to the ID, so that up to half a billion different objects could exist, in theory, in the same network. This is a fairly high value, which is virtually sufficient for any kind of application.

Using extended IDs in a network that includes 2.0A compliant CAN controllers, too, usually leads to unmanageable transmission errors, which make the network unstable. Thus, a third category of

CAN controllers was developed, known as 2.0B passive: they can manage the transmission and reception of standard frames in a correct way, while extended frames are simply ignored in order not to hang the network.

It is worth noting that, in most practical cases, the number of different objects allowed by the base frame format is more than adequate. Since standard CAN frames are shorter than the extended ones because of the shorter arbitration field, they enable higher communication efficiency (unless part of the payload is moved into the arbitration field). As a consequence, they are typically adopted in the majority of the existing CAN systems, and also, most of the CAN-based higher-layer protocols, such as CANopen and DeviceNet, basically rely on this format.

Error and overload frames are also very similar. They are not used to convey any explicit information. Rather, they are sent automatically by the CAN controller when some specific condition occurs. In particular, the first kind of frame is used to notify error conditions, whereas the second is used to provide some additional delay between subsequent data (or remote) frames.

The format of all CAN frames, as defined in the current CAN 2.0B specification, is described in detail in the following subsections.

### 52.2.2.1 Data Frame

Data frames are used to send information over the network. Each CAN data frame begins with an SOF bit at the dominant level, as shown in Figure 52.5. Its role is to mark the beginning of the frame as in serial transmissions carried out by means of conventional Universal Asynchronous Receiver-Transmitters (UART). The SOF bit is also used to synchronize the receiving nodes.

Immediately after the SOF bit, the *arbitration field* follows, which includes both the *ID* field and the *remote transmission request* (RTR) bit. The arbitration field as a whole is used by the MAC sublayer to detect and manage the priority of the frame whenever a collision occurs. In particular, the lower the numerical value of the ID, the higher the priority of the frame.

As the name suggests, the ID field also uniquely denotes in the whole network (at the LLC level) the content of the frame that is being exchanged. Its encoding is different for either the base or extended frame format. In the former case, a single 11-bit ID field is used, whereas in the latter, an 11-bit *base ID* is followed by an 18-bit *ID extension*, so as not to change the format too much with respect to the base frame. In both cases, the ID is sent starting from the most significant bit up to the least significant one.

The RTR bit is used to discriminate between data and remote frames. Since a dominant value of RTR denotes a data frame while a recessive value stands for a remote frame, a data frame has a higher priority than a remote frame with the same ID. This helps when they are sent at the same time by different nodes in the network.

The control field comes next to the arbitration field and consists of 6 bits. In the case of base frames, the first two control bits are the identifier extension (IDE) bit (which coincides with the reserved bit r1

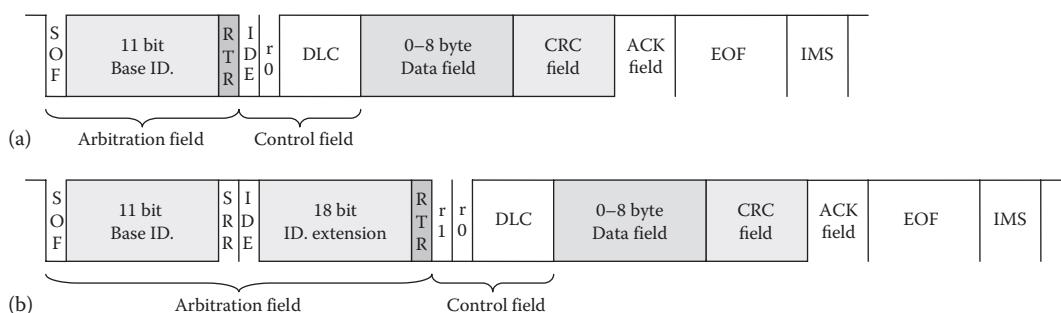

FIGURE 52.5 Format of CAN data frames. (a) Base frame format and (b) extended frame format.

in CAN 2.0A) and the reserved bit r0. The IDE bit discriminates between base and extended frames: in particular, a dominant value identifies the first format, whereas a recessive value is used for the second. Since the IDE bit is dominant in base format frames while it is recessive in the extended ones, standard frames have precedence over their extended counterparts when the same base ID is considered.

It is worth noting that, in extended frames, the IDE bit belongs conceptually to the arbitration field, as well as the *substitute remote request* (SRR) bit—a placeholder that precedes the IDE bit and is sent at recessive value to preserve the structure of the frames. In this case, the IDE bit is followed by the 18-bit IDE and, again, terminates with the RTR bit. The control field follows immediately and begins with the two reserved bits r1 and r0. Reserved bits shall be sent by the transmitting node at the dominant value, while receivers simply ignore their values.

The last 4 bits of the control field (after the reserved bit r0) are the *data length code* (DLC), which specifies the length (in number of bytes) of the data field. For the DLC field, values ranging from 0 to 8 are allowed. According to the most recent specifications, higher values (from 9 to 15) can also be used for application-specific purposes. In this case, however, the length of the data field is assumed to be 8 bytes.

The data field is used to store the effective payload of the frame. According to the OSI terminology, it represents the *service data unit* (SDU) of the data link layer also known as link-layer SDU (LSDU). As such, it is not interpreted in any way by the CAN protocol (and by controllers). One of the reasons why the size of the data field is limited to 8 bytes at most is to ensure a high degree of responsiveness, by reducing the maximum transmission time for frames and hence the priority inversion phenomenon.

The CRC and acknowledgment (ACK) fields are placed after the data field. The CRC is made up of a *cyclic redundancy check* sequence encoded on 15 bits, which is followed by a CRC delimiter at the recessive value. The kind of CRC adopted in CAN is particularly suitable to cover short frames (i.e., counting less than 127 bits). The acknowledgment field, instead, is made up of 2 bits, that is to say the ACK slot is followed by the ACK delimiter. Both of them are sent at the recessive level by the transmitter. The ACK slot, however, is overwritten with a dominant value by each node that receives the frame correctly (i.e., no error is detected up to the ACK field). It is worth noting that the ACK slot is actually surrounded by 2 bits at recessive level, namely, the CRC and ACK delimiters. By means of the ACK bit, the transmitting node is enabled to discover whether or not at least one node in the network has received the frame correctly.

The frame is closed by the *end of frame* (EOF) field, made up of seven recessive bits, which notifies all the nodes the end of an error-free transmission. In particular, the transmitting node assumes that the frame has been exchanged correctly if no error is detected until the last bit of the EOF field, while for receivers, the frame is valid if no error is detected until the last but one (i.e., sixth) bit of EOF. When a bus error occurs that affects the very last bit of the frame, this could lead to duplicate message transmissions. In fact, in this case, the sender node retransmits a frame that was already accepted by receivers, which may cause problem when, for instance, incremental or differential values are exchanged.

Subsequent frames are interleaved by the *interframe space*, which is made up of the *intermission* (IMS), possibly followed by a period of time (whose duration is arbitrary) during which no transmission takes place (*bus idle*). The IMS, which consists of three recessive bits, is mandatory and effectively separates any two consecutive frames exchanged on the bus. It is used both to permit the hardware in the CAN controller to prepare for a new transmission/reception and for overload notification. The bus turns in the idle state only if no node has a message ready to be sent.

### 52.2.2.2 Remote Frames

Remote frames are very similar to data frames. The only difference is that they do not carry data (i.e., the data field is not present in this case). They are used to request the transmission of a given message by a remote node. It is worth noting that the requesting node does not know who the actual producer of the relevant information is. It is up to receivers to discover the one that has to reply, by checking the ID field in the remote frame.

Indeed, the DLC field in remote frames is not used by the CAN protocol. However, it should be set to the same value as in the corresponding data frame, so as to cope with situations where several nodes send remote requests with the same ID at the same time (this is legal in a CAN). In that case, it is necessary for the different request frames to be perfectly identical, so that the related signals on the bus can overlap totally in the case of a collision.

It should be noted that, because of the way the RTR bit is encoded, if a request is made for an object at the same time as the transmission of that object is started by the producer, the contention is resolved in favor of the data frame.

### 52.2.2.3 Error and Overload Frames

Error frames are used to notify nodes in the network of error occurrences. They consist of two fields, namely, the *error flag* and the *error delimiter*. There are two kinds of error flags: active error flags are made up of six dominant bits, while passive error flags consist of six recessive bits. An active error flag either violates the bit stuffing rules or corrupts the fixed-format parts of the frame that is currently being exchanged. Hence, it enforces an error condition that is detected by all the stations connected to the network. Each node that detects an error condition starts transmitting an error flag on its own. In this way, as a consequence of the transmission of an error flag, a sequence of dominant bits appears on the bus whose duration lies between 6 and 12 bit times.

The error delimiter, instead, is nominally made up of eighth recessive bits. After the transmission of an error flag, each node starts sending recessive bits and, at the same time, it monitors the bus level until a recessive bit is detected. At this point, the node sends seven more recessive bits, hence completing the error delimiter.

Overload frames can be used by slower receivers to slow down operations on the network. This is done by adding extra delays between consecutive data and/or remote frames. The overload frame format is very similar to error frames. In particular, it is made up of an overload flag followed by an overload delimiter. It is worth noting that today's CAN controllers are very fast, so overload frames have become almost useless.

### 52.2.3 Medium Access Technique

The MAC mechanism, on which CAN relies, is basically the CSMA scheme. When no frame is being exchanged, the network is idle; in this condition, the level on the bus is steadily recessive. Before transmitting a frame, a node has to sense the state of the network. If the network is found idle, the frame transmission begins immediately; otherwise, the node must wait for the end of the current frame transmission (including the IMS). Each frame starts with the SOF bit at the dominant level. This bit disrupts the recessive state of the bus and informs all the other nodes that the network is no longer in the idle state.

Although not very frequently, two or more nodes might start sending their frames exactly at the same time. This may actually occur, because both the delay between the beginning of the bit time and the sample point in controllers and propagation delays on the bus, even though very small, are anyway greater than zero. Thus, one node might start its transmission while the SOF bit of another frame is already travelling on the bus. In this case, a collision occurs. In CSMA networks that are based on collision detection, such as nonswitched Ethernet, this unavoidably leads to the corruption of all frames involved, which implies that they have to be retransmitted. The consequence is a waste of time and a net decrease of the available network bandwidth. In high load conditions, this may lead to congestion: when the number of collisions is so high that the net throughput on the Ethernet network falls below the frame arrival rate, the network is stalled.

Unlike Ethernet, the medium access technique of CAN is able to resolve such *contentions* in a deterministic way, so that neither time nor bandwidth is wasted. As a consequence, congestion conditions can no longer occur and all the theoretical system bandwidth is effectively available for communications.

For the sake of truth, it should be said that contentions in CAN occur more often than one may think. In fact, when a node that has a frame ready to be sent finds the bus busy or loses the contention, it waits

for the end of the current frame exchange and, immediately after the IMS has elapsed, it starts transmitting. Here, the node may compete with other nodes for which, in the meanwhile, a transmission request was issued. The likelihood that this event takes place is basically related to the number of nodes in the network and their message generation rate. In this case, different nodes synchronize on the falling edge of the first SOF bit that is sensed on the network.

The access technique described earlier implies that, as long as transmission errors are neglected, a CAN could be modeled as a work-conservative system. This means, if there is (at least) one message waiting for transmission in the whole system, it will be sent as soon as the bus becomes idle. CAN effectively behaves like a system-wide distributed priority queue, where messages are selected for transmission according to a priority order.

### 52.2.3.1 Bus Arbitration

The most distinctive feature of the MAC sublayer of CAN is the ability to resolve in a deterministic way any collision that may occur in the network. In turn, this is made possible by the arbitration mechanism, which is able to find out the most urgent frame each time a contention for the bus takes place between two or more nodes.

The CAN arbitration scheme operates by stopping transmissions of all frames involved except the one that is assigned the highest priority (i.e., the lowest ID). The arbitration technique exploits the peculiar behavior of the physical layer of CAN, which conceptually provides a wired-AND connection among all nodes. In particular, bus level is dominant (i.e., at the 0 level) if at least one node is sending a dominant bit; vice versa, the bus level is recessive (i.e., at the 1 level) only if all nodes are currently sending recessive bits (or, which is the same, if they are not transmitting).

Each node transmits the arbitration field on the bus serially, starting with the most significant bit, immediately after the SOF bit and by means of the so-called *binary countdown* technique. While transmitting, each node compares the level sensed on the bus to the value of the bit it is writing out. If a node is transmitting a recessive bit, whereas the level on the bus is dominant, the node understands it has lost the contention and withdraws immediately. In particular, it ceases transmitting and sets its output port to the recessive level, so as not to interfere with other contending nodes. At the same time, it switches to the receiving mode to be ready to read the incoming (winning) frame.

The binary countdown technique ensures that, in the case of a collision, all nodes that are sending lower-priority frames will abort their transmissions by the end of the arbitration field. Only the node that is sending the frame with the highest priority is allowed to complete the transmission of the arbitration field. It does not even realize that a collision has occurred.

A prerequisite for the correct behavior of arbitration is that, in every CAN, no two nodes can be transmitting frames having the same ID at the same time. If this is not the case, in fact, unmanageable collisions could take place, which in turn cause transmission errors. Because of the automatic retransmission feature of CAN controllers, this would almost certainly lead to a burst of errors on the bus, until the involved stations are disconnected by the fault confinement mechanism. This implies that, in general, only one node can be the producer of each object.

One exception to this rule is given by frames that have no data field, such as remote frames and data frames where the DLC field is set to 0. In this case, should a contention occur involving frames with the same ID, they would overlap perfectly and hence no collision would effectively occur. The same is also true for data frames whose data field is not empty, provided that its content is the same for all the frames sharing the same ID. However, it makes no sense in general to send frames with a fixed data field. Another exception to the rule is when a mechanism is defined by the upper protocol layers that provide nodes the exclusive use of shared IDs at runtime.

All the nodes that lose a contention have to retry the transmission as soon as the exchange of the current (winning) frame ends. They all try to send their frames again, immediately after the IMS is read on the bus. It is worth noting that a new collision may still possibly take place, which could also involve frames sent by nodes for which a transmission request was issued while the bus was busy.

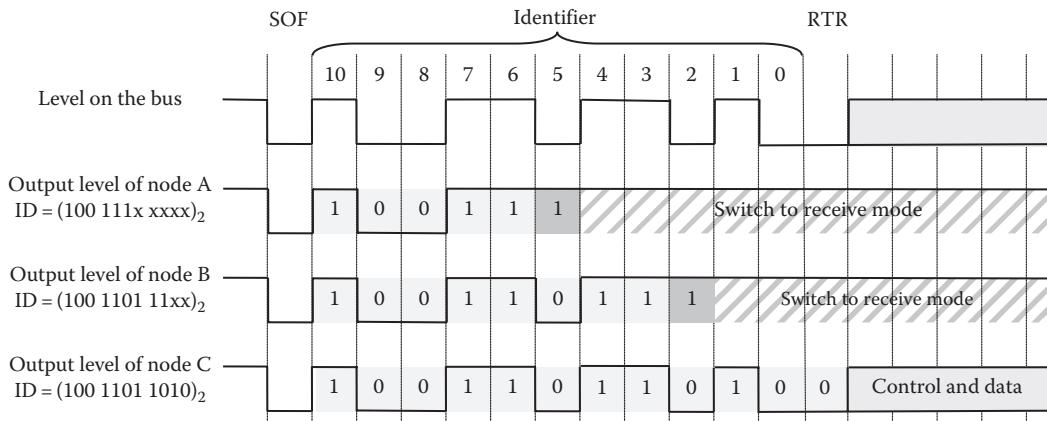

FIGURE 52.6 Arbitration phase in CAN.

An example that shows the detailed behavior of the arbitration phase in CAN is depicted in Figure 52.6. Here, three nodes (which have been indicated symbolically as A, B, and C) start transmitting at the same time—possibly at the end of the IMS following the previous frame exchanged over the bus. The ID of the frame sent by each node is specified in the figure (only the relevant prefix is shown for clarity). As said before, as soon as a node understands it has lost the contention, it switches its output level to the recessive value, so that it no longer interferes with the other transmitting nodes. This event takes place when bit ID<sub>5</sub> is sent for node A, while the same happens at bit ID<sub>2</sub> for node B. Node C manages to send the whole ID field, without incurring in discrepancies between the transmitted bit and the level detected on the bus. Therefore, it is the only winner of the arbitration and keeps on transmitting the remaining part of the frame (which starts with the control field).

### 52.2.3.2 Error Management

One of the fundamental requirements, which drove the definition of the CAN protocol, was the need to have a robust communication system, that is, one that is able to detect most transmission errors. Hence, particular care was taken in defining the support for error management. The CAN specification foresees five different mechanisms to detect transmission errors:

1. *Cyclic redundancy check*: When transmitting a frame, the originating node appends a 15-bit CRC to the end of the frame, which is calculated on the part of the frame included between the SOF bit and the data field. Receiving nodes reevaluate the CRC for the frame read from the bus and check if it matches the value included in the frame (from a practical viewpoint, the CRC checking is carried out by controllers in a slightly different way). If this is not the case, a CRC error is issued. Unlike other mechanisms, which are able to discover errors as soon as they occur, error detection takes place in this case only after the CRC sequence has been completely received. Generally speaking, the CRC used in CAN is able to discover up to five erroneous bits arbitrarily distributed in the frame and also errors bursts including up to 15 bits.
2. *Frame check*: Fixed-format fields in the received frames can be easily checked against their expected values. For example, the CRC and ACK delimiters as well as the EOF field have to be at the recessive level. If one or more illegal bits are detected, a form error is immediately generated.
3. *Acknowledgment check*: Every node verifies whether the ACK bit in the frame that is being sent has been changed to the dominant value or it is still at the recessive level. In the latter case, an acknowledgment error is immediately issued. Such a kind of check is useful, for example, to discover if there are other active nodes in the network. In particular, it can be used by the transmitting node to determine if its connector (or the related link) is broken.

4. *Bit monitoring*: Each transmitting node compares the level on the bus to the value of the bit that is being written out. Should a mismatch occur, a bit-monitoring error is generated immediately. It is worth noting that the same does not hold for the arbitration field and the acknowledgment slot. Such a check is very effective to detect bus errors that affect also the transmitting node (like global errors). Conversely, it is mostly useless in the case of local errors that only affect one or more receivers.
5. *Bit stuffing*: Each node verifies whether or not the bit stuffing rules have been violated in the portion of the frame from the SOF bit up to the end of the CRC sequence. Whenever 6 bits of identical value are read from the bus, a bit stuffing error is generated immediately. Although this error detection mechanism depends directly on the bit stuffing technique employed in CAN for bit encoding, the two concepts are distinct and should not be confused.

The theoretical residual probability that a corrupted message goes undetected in a CAN—under realistic operating conditions—has been evaluated to be less than  $4.7 \times 10^{-11}$  times the message error rate. Unfortunately, the bit stuffing mechanism may sometimes interfere with the CRC calculation. In particular, a pair of bit flip errors (the former turning a stuff bit into a regular bit and the other doing the opposite) could create error bursts longer than 15 bits, which might trick the CRC mechanism to think no error has taken place. The net result is that the actual residual error probability may be higher than expected, which could be a nonnegligible issue for highly dependable systems.

#### 52.2.4 Fault Confinement

A *fault confinement* mechanism has been included in the CAN specification so as to prevent any node, which is not operating properly, from sending corrupted frames repeatedly and blocking the whole network. The fault confinement unit supervises the correct operation of the MAC sublayer and disconnects the node from the bus if it becomes defective. This mechanism has been conceived so as to discriminate, as long as it is possible, between permanent failures and short disturbances that may cause bursts of errors on the bus. According to this approach, each node can be in one of three states, namely, *error active*, *error passive*, and *bus off*.

The error-active state corresponds to the normal operating mode and is entered automatically upon device start-up or reset. Basically, error-active and error-passive nodes take part in the communication in the same way. The main difference is that, after transmitting a frame, an error-passive node has to wait for eight additional bits after the IMS before starting a new transmission (*suspend transmission*). Moreover, they react to error conditions differently. Active error flags and passive error flags are used alternatively in the two cases. This is because an error-passive node has already experienced several errors, so it should avoid interfering with the network operations. A passive error flag cannot corrupt the ongoing exchange of a frame that is sent by another node.

The fault confinement unit uses two counters to track the behavior of the node with respect to transmission errors: they are known as *transmission error count* (TEC) and *receive error count* (REC), respectively. The rules by which TEC and REC are managed are actually not trivial; however, they can be summarized as follows: Each time an error is detected, the counters are increased by a given amount, whereas successful exchanges decrease them by one. Furthermore, the amount of the increase for the nodes that first detected the error is higher than the nodes that simply replied to the error flag. In this way, counters are likely to increase more quickly in faulty nodes than in nodes that are operating properly, even when sporadic errors, caused, for instance, by electromagnetic noise, are considered.

When one of the error counters exceeds a first threshold (127), the node is switched to the error-passive state, so as to try not to affect the network. It may return to the error-active state as soon as both counters fall below (or equal) the threshold given earlier. When a second threshold (255) is exceeded, instead, the node is switched to the bus-off state. At this point, it can no longer transmit any frame on the network. It can be switched back to the error-active state only after it has been reset and reconfigured.

## 52.2.5 Logical Link Control

The communication model offered to users of the LLC sublayer is based on the exchange of objects between nodes, where each object is assigned its own ID and has an associated value (LSDU). According to the ISO specification [ISO1], the LLC of CAN provides two communication services only, namely, *L\_DATA* and *L\_REMOTE*. The former is used to broadcast the value of any object over the network, whereas the latter is used to ask for the value of an object to be broadcast by its (remote) producer. Both services are unacknowledged and mapped on the corresponding frames defined at the MAC level. From a practical point of view, the service primitives are implemented directly in the hardware by all the CAN controllers currently available off the shelf.

### 52.2.5.1 Model for Information Exchanges

Unlike most network protocols conceived for the use in automated factory environments, which rely on node addressing, CAN adopts an object addressing scheme. In other words, messages are not tagged with the address of the destination (and, possibly, originating) node(s). Instead, each piece of information that is exchanged over the network (often referred to as an *object*) is assigned a unique ID, which denotes unambiguously the meaning of the object itself in the whole system.

This fact has important implications on the way communications are carried out in CAN. In fact, identifying objects according to their meaning rather than to the nodes they are intended for allows implicit multicasting and makes it very easy for the control applications managing interactions among devices according to the producer/consumer paradigm.

In CAN, the exchange of information takes place according to the three phases shown in Figure 52.7:

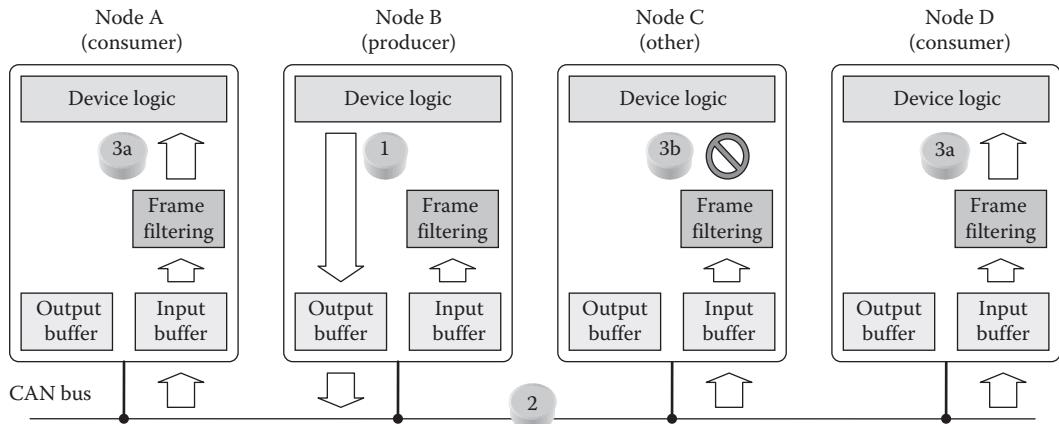

1. The producer of a given piece of information encodes and sends the related frame on the bus using the MAC transmission services. The arbitration technique will transparently resolve any contention that may occur.
2. Because of the intrinsic broadcast nature of the underlying physical bus, the frame is propagated all over the network, and every node reads its content in a local receive buffer.
3. The *frame acceptance filtering* function in each node determines whether or not information in the frame is relevant to the node itself. In the former case, the frame is passed to the upper communication layers; from a practical point of view, this means that the CAN controller raises an interrupt to the local device logic (e.g., microcontroller), which will then read and use the information in the frame. On the contrary, the frame is simply ignored, which means discarding information.

In the sample data exchange depicted in Figure 52.7, node B is the producer of some kind of information, which is relevant to (i.e., consumed by) nodes A and D. This requires that nodes A and D configure explicitly their filtering function to accept the related frames. Node C, instead, is not interested in such information, which is therefore rejected (this is the default behavior of the filtering function).

### 52.2.5.2 Model for Device Interaction

The access technique of CAN makes this kind of network particularly suitable for distributed systems where devices interact according to the producer/consumer model. In this case, data frames are used by producer nodes to broadcast new values over the network, and each datum is identified unambiguously by means of its ID. Unlike networks based on the producer/consumer/arbitrer model such as the Factory Instrumentation Protocol (FIP), information is sent in CAN as soon as it becomes available from either the control application(s) or the controlled physical system (by means of sensors), without any need for the intervention of a centralized arbiter. This noticeably improves the responsiveness and robustness of the whole system and makes CAN particularly suitable for networked embedded systems.

CANs work equally well when they are used to interconnect devices in systems based on the more conventional master/slave model, which relies on the request–reply paradigm. In this case, the master can

**FIGURE 52.7** Producer/consumer model.

use remote frames to solicit some data to be sent on the network. As a consequence, the data producers reply with data frames carrying the relevant values.

It is worth noting that this kind of interaction is implemented in CAN in a way that is fairly more flexible than in conventional master/slave networks, such as PROFIBUS-DP. In CAN, in fact, the reply (data frame) does not need to follow the request (remote frame) immediately. In other words, the network is not kept busy while waiting for the device reply. This allows the system bandwidth to be, in theory at least, fully available to applications. Furthermore, the reply containing the requested value is broadcast on the whole network, and hence it can be read by all the interested nodes (consumers), besides the one that actually issued the remote request.

### 52.2.5.3 Implementation

According to their internal architecture, CAN controllers can be broadly classified into two categories, namely, *BasicCAN* and *FullCAN*. Differences do not concern the communication protocol, which shall comply to the MAC specification completely, but the interface between the network controller and the host that uses the LLC services.

Conceptually, BasicCAN controllers are provided with one transmit and one receive buffer, as conventional UARTs. The frame filtering function, in this case, is generally left to application programs (i.e., it is under control of the host microcontroller), even though some kind of filtering can typically be carried out by the CAN controller itself. So as to avoid overrun conditions, a double-buffering scheme based on shadow receive buffers is usually provided. This enables the reception of a new frame from the bus while the previous one is being read by the host controller. An example of controller based on the BasicCAN architecture is the PCA82C200 component by Philips. In more recent controllers, such as the Philips SJA 1000, an extended 64-byte receive First In, First Out (FIFO) queue is available.

FullCAN implementations, instead, foresee a number of internal buffers that can be configured to either receive or transmit some particular messages. In this case, the filtering function is implemented directly by the CAN controller. When a new frame, which is of interest for the node, is received from the network, it is stored in the related buffer, where it can be subsequently read by the host controller. Typically, newer values overwrite the older ones. Mechanisms could be also provided in order to avoid overrun conditions. The Intel 82526 and 82527 CAN controllers are based on the FullCAN architecture.

Because of the architectural choices mentioned earlier, FullCAN controllers free the host controller from a number of activities, and hence they are historically considered more powerful than BasicCAN components. It is worth noting, however, that recent CAN controllers are typically packed with many advanced functions and are somehow able to offer the advantages of both architectures. Hence, the earlier claim is no longer true in absolute terms.

## 52.3 Schedulability of CANs

---

Since CAN relies on a shared communication support, whose access is regulated through an arbitration phase carried out at runtime, transmissions may unavoidably suffer from delays because of messages that are currently being sent by the other nodes. From a theoretical point of view, the MAC sublayer of CAN can be seen as a (distributed) priority-based nonpreemptive queuing system, where messages are queued for transmission and are served according to their priority. This is why several techniques are available in literature, most of which inspired to fixed-priority scheduling in real-time operating systems, to analyze timings in a CAN. In particular, under well-defined yet typical assumptions, the maximum latency can be evaluated, which a message may experience before it is delivered to the intended destination. This, in turn, enables assessing whether or not a given set of messages, which have to be exchanged over the network as a consequence of the operations of a real-time distributed control application, is actually schedulable (i.e., if the related timing requirements can always be fulfilled).

From a general viewpoint, nothing can be said about communication latencies if messages are generated in a completely arbitrary way. However, if the message generation pattern is known in advance (e.g., either each message is exchanged periodically or a minimum time has to elapse between subsequent instances of the same message), worst-case transmission times can be evaluated. This is also true when the message generation processes on the different nodes are not coordinated in any way, as it happens in CANs. If nodes are not synchronized, the different message transmission patterns are displaced by arbitrary and unknown offsets.

The theory behind schedulability analysis in CAN is not trivial and has been clearly introduced and thoroughly explained in several papers [TIN94,TIN94b,TIN95]. Such an approach may sometimes lead to erroneous conclusions about worst-case transmission times. For this reason, a revised study was published in 2007 [DAV07]. In the following, however, the original approach, which first appeared in 1994, will be described, since it is much simpler and provides nevertheless useful results in many real-world operating conditions, particularly for the networked embedded systems typically found in most automotive applications.

### 52.3.1 Communication Requirements

The first step to analyze schedulability in CAN is the exact definition of the set of messages exchanged by the distributed control application. In particular, we are interested in message streams, which must not be confused with single message instances even though, for the sake of simplicity, the term message is typically used in the literature to refer to both concepts.

#### 52.3.1.1 Message Set

Let  $MS = \{m_1, m_2, \dots, m_n\}$  be the *message set* (MS), where  $m_i$  is the  $i$ th message (stream) in MS, characterized by its own unique ID. From the point of view of applications, each message  $m$  is completely described by means of the following parameters:

- *Period ( $T_m$ )*: It is the cycle time for periodically exchanged messages, as specified by the control application. Instead, for messages generated sporadically,  $T_m$  specifies the minimum interarrival time, that is, the shortest time interval that may elapse between any two consecutive generations of the same message.
- *Deadline ( $D_m$ )*: It is the maximum time allowed for completing the reception of message  $m$  by the intended destination node(s). If exceeded, the correct behavior of the control application is no longer ensured. In the worse cases, safety problems might occur as well. This is clearly a condition that should never happen in properly operated systems and is what schedulability analysis is aimed to verify.
- *Jitter ( $J_m$ )*: This parameter (also known as queuing jitter) models all latencies that are not directly caused by the communication protocol. It depends on both hardware overheads (basically

related to the actual implementation of network controllers and, in particular, the host controller interface) and latencies introduced by the communication software (drivers) and task scheduler (operating system). In particular,  $J_m$  is the maximum delay that may affect message  $m$ , from the instant its transmission is set (at the application level) to the time it is ready to be sent on the bus (i.e., when it is actually available to the protocol machine inside the communication controller).

- **Size ( $S_m$ ):** It is the size (in bytes) of the message payload. In real control systems, each message may include one or more signals (as defined by the application), each one encoded on several bits. These bit strings are first concatenated and then padded to the next byte boundary.

### 52.3.1.2 Schedulability of Messages

The parameters given earlier are defined in the design phase of the control system and do not depend on the characteristics of the network used to interconnect devices. Starting from them, several other parameters can be derived, which are explicitly related to the underlying network and are used to assess the message schedulability:

- **Transmission time ( $C_m$ ):** It is the longest time taken to transmit all the bits of the frame, which embeds message  $m$ , serially over the bus (in the case the transmitting node wins the arbitration).
- **Utilization ( $U_{MS}$ ):** It is the fraction of the available network bandwidth needed to exchange all the messages included in the MS.
- **Queuing delay ( $w_m$ ), also known as *transmission delay*:** It is the maximum delay the transmitting node of message  $m$  may experience before it wins the arbitration and starts the successful transmission of the frame on the bus.
- **Worst-case response time ( $R_m$ ), also denoted WCRT:** It is the maximum end-to-end delay that message  $m$  may experience under the specified conditions (namely, for the given MS and bit rate  $R$  on the network).

The frame transmission time  $C_m$  can be computed directly from the message size  $S_m$  by taking into account the overhead due to the protocol control information added by CAN. Besides fixed-size fields (ID, DLC, CRC, etc.), a variable number of stuff bits may be inserted into the transmitted frame by the bit stuffing mechanism, which depends on the actual content of the frame. As schedulability has always to be ensured, irrespective of the information carried by messages, the worst case has to be considered (i.e., when the maximum number of stuff bits are added).

Each standard CAN frame includes 44 bits of protocol control information (SOF, arbitration, control, CRC, ACK, and EOF fields), while 3 bits have to be added for the IMS. The bit stuffing mechanism affects 34 of those bits (from the SOF bit up to the CRC field) and the payload (data field) too. Up to one stuff bit could be added, in the worst case every 4 bits of the original frame (an exception is at the very beginning of the frame, where the first stuff bit can be added only after 5 bits). This means that the (worst-case) transmission time  $C_m$  for frames with 11-bit IDs is simply given by

$$C_m = \left( 34 + 8 \cdot S_m + \left\lfloor \frac{34 + 8 \cdot S_m - 1}{4} \right\rfloor + 13 \right) \cdot T_{bit} = (55 + 10 \cdot S_m) \cdot T_{bit}$$

where

$T_{bit} = 1/R$  is the bit time in the network

$R$  is the transmission speed

In a similar way, the transmission time for frames with extended 29-bit IDs can be found as

$$C_m = (80 + 10 \cdot S_m) \cdot T_{bit}$$

A message  $m$  is said to be schedulable if its WCRT is lower than its deadline, that is,  $R_m \leq D_m$ . The MS is said to be schedulable if the response time of every message in the set is always (i.e., in the worst case, too) lower than or equal to its deadline. This means that the condition in the earlier text must hold for every message  $m$  in MS, that is,

$$R_m \leq D_m, \quad \forall m \in MS$$

Schedulability in a CAN is related to the network utilization  $U_{MS}$ . This parameter can be easily computed from the transmission time and period of messages in the set as

$$U_{MS} = \sum_{m \in MS} \frac{C_m}{T_m}$$

Obviously, utilization must be strictly less than 1 in order to have a feasible schedule (this means that the offered load is not allowed to exceed the available bandwidth). It is worth noting, however, that despite this condition being necessary, it is not sufficient to ensure schedulability. Generally speaking, the closer the utilization is to one, the higher the likelihood that the MS is not schedulable.

Besides the characteristics of the MS, schedulability also depends heavily on the priority assignment. Priorities define an order relation on the MS. As a consequence, for every message  $m \in MS$ , two subsets of MS are defined:  $hp(m)$  includes all messages whose priority is higher than  $m$ , whereas  $lp(m)$  includes those having lower priority. For such sets, the property  $MS = hp(m) \cup \{m\} \cup lp(m)$  holds. Suitable techniques exist to assign priorities so that some properties hold for the MS. Ensuring schedulability is with no doubt the first and most important goal of such techniques.

### 52.3.1.3 Worst-Case Response Time

The most interesting element in schedulability analysis is certainly the WCRT for messages, which can be defined as follows. Let  $t_{sched(m)}$  be the time when the transmission for message  $m$  is scheduled in the originating node,  $t_{start(m)}$  the time when the transmission of the related frame can be started on the bus (irrespective of whether or not the transmitting node will win the contention),  $t_{win(m)}$  the time when the successful transmission is started (i.e., when the node actually wins the contention), and  $t_{end(m)}$  the time when the frame is completely and successfully received at the intended destination(s). For simplicity, transmission errors will be neglected in the following.

As shown in Figure 52.8, the WCRT  $R_m$  for message  $m$  can be evaluated as the sum of the worst-case jitter  $J_m$  introduced by the hardware and software in the transmitting node, the queuing delay  $w_m$  possibly caused by lost bus contentions, and the time  $C_m$  taken to transmit all the bits of the frame serially over the bus, that is,

$$R_m = J_m + w_m + C_m$$

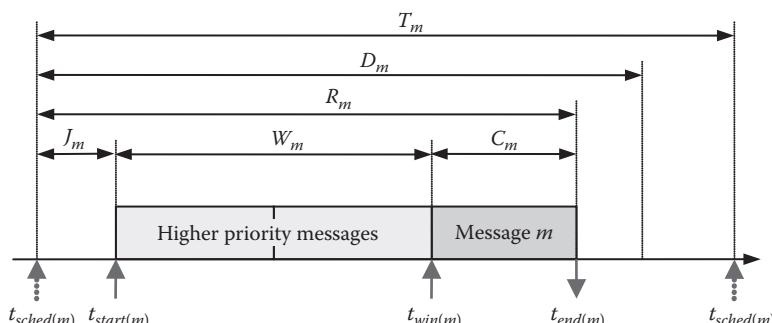

FIGURE 52.8 WCRT in CAN.

### 52.3.2 Schedulability Analysis

The main problem in schedulability analysis is evaluating the queuing delay  $w_m$  for every message in the MS. In fact,  $J_m$  can be derived from data sheets for what concerns latencies introduced by the communication hardware and code profiling for the software, whereas  $C_m$  can be easily computed from network parameters as described earlier.

#### 52.3.2.1 Queuing Delay

The queuing delay  $w_m$  basically includes two kinds of contributions. The first one is due to one message at most, with a priority lower than  $m$ , which may already be in the process of being transmitted at time  $t_{start(m)}$ . The second concerns every message, with a priority higher than  $m$ , that might be generated in the time interval when message  $m$  is queued waiting to be sent. It is worth remembering that in CAN, the (numerically) lower the ID, the higher the priority.

The first kind of contribution gives rise to the so-called blocking time ( $B_m$ ). It can be computed as the maximum transmission time, evaluated among every message  $k$  where  $k$  is (numerically) greater than  $m$ :

$$B_m = \max_{k \in hp(m)} (C_k)$$

The latter contribution, instead, is known as *interference*. Every message  $j$ , whose priority is higher than  $m$ , which is generated (or queued waiting for transmission) in the interval from  $t_{start(m)}$  to 1 bit time after  $t_{win(m)}$ , in fact, certainly wins the contention with message  $m$  and delays it.

Let  $h_j(T)$  be the maximum number of times the higher-priority message  $j \in hp(m)$  may interfere with message  $m$  over a time interval  $T$ . Basically,  $h_j(T)$  depends on the duration  $T$  of the interval and the generation period of message  $j$ :

$$h_j(T) = \left\lceil \frac{T + J_j + t_{bit}}{T_j} \right\rceil$$

In the example shown in Figure 52.9, message  $j$  interferes with message  $m$  three times, each time making  $m$  lose the contention. On the contrary, the fourth instance of message  $j$  no longer causes interference, as the related transmission may only take place after time  $t_{sched(j,4)}$ , when the SOF bit of message  $m$  has already been successfully sent (and no other higher-priority message is assumed waiting for transmission at that time).

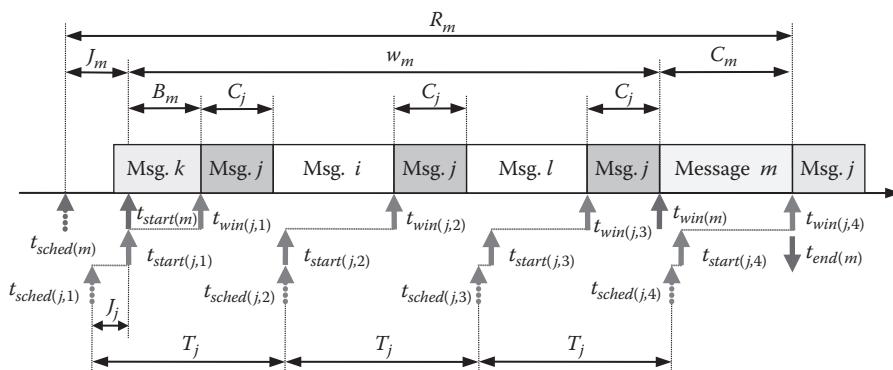

FIGURE 52.9 Blocking time and interference.

It is worth noting that the generation of interfering messages could be affected by jitters as well, because of the overhead caused by network controllers. This is the case of message  $j$  in Figure 52.9, whose first occurrence is delayed by  $J_j$ .

### 52.3.2.2 Recurrence Relation

As seen in the earlier text, the interference message  $m$  may suffer in a given time interval is related to its duration. This also holds when the considered time interval is the same as the queuing delay  $w_m$ .  $w_m$ , however, depends on both the blocking time  $B_m$  and the interference caused by all the higher-priority messages. The contribution to the overall interference due to each single message  $j$  depends in turn on its duration  $C_j$  and how many times it may interfere (at most) with  $m$  in a time lapse whose width equals  $w_m$  (i.e., the  $h_j$  parameter introduced earlier). Overall,

$$w_m = B_m + \sum_{j \in hp(m)} h_j(w_m) \cdot C_j$$

This leads to the following recurrence relation, which specifies the queuing delay at step  $n + 1$  as a function of  $w_m$  at step  $n$ :

$$w_m^{n+1} = B_m + \sum_{j \in hp(m)} \left\lceil \frac{w_m^n + J_j + t_{bit}}{T_j} \right\rceil \cdot C_j$$

From a practical point of view, the evaluation of  $w_m$  proceeds as follows: the initial value  $w_m^0$  is set to 0, and then the recurrence relation is repeatedly evaluated until either the value of  $w_m$  settles (i.e.,  $w_m^{n+1}$  equals  $w_m^n$ ) or the deadline  $D_m$  is exceeded. Convergence of this iterative approach is ensured, provided that the network utilization is below one, that is,  $U_{MS} < 1$ . This means that the recurrence relation eventually provides the queuing delay  $w_m$ .

The earlier technique enables the evaluation of the queuing delay—and, consequently, of the WCRT—for every single message. By checking them against the related deadlines, schedulability of the whole MS can be formally assessed.

In 2007, Davis et al. [DAV07] found that, in some cases, the earlier analysis is optimistic. As a consequence, they developed a new analysis that always provides meaningful results. Despite it corrects the flaws in the original method, the new version of the schedulability test they introduced is more complex and less intuitive.

A sufficient (but not necessary) schedulability test can be obtained by replacing  $B_m$  in the recurrence relation given earlier with  $\max(B_m, C_m)$ . If approximate results are acceptable, an even simpler way to compute the recurrence relation correctly is the following:

$$w_m^{n+1} = B_{MAX} + \sum_{j \in hp(m)} \left\lceil \frac{w_m^n + J_j + t_{bit}}{T_j} \right\rceil \cdot C_j$$

where  $B_{MAX}$  is the transmission time of the longest message in the considered network. In its turn, it is upper bounded by the duration of the largest CAN frame (8-byte payload). In this case, the obtained results are pessimistic.

### 52.3.3 Usage

Schedulability analysis has been (and still is) widely used for designing networked embedded system based on CAN, in order to check whether or not the network is correctly configured and/or dimensioned.

It can be applied to all systems where communications are based on asynchronous data exchanges (either cyclic or sporadic). One of the most interesting and popular real-world examples of this kind of systems is in-vehicle networks used in the automotive domain. In the case of production cars, in fact, the system is made up by several *ECUs*—from about ten up to slightly less than one hundred—each one producing several messages according to either a periodic or a sporadic schedule.

In the earlier analysis, data exchanges have been assumed uncorrelated from the point of view of communications. Indeed, they could be correlated at the application level, as in the case of message exchanges based on the request–response paradigm. Whatever the case, upper bounds are provided on transmission delays, so enabling the verification of whether or not timing constraints are met. More sophisticated approaches are also available if correlations are known, and tighter bounds can be provided in this case.

### 52.3.3.1 Identifier Assignment

Several aspects have to be considered carefully in the design phase, particularly when assigning IDs to messages that are exchanged in a CAN-based real-time distributed control application. From an intuitive point of view, the most urgent messages (i.e., those characterized by either the tightest deadlines or higher transmission rates) should be assigned the lowest IDs. For example, ID 0 denotes the message that has the highest priority in any CAN.

If the period of cyclic data exchanges (or the minimum interarrival time of acyclic exchanges) is known in advance, a number of techniques exist for assigning IDs, which are based on either the *deadline monotonic* (DM) or *rate monotonic* (RM) approaches [TIN94]. They can be profitably used to find, provided it exists, a suitable assignment of IDs to messages, so that the resulting schedule is feasible (i.e., deadlines of all messages are always met). More sophisticated techniques also exist, which grant optimal assignments according to some specific metric. For instance, the ability to tolerate (a limited amount of) transmission errors without losing schedulability can be a meaningful goal.

Typically, the assignment of priorities is performed statically during the system design so that more sophisticated approaches like the *earliest deadline first* (EDF) are seldom used in practice.

---

## 52.4 CAN Advantages and Drawbacks

Each CAN node is enabled to compete for bus ownership directly, so that it can send messages on its own. This means that CAN is a true multimaster network, which can be advantageous for use in systems that rely on the event-driven paradigm. However, it also suffers from several limitations, some of which depend on the adopted arbitration technique and cannot be overcome. Although serious, they are not going to rule out CAN completely, since it is (and will likely remain for several years) the preferred solution to implement cheap and robust networked embedded systems (including most of those used in automotive applications). Advantages and drawbacks of CAN are briefly sketched in the following, along with some solutions conceived to enhance its behavior.

### 52.4.1 Advantages

CAN is particularly suitable for networked embedded systems. Many inexpensive microcontrollers currently exist, which embed one (or more) CAN controllers at no additional cost and can be readily employed in both existing and new projects. This aspect, together with the fact that the protocol is mature, stable, and very well known, makes CAN a viable solution for many years to come, in spite of the availability of newer real-time solutions whose transmission speed is one or two orders of magnitude higher than CAN.

#### 52.4.1.1 Compared to Fieldbuses

CAN shows several advantages when compared to the traditional networks adopted to exchange real-time process data at the shop floor in factory environments. For instance, it is by far simpler

and more robust than access schemes based on token passing (such as PROFIBUS, when used in multimaster configurations). In CAN, there is no need to build or maintain the logical ring nor to manage the circulation of the token around the master stations. In the same way, it is noticeably more flexible than solutions based on the *time division multiple access* (TDMA) or *combined message* approaches—two techniques adopted by SERCOS and INTERBUS, respectively. This is because message exchanges are not required to be known exactly in advance. With respect to older schemes based on *centralized polling* such as FIP, there is no need to have a node in the network acting as the bus arbiter, which may become a single point of failure for the whole system, and this improves reliability in a noticeable way.

From the point of view of the MAC mechanism, all CAN nodes behave like masters, and hence the notification of asynchronous events, such as alarms or critical error conditions, becomes very simple. In all cases where this aspect is important, CAN is clearly a better option than the other solutions mentioned earlier. Thanks to the arbitration scheme, no message can be delayed by lower-priority exchanges (this phenomenon is known as *priority inversion*). Since CAN, as the vast majority of communication protocols, is not preemptive, a message may still be delayed by a lower-priority transmission if this has already been started. However, as any CAN frame is very small (standard frames are 135-bit long at most, including stuff bits), the blocking time experienced by very urgent messages is quite low (usually well below 1 ms, if medium-to-high transmission speeds are selected). This makes CAN a very responsive network, which explains why it is used in many real-time control systems despite its relatively low bandwidth.

#### 52.4.1.2 Compared to Newer Solutions

When CAN is compared to the communication protocols introduced in the last decade, things are a bit different, but it still keeps some advantages. Although *real-time Ethernet* (RTE) solutions have much higher bit rates, which make them perfectly suitable for industrial plants and factory automation environments, they are not very popular in networked embedded systems. This is because of several reasons, the most relevant being the higher cost. Ethernet controllers, transceivers, magnetics, and cables are typically more expensive than CAN, and often, intermediate network devices like switches are also needed. In some cases, RTE solutions are not completely settled yet or, better, some details may be not as stable as in CAN.

In the same way, CAN proves to be a cheaper and much simpler option than solutions purposely designed for the use in automotive systems (e.g., in-vehicle networks), such as the Time Triggered Protocol-Class C (TTP/C) and, mostly, FlexRay. There is no doubt that, in the future, such technologies will take over CAN in a number of application fields. But, likely, this is not going to happen in a short time. As stated in [FRE02], CAN will remain in use for many years to come. The recent introduction of CAN FD [CANFD], pushed by some leading carmakers, is a further evidence of the intention not to abandon CAN in both automotive applications and networked embedded systems.

#### 52.4.2 Drawbacks and Solutions

CAN is affected by a number of drawbacks, the most important concerning *performance*, *determinism*, and *dependability*. Although they were considered mostly irrelevant when the protocol was introduced at the beginning of the 1990s, with the elapsing of time, they have become more and more limiting in a number of application fields, such as the advanced in-vehicle x-by-wire systems in the automotive industry. Solutions have been consequently proposed, which are aimed at coping with one or more of such limitations.

##### 52.4.2.1 Performance

Even though inherently efficient and quite elegant, the arbitration technique of CAN poses serious limitations on the performance that can be obtained by the network. In fact, in order to ensure the

correct behavior of the arbitration mechanism, the signal must propagate from a node located at one end of the bus up to the farthest node (at the other end) and come back to the first node before it samples the level on the bus (this is because all nodes must *see* the same logical value within the same bit time).

Since the sampling point is roughly located near the end of each bit (its position can be programmed through suitable registers in the CAN controller), the end-to-end propagation delay (also including hardware delays of couplers, transceivers, and controllers) must be strictly shorter than about half the bit time, the exact value depending on the bit timing configuration in the DLL.

Since the propagation speed of signals is fixed (about 200 m/ $\mu$ s on copper wires), this implies that the maximum length allowed for the bus is necessarily limited and depends directly on the bit rate chosen for the network. For example, a 250 kbit/s CAN can span at most 200 m; similarly, the maximum bus length allowed when the bit rate is set equal to 1 Mbit/s is less than 40 m. This, to some degree, explains why the maximum bit rate allowed by the CAN specification [ISO1] has been limited to 1 Mbit/s.

In Figure 52.10, an example is shown where the arbitration no longer works properly because of propagation delays, which in turn disrupts communications. Let us consider a simple CAN, made up by two nodes (A and B), which are located at the opposite ends of the bus. Initially, the bus is assumed to be idle. After some time, a transmission request is issued in node A, which starts transmission (the SOF bit has been grayed for clarity). The signal takes some time to reach node B, due to propagation delays.

Just before the signal arrives in B, let us assume that a transmission request is issued in node B. Since the bus in B is still idle, node B starts transmitting too. The signal generated by B arrives to A after a time (measured from the instant A started transmitting) that is slightly shorter than twice the end-to-end propagation delay. If this happens after node A has sampled the bus to determine the level of the current bit (which is fundamental for arbitration), the value that is read by A is obtained as the (wired) AND between the current bit it is writing out and the previous bit sent by B. In this case, the SOF bit from B, at the dominant level, overwrites the first bit of the ID in the message sent from A, at the recessive level, and tricks node A into thinking it has lost the contention.

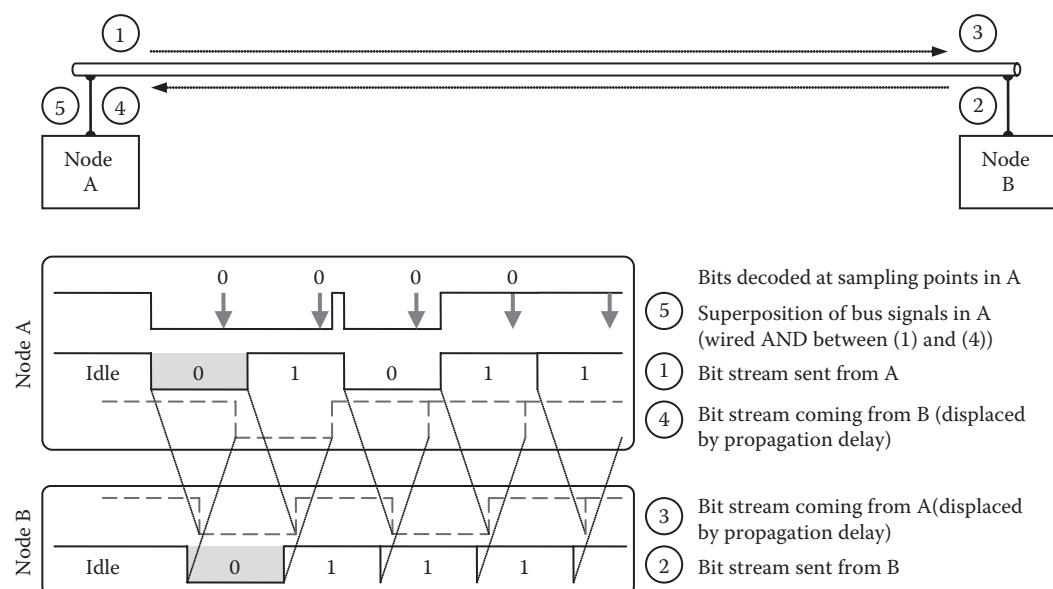

FIGURE 52.10 Effects of propagation delays on arbitration.

Generally speaking, in order for the arbitration to work properly, the following condition must hold:

$$T_{prop\_seg} > 2 \cdot (T_{CC} + T_{TR} + T_{OC} + L_{MAX} \cdot t_p)$$

where

$T_{prop\_seg}$  is the duration of the propagation delay segment (as configured in the DLLs of the nodes)  
 $T_{CC}$ ,  $T_{TR}$ , and  $T_{OC}$  are the contributions to the end-to-end delay due to the latencies introduced by, respectively, CAN controllers (~50 ns), CAN transceivers (120–250 ns), and, optionally, optocouplers (40–140 ns) on devices at both ends

$L_{MAX}$  is the distance (measured on the bus) between the farthest nodes in the network

$t_p$  is the specific propagation delay of electrical signals over the wire (about 5 ns/m)

From the previous equation, and remembering that  $T_{prop\_seg}$  is always strictly shorter than the bit time  $T_{bit}$ , an upper bound can be found for the maximum bus length allowed for any given bit rate  $R$  (inverse of  $T_{bit}$ ):

$$L_{MAX} < \frac{(1/2R) - (T_{CC} + T_{TR} + T_{OC})}{t_p}$$

Clearly, as long as the bit rate is medium to low, the maximum length can be satisfactorily described as inversely proportional to the bit rate. However, for high bit rates (close to 1 Mbit/s), the contribution of hardware latencies due to controllers and transceivers can no longer be neglected. A detailed analysis of the relationship between bit rate and maximum bus length can be found in [DIN08].

It is worth noting that the earlier limitation depends on physical factors, and hence it cannot be overcome in any way by advances in the technology of transceivers. To make a comparison, it should be mentioned that, at present, several inexpensive communication technologies are available on the market that allow bit rates in the order of tens or hundreds of Mbit/s.

Even though this may appear as a very limiting factor for CAN, it will probably not have any relevant impact in the near future for several application areas—including some automotive and process control applications—where a cheap and well-assessed technology is more important than top performance. However, in other scenarios like factory automation or x-by-wire systems, CAN is suffering from the higher bit rates of its competitors, for example, PROFIBUS-DP (up to 12 Mbit/s), SERCOS (up to 16 Mbit/s), FlexRay (up to 10 Mbit/s), and industrial Ethernet (up to 100 Mbit/s). In fact, such solutions are able to provide noticeably higher data rates, and this is a basic requirement for systems made up of many devices or having very short cycle times (1 ms or less).

It is worth remarking that little can be done to improve CAN performance significantly, unless full backward compatibility is sacrificed. Despite some solutions have appeared in the literature—such as WideCAN [CEN02], which provides higher bit rates while still relying on the conventional CAN arbitration technique—their interest has remained mainly theoretical. Recently, the *CAN FD* protocol [CANFD] has been introduced, which enables a significant increase of the data rate and resembles the original protocol closely at the same time.

### 52.4.2.2 Determinism

Because of its nondestructive bitwise arbitration scheme, CAN is able to resolve in a deterministic way any collision that might occur on the bus. The MAC mechanism ensures that the bus is always assigned to the node that is sending the message with the highest priority. As shown previously, when dealing with schedulability analysis, it is possible to determine right in the design phase of a CAN system whether or not messages are always delivered before their intended deadlines (or, equivalently, transmission latencies experienced by every message are upper bounded). This means that CAN supports real-time communications.

However, if nodes are allowed to produce asynchronous messages on their own—this is the way event-driven systems usually operate—there is no way to know in advance the exact time when a given message will be sent. This is because the actual number of contentions (i.e., the interference) any message experiences with higher-priority transmissions is not known *a priori*. This behavior leads to transmission jitters, which in some kinds of applications—including those involved in the automotive field—may affect control algorithms in a negative way and worsen their precision. Moreover, if transmission errors due to electromagnetic noise are taken into account, some messages can even miss their intended deadline.

Another problem related to determinism is that compositability is not ensured in CANs. This means that, when several subsystems are developed independently and then interconnected to the same network, the overall system may fail to satisfy the timing constraints, even though each subsystem was tested separately and proved to behave correctly and the overall network bandwidth is theoretically sufficient to carry out all the data exchanges. This severely limits the chance of integrating subsystems made from different vendors and makes the design and test tasks much more difficult.

A possible solution conceived to enhance determinism in CAN is the so-called *time-triggered CAN* (TTCAN) protocol [ISO4], for which commercial network controllers are available even though they are not so popular. By adopting a common clock and a time-triggered approach, TTCAN achieves very-low jitters and provides a fully deterministic behavior.

#### 52.4.2.3 Dependability

The last drawback of CAN concerns dependability. Whenever safety-critical applications are considered, where communication errors may lead to damages to the equipment and even injuries to human beings (as in automotive x-by-wire systems), a highly dependable network has to be adopted.

Reliable error detection should be carried out both in the value and in the time domain. In the former case, conventional techniques such as the use of a suitable CRC are adequate. In the latter case, instead, a time-triggered approach is certainly more appropriate than the event-driven communication scheme provided by CAN. In time-triggered systems, all actions—including sampling of sensors, actuation of commanded values, task activations, as well as message exchanges—are known in advance and must take place at precise points in time. In this context, even the presence/absence of a message at a given instant provides significant information (i.e., it enables the discovery of faults). For example, *masquerading faults* (a node that is sending messages on behalf of another one) can be avoided in time-triggered networks, and a *fail silent* behavior can be easily enforced for nodes by means of *bus guardians*. TTCAN provides some advantages in this respect, by enabling error detection in the time domain.

The so-called *babbling idiot* problem is another issue that may affect CAN systems. In this case, a faulty node that repeatedly keeps transmitting a high-priority message on the bus (usually because of a flaw in the software of the generating task) may slow down the whole network and cause message deadlines to be missed. Sometimes, it can even block the communication completely. Such a kind of failures cannot be detected by the fault confinement unit embedded in CAN chips, as they do not depend on physical faults but rather are due to logical errors (e.g., correct frames that are sent at a higher rate than intended). Although bus guardians can be used, in theory, to cope with these errors in CAN as well, they cannot be implemented easily and efficiently for networks based on the event-driven communication paradigm.

Concerning fault tolerance, several interesting proposals have appeared in the literature to tackle the cases of broken links or faulty transceivers, which can be profitably adopted in real-world systems. For example, in [PRO06], a novel architecture for CAN, which is based on a star topology, is described. Unlike the conventional bus topology, such an arrangement helps avoiding *partitioning faults*, that is, a broken link only affects one node and does not prevent the others from communicating. Such a solution has been subsequently extended in order to deal with redundant media as well.

## 52.5 Time-Triggered CAN

The TTCAN protocol was introduced by Bosch in 1999 with the aim of making CAN suitable for the new needs of the automotive industry and, in particular, to satisfy, at least in part, the requirements of the upcoming x-by-wire systems. TTCAN can be profitably used in all those applications, characterized by tight timing requirements, that demand for a strictly deterministic behavior. TTCAN, in fact, allows the exact selection of the point in time when messages have to be exchanged, irrespective of the network load.

The TTCAN specification was then standardized by ISO [ISO4]. Its definition was mainly driven by the need to improve determinism of CAN, by providing support for time-triggered communications, as well as to permit higher bus loads while maintaining the highest degree of compatibility with existing devices and development tools. As a consequence, significant savings in communication technology investments were expected. A further advantage has to do with *composability*, which in TTCAN is improved with respect to CAN. In particular, a system can be split into several subsystems in the design phase, which can be developed and tested separately.

Unfortunately, TTCAN failed in establishing itself as the successor of CAN, the main reason being the need for system designers to switch from the event-driven to the time-triggered paradigm. Nevertheless, the availability on the market of CAN controllers that support the TTCAN time-stamping features and time-triggered operations may still be useful in those application contexts where the accuracy of timing is important, in particular when inexpensive implementations are required.

### 52.5.1 Main Features

One of the most appealing features of TTCAN is that both event-driven and time-triggered operations can coexist in the same network at the same time. In order to ease a graceful migration from CAN, TTCAN foresees two levels of implementation, which are known as level 1 and 2, respectively. Level 1 implements only basic time-triggered communications over CAN. Level 2, which is a proper extension of level 1, also offers a means for maintaining a global system time across the whole network, irrespective of tolerances and drifts of local oscillators. This enables accurate synchronization up to the application level, and hence true time-triggered operations can take place in the system.

The TTCAN protocol is conceptually placed above the unchanged CAN data link layer and allows time-triggered exchanges to take place in a quasi-conventional CAN. For this reason, it suffers from the same performance limitations as the underlying CAN technology. In particular, the transmission speed cannot exceed 1 Mbit/s in practice, and the same limitations concerning the network extension still hold. However, because of the time-triggered paradigm it relies on, TTCAN is able to ensure strictly deterministic communications, which means that, for example, it is deemed suitable for the first generation of drive-by-wire automotive systems—which are provided with hydraulic/mechanical backups. Conversely, TTCAN is likely not adequate for next-generation steer-by-wire applications. In fact, requirements on both fault tolerance and available data rate are noticeably more severe in this case.

### 52.5.2 Protocol Specification

TTCAN adopts the very same frame format and transmission technology as CAN. In TTCAN, however, nodes are not allowed to send frames at any time. Transmissions, instead, take place according to specific triggers that are driven by time. Accordingly, some means have to be provided by the protocol so that all nodes can synchronize their activities.

#### 52.5.2.1 Time-Triggered Communication

Unlike new-generation automotive protocols (e.g., FlexRay [FR3]), which rely on distributed synchronization mechanisms, TTCAN is based on a centralized approach, where a special node called the *time master* (TM) keeps the whole network synchronized by regularly broadcasting a *reference*

*message* (RM), usually implemented as a high-priority CAN message. Redundant TMs can be envisaged so as to increase reliability. In particular, up to eight *potential TMs* can be deployed in a TTCAN. Their priority is encoded in the three least significant bits of RM. At any time, only one node is allowed to be the actual TM, whereas the others behave as backup substitutes. The procedure for (re)electing the current TM relies on CAN arbitration. It operates in a completely dynamic fashion and ensures that faulty masters are replaced on the fly.

Transmission of data is organized as a sequence of *basic cycles* (BCs). Each BC begins with the reference message, followed by a fixed number of time windows that are configured off-line and can be of three different types:

1. *Exclusive windows*: Each exclusive window is statically reserved to one predefined message, so that collisions cannot occur. Exclusive windows are used for safety-critical data that have to be sent deterministically and without jitters.
2. *Arbitration windows*: These windows are not preallocated to any given message, and thus different messages may possibly be competing for transmission; in this case, any collision is solved thanks to the nondestructive CAN arbitration scheme.
3. *Free windows*: These are placeholders, which are reserved for future expansions of TTCANs.

The beginning of each time window corresponds to a time trigger defined in one (or more) producing nodes. Since boundaries of time windows shall never be exceeded, TTCAN controllers must disable the automatic retransmission feature of CAN (which retransmits the same message whenever the contention is lost or transmission errors are detected). The only exception occurs when several adjacent arbitrating windows are present. In this case, they can be merged together, so as to build a single, larger window, which is able to accommodate a number of asynchronously generated messages in a more flexible way. The only constraint is that the transmission in such a *merged arbitrating window* is allowed only if the complete message can be sent in the time remaining before the end of the window itself.

Despite it seamlessly mixes both synchronous and asynchronous messages (in exclusive and arbitrating windows, respectively), TTCAN is very dependable indeed. Besides the intrinsically deterministic time-driven access to the shared communication support, in fact, the arbitration mechanism of CAN is used to solve the collision whenever a temporary lack of synchronization occurs and more than one node tries to transmit in the same exclusive window.

### 52.5.2.2 System Matrix

More than one BC can be adopted to increase flexibility. A *system matrix* can be defined, which consists of up to 64 different BCs (the exact number has to be a power of two), which are repeated periodically (see Figure 52.11). Thus, the actual periodicity in TTCAN is given by the so-called matrix cycle. A *cycle*

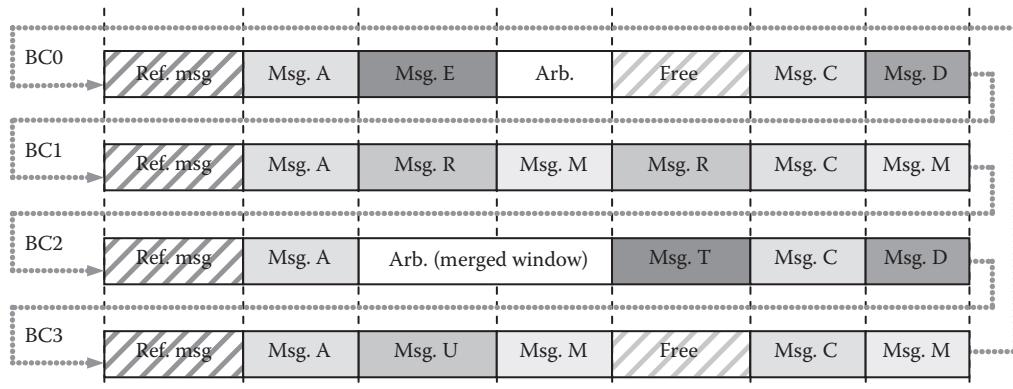

FIGURE 52.11 System matrix in TTCAN.

*counter*—included in the first byte of RM—is used by every node to distinguish the current BC inside the matrix cycle. The TM increases the cycle count by one on every BC, until the maximum value (which is selected on a network-wide basis before operation is started) is reached and the counter is restarted.

The system matrix is highly column oriented. In particular, each BC is made up of the same sequence of time windows, that is, corresponding windows in different BCs do have exactly the same duration. However, they can be used to convey different messages, depending on the cycle counter. In this way, it is possible to have messages in exclusive windows that are repeated once every any given number of BCs. Each message is assigned a *cycle offset* and a *repeat factor* to characterize its transmission schedule (both these parameters are expressed as an integral number of BCs). The cycle offset is the first row in the system matrix when the message shall be sent. It is a displacement to prevent collisions among different messages whose time windows share the same column. The repeat factor, instead, specifies how often a given message has to be sent, and it is expressed as a power of two. This *multiplexing* mechanism enables the optimization of the bus allocation with respect to the timing requirements of different message streams and allows significant savings for the network bandwidth.

More than one exclusive window can be allocated to the same message in the same BC. This is useful for either having redundant transmissions of critical data or refreshing some variables with a rate higher than the BC.

### 52.5.2.3 Implementation

Each TTCAN controller has its own clock and is provided with a *local time*, which is basically a counter that is increased by one every *network time unit* (NTU). The NTU must be the same (at least, nominally) on the whole network. Each node derives it from the local clock and a local parameter known as *time unit ratio* (TUR). The biggest difference between the level 1 and level 2 variants of the protocol is that the latter defines an adaptive mechanism that is able to keep the NTUs (and, hence, the global time) accurately synchronized by constantly updating the TUR parameters of the different nodes.

Whenever RM is received, each node restarts its *cycle timer*, so that a common view of the elapsing time is ensured across the whole network. In practice, each time the SOF bit of a new message is sampled on the CAN bus, a synchronization event is generated in every network controller, which causes the local time to be copied in a *sync mark* register. After the message has been completely read, a check is made by controllers: if the SOF bit concerns a valid reference message, the sync mark register is copied into the *reference mark* register. At this point, the cycle time can be evaluated simply as the difference between the current local time and the reference mark (see Figure 52.12a).

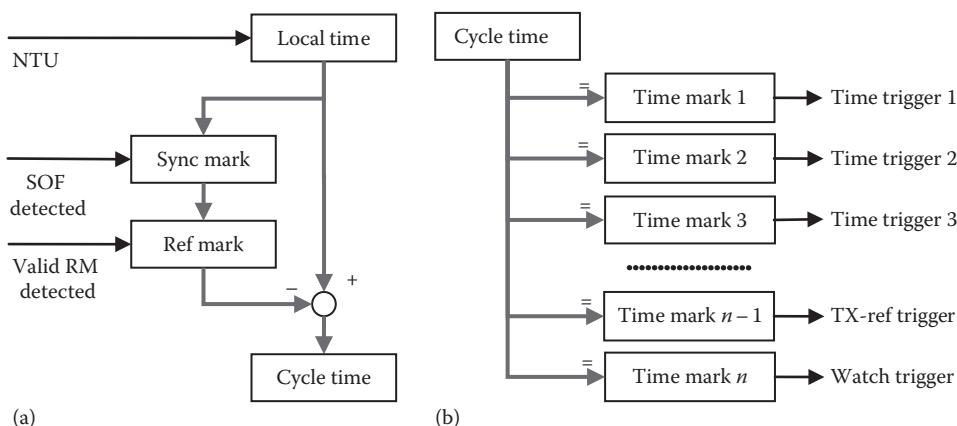

FIGURE 52.12 Time-triggered operation in TTCAN. (a) Synchronization of the cycle time and (b) scheduling driven by the cycle time.

Two kinds of RM are actually foreseen: in level 1 implementations, this message is 1 byte long, whereas level 2 relies on a 4-byte RM that is backward compatible with level 1 (from a practical point of view, three more bytes are appended for distributing the global time as seen by the TM).

In each node, the protocol execution is driven by the progression of the cycle time. In particular, a number of *time marks* are defined in each network controller and work as either transmission or receive triggers to send messages or validate message receptions, as shown in Figure 52.12b. As soon as the cycle time equals a particular time mark, the related trigger is activated. It is worth noting that in TTCAN, nodes are not requested to know the schedule of all messages in the network. Indeed, only the details of those messages the node sends/is interested in are needed.

Two triggers are also foreseen that are not used for exchanging data and are known as *TX-ref trigger* and *watch trigger*, respectively. The former is employed by potential TMs to trigger the generation of RM for the next BC. The latter, instead, is used to detect the absence of reference messages on the network, which implies a faulty condition.

From a general perspective, TTCAN requires slight (and mostly inexpensive) changes to the internal architecture of conventional CAN chips. In particular, transmit and receive triggers plus some counters and registers for managing the cycle time are necessary to ensure time-triggered operations.

Even though level 1 could be implemented completely in software—the ability to support single-shot mode or the cancellation of a transmission request is enough in this case—specialized hardware can reduce the host processor burden for managing time-triggered operations. As level 2 compliant controllers provide support for drift correction and calibration of the local time, they need the hardware to be modified accordingly.

The structure of TTCAN modules resembles the conventional architecture. In particular, only two additional blocks are needed, that is, the *trigger memory* and the *frame synchronization entity*. The former is used for storing the time marks of the system matrix, which are linked to the message buffers held in the controller's memory. The latter, instead, is used to control TTCANs according to the protocol.

At present, a limited number of controllers are available off the shelf that comply with the TTCAN specifications. However, this shows that this solution is not only theoretical, but it can be actually embedded in new projects.

## 52.6 CAN FD

---

As pointed out in the previous sections, one of the main bottlenecks of CAN is its limited data throughput. Basically, this is because of two main reasons: The first is the trade-off between network speed and extension, which limits the practical bit rate to 1 Mbit/s (in this case, the bus length is limited to 40 m at best). In order to cover larger areas, the bit rate has to be reduced consequently. The second reason is the limited size of the payload: in fact, in order to ensure high responsiveness, 8 bytes at most can fit in the data field of a frame. This consequently reduces the communication efficiency, which, in the best case, reaches 47% with standard IDs.

Recently, a proposal has been made by Bosch [FLO12] in order to overcome both the drawbacks presented earlier, which is known as CAN FD. CAN FD builds on the basic idea first outlined, more than 10 years ago, in [CEN99]. In that paper, we pointed out that the limitation affecting the maximum bit rate only holds for specific parts of the frame transmission, where more than one node is allowed to transmit on the bus at the same time. These regions were referred to as *multiple-writer-allowed zones* (M-zones) and concern, in practice, the arbitration and acknowledgment fields, placed at the very beginning and end of the frame, respectively. It is worth noting that, in order to denote the end of a frame unambiguously, the duration of the EOF field cannot be changed, too.

In the remaining (inner) fields, denoted in [CEN99] as *single-writer-allowed zone* (S-zone), only one transmitter (i.e., the winner of the arbitration phase) is transmitting over the bus, at least in a properly configured network. In fact, CAN mandates that no two nodes can be enabled to send nonempty data frames having the same ID at the same time. This means that the bit rate can be

safely increased in the S-zone (which includes the DLC, DATA, and CRC fields), while it must be left unchanged in the M-zones. This approach was called *overclocking* technique in [CEN99], where the use of *oversized* CAN frames was also envisaged to better exploit the higher bit rate enabled by the payload overclocking, so as to increase the communication efficiency. In fact, the frame header and trailer almost have a fixed duration, so that the communication overhead they introduce becomes proportionally smaller as the payload increases in size. For instance, in [CEN00], the use of an extended length field was assumed that could accommodate up to 80 bytes in the compressed payload.

### 52.6.1 Main Features

CAN FD brings two main improvements to CAN. First, data frames longer than legacy CAN are foreseen. Up to 64 bytes can be included in the data field of CAN FD frames, which actually increases the maximum amount of data in the frame payload by a factor 8. On the one hand, this improves the communication efficiency, which can now reach 72% in the case of 11-bit IDs. On the other hand, fragmentation is either prevented or significantly reduced, at least, especially when remote device parameterization is carried out.

The second improvement is the increased bit rate for selected portions of the frame. According to the CAN FD specification, two (possibly different) bit rates are defined, which are known as *nominal bit rate* and *data bit rate*. The first one is used during both the arbitration phase and the operation of the ACK mechanism (including the EOF field), whereas the second is used in transmitting the body of the frame (basically the DLC, DATA, and CRC fields). Supporting a higher bit rate, however, requires an alternate set of configuration registers. As a consequence, the duration of the time segments has to be defined separately for the 2 bit rates.

### 52.6.2 Protocol Specification

From the point of view of the protocol machine, CAN FD basically behaves as conventional CAN. The main differences are the format definition of additional frames and the option to increase the bit rate temporarily for transmitting the inner part of the frame. Other improvements were also brought in order to improve reliability.

#### 52.6.2.1 Frame Format

CAN FD defines two new frame formats [CANFD], namely, CAN FD frames with base (11 bits) and extended (29 bits) IDs. They are sketched in Figure 52.13. As mentioned before, the main goal of CAN FD is increasing the throughput by using either oversized frames or overclocking (or both at the same time). For this reason, no additional format is defined for remote frames; in fact, they do not include any data field and would hardly benefit from new encoding schemes. Conventional remote frames can be used, if needed. As a consequence, the RTR bit in CAN FD frames has been renamed *reserved bit r1* and is set at the dominant value.

As shown in Figure 52.13, a couple of new bits have been added to the control field, which are not found in conventional CAN frames. The *extended data length* (EDL) bit—which takes the place of a reserved (dominant) bit in conventional frames—is sent at the recessive level in CAN FD and allows distinguishing between the two formats.

The *bit rate switch* (BRS) bit, instead, is used to decide whether or not the transmission speed has to be increased from the nominal bit rate (used in the arbitration phase and for the frame trailer) to a higher, alternate bit rate, whose value has to be configured in advance. In particular, a recessive value means a bit rate switching, whereas a dominant value indicates that the same bit rate is used all over the frame. The BRS bit also marks the point in time where the transmission bit rate is possibly switched. The transmission speed is restored to the nominal bit rate during the CRC delimiter.

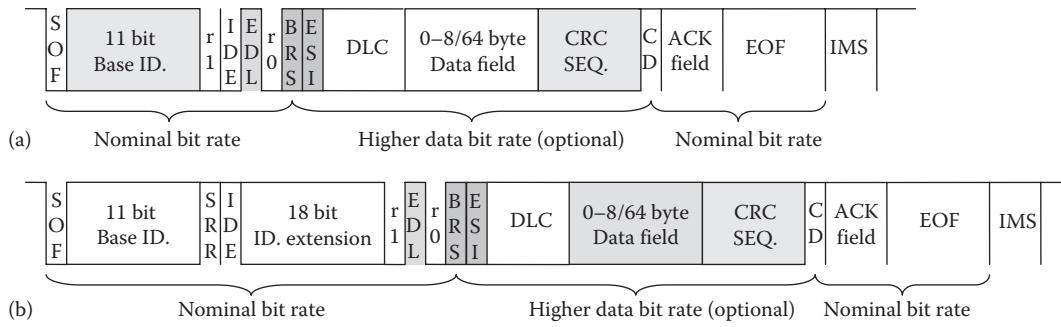

FIGURE 52.13 Format of CAN FD frames. (a) CAN FD base frame format and (b) CAN FD extended frame format.

The third bit defined by CAN FD is the *error state indicator* (ESI) flag. ESI is sent at the dominant value by error-active nodes, whereas passive nodes leave it at the recessive level. For the sake of truth, its purpose has little or nothing to do with enhancing the data rate.

Also the meaning of the DLC field has been extended in CAN FD, in order to cover additional payload sizes besides those originally supported in CAN. In particular, when the value of DLC is greater than 8 (i.e., from 9 to 15), seven additional sizes can be specified for the data field, namely, 12, 16, 20, 24, 32, 48, and 64 bytes. It is worth remarking that the same bit patterns are not illegal in conventional CAN, but they are always interpreted as an 8-byte-long payload.

CAN FD frames can carry a significantly larger amount of information. Three different generator polynomials were then envisaged to maintain the same degree of reliability as conventional CAN; in fact, besides the classical CRC-15, two additional CRCs are defined for frames that comply with the new formats: the first one (CRC-17) is used when the data field is up to 16 bytes in size, whereas the second (CRC-21) is used for larger frames. In this way, a *Hamming distance* (HD) equal to 6 is obtained, irrespective of the actual frame size.

### 52.6.2.2 Other Differences with CAN

A couple of modifications were also added to the basic CAN protocol. Bit stuffing rules were slightly changed for CAN FD frames. In particular, stuff bits are inserted in fixed positions in the CRC field of such frames. The first stuff bit is inserted just before the first bit of the CRC, while a further stuff bit is added after each fourth bit of the CRC sequence, which is computed as the inverse of the immediately preceding value. Moreover, in the new CAN FD frame formats, stuff bits included in the bit stream are relevant to the CRC calculation, whereas in conventional CAN, they were not considered.

These approaches are intended to improve the error detection capability. In fact, as pointed out in the literature [CHA94], the bit stuffing mechanism may interfere with the CRC calculation and increases the residual error probability (i.e., the probability that a message suffering from a transmission error is considered correct by one or more receivers). In particular, a pair of bit flip errors located more than 15 bits apart lead to an error burst that might go undetected by the conventional CRC mechanism.

In order to decrease implementation costs and improve compatibility with the current controller-host interfaces for CAN, support for all long frame sizes is not mandatory in CAN FD. Nevertheless, every receiver must be able to read frames up to the maximum allowed size without generating any errors. Data bytes exceeding the handling capabilities of the CAN controller can simply be discarded.

## 52.7 CANopen

Almost all the functions of the CAN data link layer (including services for frame transmission and reception) are implemented directly in the communication hardware. This choice provides a very good degree of efficiency and reliability for data exchanges. Therefore, in many control systems, application

processes access the CAN controller directly (possibly through suitable device drivers). Although this solution is acceptable in many scenarios, only basic communication services are offered by the data link layer, and this may be inadequate for other complex applications.

In order to reduce the design and implementation effort of automation and networked systems, a number of higher-level solutions have been defined in the past years, which rely on CAN for message transfers and also define their own *application layer*. The main purpose of the application layer is to provide a usable and well-defined set of service primitives, which can be invoked to interact with devices in a standardized way. The goal of reducing the design and development costs is easily achieved thanks to standardization.

To this purpose, several solutions are currently available off the shelf, such as CANopen [EN4] for networked control systems, DeviceNet [EN2] for factory automation, and J1939 [J1939] for trucks and other vehicles. In the following, the CANopen protocol will be described, focusing in particular on its use in industrial and networked embedded systems.

## 52.7.1 Protocol Basics

CANopen is a CAN-based application layer protocol with very flexible configuration capabilities that was explicitly defined for automation systems. It unburdens the developer from dealing with CAN-specific details, such as bit timing and implementation-specific functions. Moreover, it defines standardized communication objects (COBs) able to cope with both real-time and configuration data, as well as network management (NMT).

CANopen was initially conceived to rely on the communication services provided by the CAL [CiA20X]. However, the current specifications [CiA301] no longer refer explicitly to CAL. Instead, the relevant services and definitions have been included directly in the CANopen specification. CANopen was subsequently accepted as the international standard EN 50325-4 [EN4]. Specifications include the application layer, the communication profile, as well as several application, device, and interface profiles. These documents are developed and maintained by the CiA organization.

At present, CANopen is used in a very broad range of application fields, such as off-road and rail vehicles, maritime electronics, machine control, medical devices, building and industrial automation, as well as power generation.

### 52.7.1.1 Communication Objects

In CANopen, information is exchanged by means of COBs, which model application layer services. A number of different COBs exist, which are conceived for different functions:

- *Process data objects* (PDOs) are used for real-time data exchanges, such as measurements read from sensors and command values issued to actuators for controlling the physical system.
- *Service data objects* (SDOs) are used for non-real-time communications, for example, device parameterization and diagnostics.
- *Emergency objects* (EMCYs) are used by devices to asynchronously notify the occurrence of error conditions.
- *Synchronization object* (SYNC) is used to achieve synchronized and coordinate operations in the system.
- *Time stamp object* (TIME) is used to broadcast global system time information, which can be used by devices to adjust their local time base.
- *NMT* defines a number of objects for dealing with management services, including mechanisms to check whether devices are alive or not.

Every COB is mapped onto one (or more) CAN frames for transmission over the bus. More details about how such a mapping takes place, as well as the way information is encoded, are provided in the following paragraphs.

### 52.7.1.2 Communication Protocol

CANs are based on the producer/consumer interaction model and rely on object addressing. However, for a number of application layer services, this arrangement is not the best choice to interact with devices. For this reason, both the master/slave and the client/server protocols are additionally defined in CANopen.

Although every CAN node behaves as a master from the point of view of the MAC mechanism, that is, it can access the bus autonomously whenever it needs to transmit information, the master/slave protocol is a better approach for dealing with NMT. In particular, each device in any CANopen network is identified by means of a unique 7-bit node address, which lies in the range from 1 to 127. In addition, to make the system configuration easier, a *predefined master-slave connection set* must be provided by each device, which consists of a standard allocation scheme of CAN-IDs to COBs and is made available after initialization. Device configuration, instead, is carried out over peer-to-peer connections using the client/server protocol.

### 52.7.2 Device Model

The behavior of a CANopen device is completely described by means of a number of objects. Each object, in turn, is devoted to some specific aspect concerning the device configuration, the communication on the CAN bus, or the functions for interacting with the controlled physical system (e.g., some objects define the device type, the manufacturer's name, the hardware and software version).

All the objects relevant to a given device are stored in the *object dictionary* (OD) of that node. As shown in Figure 52.14, interactions between frames exchanged on the CAN and local applications that act on the physical system take place through the OD. This choice offers a standardized view of devices and their behavior for control applications, as well as an easy interaction model through the CAN bus.

#### 52.7.2.1 Object Dictionary

The OD can be seen as a table, which stores all information concerning a device. Both parameterization and process data are kept in the OD, which is the only repository of information for the device. The OD can include up to 65,536 different objects, each one accessed through a unique 16-bit address (index 0000<sub>h</sub> is not used). Any object, in turn, can be either of simple (Boolean, integer, floating point, string, etc.) or complex (arrays and records) type. In the latter case, it may consist of up to 256 subentries, each one addressed via an 8-bit subindex.

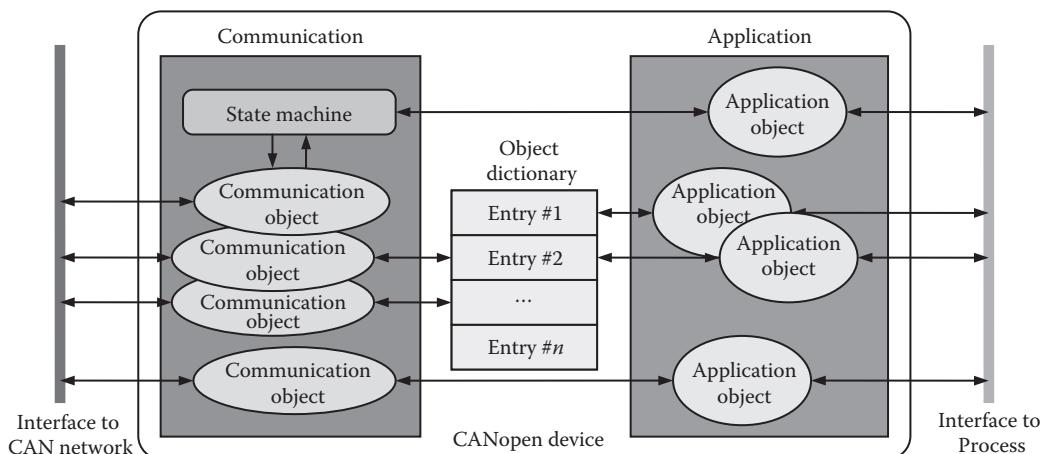

FIGURE 52.14 Model of CANopen devices.

In the case of simple-type entries, subindex 00<sub>h</sub> is used to access the information directly. Instead, for complex data types, subindex 00<sub>h</sub> encodes the highest subindex supported for the related entry, that is, the number of either array elements or record fields. In this case, subindex FF<sub>h</sub> may optionally encode the relevant data type and object type. This means that each single item in the OD can be uniquely identified through a 24-bit multiplexer.

### 52.7.2.2 OD Structure

From a conceptual point of view, the OD is split into separate areas, according to the indexes of entries.

These areas are then used to store different kinds of information, which concerns, for instance, CANopen communications or device functionalities. The meaning of an entry can be roughly deduced by looking at its index:

- Entries below 1000<sub>h</sub> are used to specify *data types* (static, complex, specific to either the manufacturer or the device profile). Most of them (from 0260<sub>h</sub> to 0FFF<sub>h</sub>) are reserved for future use.
- Entries from 1000<sub>h</sub> to 1FFF<sub>h</sub> make up the *communication profile area*. They are used to describe communication-specific parameters, that is, to model the interface of the device to the CAN. These objects are common to all CANopen devices.
- Entries from 2000<sub>h</sub> to 5FFF<sub>h</sub> correspond to the *manufacturer-specific profile area*. They can be freely used by manufacturers to extend the basic set of functions of their devices. Their use has to be considered carefully, in that it could make the device no longer interoperable.
- Entries from 6000<sub>h</sub> to 9FFF<sub>h</sub> belong to the *standardized profile area*. They describe all aspects concerning a given class of devices, as defined in the related device profile, in a standardized way. This area is split into up to eight parts, each one corresponding to one logical device. For instance, the entries related to the first logical device are found in the range from 6000<sub>h</sub> to 67FF<sub>h</sub> and those concerning the second one fall between 6800<sub>h</sub> and 6FFF<sub>h</sub>.
- The meanings of some entries above A000<sub>h</sub> have been defined in the most recent versions of CANopen. Version 4.2.0, in particular, assigns entries from A000<sub>h</sub> to BFFF<sub>h</sub> to the standardized network and system variable areas. Other indexes (from C000<sub>h</sub> on) are either reserved for future use or concern new functionalities that are in the process of being defined at the time of writing.

### 52.7.3 Process Data Objects

Real-time process data, involved in the physical system control, are exchanged by means of PDOs according to the producer/consumer model. Every PDO is mapped onto exactly one CAN frame and does not introduce any protocol overhead, so that it can be exchanged quickly and reliably. As a direct consequence, the amount of data that can be embedded in one PDO is limited to 8 bytes at most. In the majority of cases, this is more than sufficient to encode one or more signals managed by the control application.

From the point of view of CANopen devices, two kinds of PDO exist: *transmit PDO* (TPDO) and *receive PDO* (RPDO). The former is produced (i.e., sent on the CAN bus) by a device, whereas the latter models consumed objects (which must not be discarded by the frame filtering function). In theory, up to 512 TPDOs and 512 RPDOs can be defined for each device. However, according to the predefined connection set, each node in CANopen is equipped with up to 4 RPDOs and up to 4 TPDOs. RPDOs are used for transferring process data (commands, set points, etc.) from the application master to the device, whereas TPDOs are used to convey process data (e.g., values sampled by sensors) from the device to the application master.

The predefined connection set is often sufficient to set up simple master/slave configurations in small factory automation systems. In the case a larger number of PDOs are needed, the *PDO communication parameters* of the device (stored as entries in the OD) can be used to either define additional messages or just change the existing ones. In particular, the *PDO linking* mechanism can be exploited in those networked embedded systems that need high flexibility and where device-to-device communication

or multicasting is required. From a practical point of view, this involves the explicit configuration of matching PDO communication parameters in two or more devices, so that they are enabled to exchange process data directly according to the conventional CAN paradigm.

Finally, a suitable configuration of the *PDO mapping parameters*, if supported by the device, can be exploited to define dynamically what application objects (i.e., signals) have to be included in each PDO. In particular, either a number of OD entries can be collected in the same TPDO for transmission or the information extracted from an RPDO can be scattered over several entries in the OD.

The transmission of PDOs can be triggered by some local event taking place on the node, such as the expiration of a time-out, but it can also be remotely requested from the application master. This gives system designers a high degree of flexibility in choosing the way devices interact and enables a better exploitation of the features offered by intelligent devices.

Process data of a PDO are encoded in the data field of a CAN data frame and, as mentioned before, no additional control information is added by CANopen. As a consequence, PDOs resemble conventional CAN data exchanges closely, and communication efficiency is kept as high as in plain CAN. The meaning of each PDO is determined through the related CAN-ID. As multicasting is allowed for PDOs, their transmission is unconfirmed, that is, the producer has no way to know whether or not a PDO was received by all the intended consumers.

### 52.7.3.1 Transmission Modes

From a general point of view, two transmission modes are possible in CANopen, namely, *event driven* and *synchronous*. The former resembles the typical interaction model provided by plain CAN, whereas the latter enables synchronous operations for devices.

The transmission of event-driven PDOs can be started by nodes at any time, and hence it is typically asynchronous. The transmission of synchronous PDOs, instead, is driven by the occurrence of a network synchronization event, which is triggered by a special message (SYNC) generated at regular time intervals by a specific node (usually, the node acting as the application master). The transmission period for synchronization messages is referred to as *communication cycle period*. As a consequence, synchronous PDO exchanges take place in periodic cycles.

When synchronous operations are selected for one or more PDOs, commanded values are not actuated immediately by devices as they are received, and the same occurs for the transmission of sampled values. As depicted in Figure 52.15, every time a SYNC message is read from the network, the synchronous PDOs received in the previous communication cycle are actuated by the relevant output devices. At the same time, all sensors sample their input ports and related values are sent as soon as possible in the next cycle. Optionally, a *synchronous windows length* parameter can be defined, which specifies the

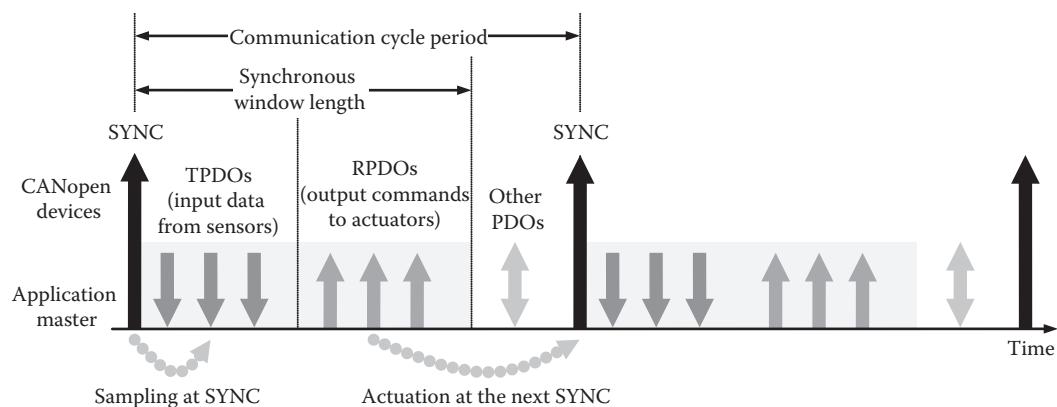

FIGURE 52.15 Synchronous operation.

time when all synchronous values have been exchanged for sure (late PDOs may be discarded). After this time has elapsed, each device can start processing the input/output (I/O) values.

Synchronous operations provide a tangible improvement for lessening the effect of jitters: in this case, in fact, system operations and timings are decoupled from the actual times PDOs are exchanged over the CAN bus.

### 52.7.3.2 PDO Triggering

Three triggering modes are defined for PDOs in CANopen, which specify in detail the conditions upon which a particular PDO is sent over the network. In particular, they identify the entity that is actually in charge of initiating the data exchange (see Figure 52.16):

- *Event and timer driven:* The decision on when a certain PDO has to be sent is completely up to its producer; the PDO transmission could be triggered by either the occurrence of an application-specific event (whose exact nature depends on the device profile/manufacturer) or the expiration of a local timer because no event has occurred (*event time*).
- *Remotely requested:* The transmission of the PDO has to be requested explicitly by its consumer(s), and it is triggered by a suitable remote frame according to the mechanisms CAN provides at the data link layer.
- *Synchronously triggered:* A third entity in the network (besides the PDO producer and consumers), which is known as SYNC producer, drives the data exchange. In practice, the PDO transmission is triggered by the reception of the SYNC object.

PDO transmission and triggering modes are configured through the *transmission-type* parameter, encoded as an 8-bit unsigned integer. For TPDOs, values in the range from 00<sub>h</sub> to F0<sub>h</sub> denote *synchronous* transmissions. In particular, the value 01<sub>h</sub> means that the PDO has to be sent at every SYNC, whereas values in the range 02<sub>h</sub>-F0<sub>h</sub> mean that it is sent every *n*th SYNC, where *n* is the numeric

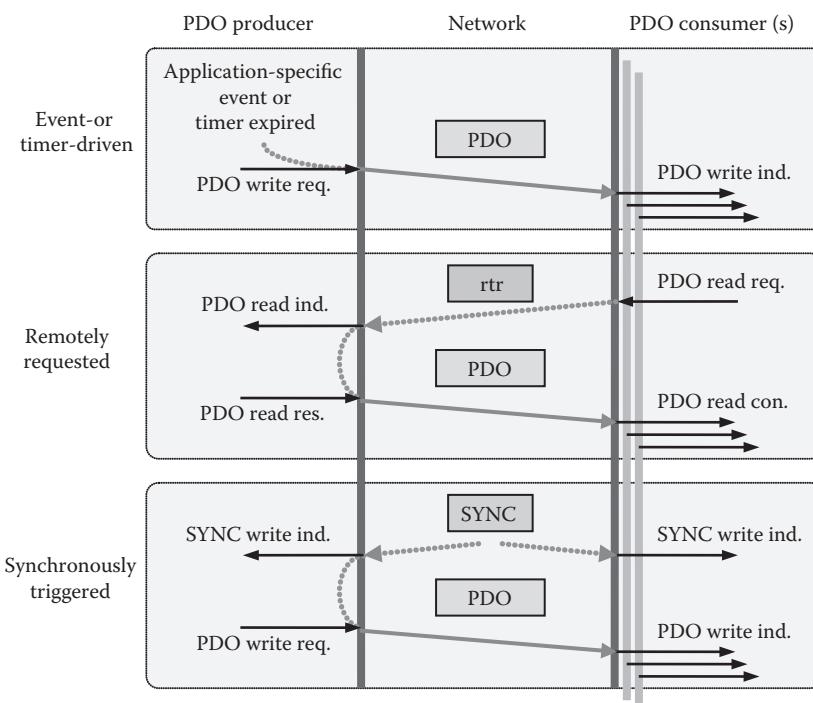

FIGURE 52.16 Triggering modes.

value of the transmission type ( $2 \leq n \leq 240$ ). These values denote *cyclic* transmissions and also specify the PDO transmission period as a multiple of the communication cycle ( $n$  times the communication cycle period). The value 0, instead, is used when the TPDO generation is *acyclic*. This means that it depends on an internal event, but transmissions have to take place synchronously nevertheless.

Values  $FC_h$  and  $FD_h$  denote *RTR-only* triggering schemes. In particular, the former (*synchronous RTR only*) means that data are sampled at SYNC, temporarily buffered, and then sent when the related remote frame is received. The latter (*event-driven RTR only*), instead, implies that both sampling and transmission take place (in this order) at the remote frame reception.

Finally, values  $FE_h$  and  $FF_h$  concern the *event-driven* triggering schemes. Triggering is a pure local matter, which can be either manufacturer specific in the former case or specified in the device/application profile in the latter.

Similar considerations apply to RPDOs, where either event-driven or synchronous transmission can be selected. In the event-driven case (transmission types  $FE_h$  and  $FF_h$ ), data are passed to the application (e.g., actuated) as soon as they are received from the network, whereas in synchronous operations ( $00_h$ - $F0_h$ ), values are first buffered and then actuated at the next SYNC.

### 52.7.3.3 PDO Configuration

As usual for CANopen, configuration of PDOs takes place via the OD. In particular, every PDO is assigned a number of entries in the OD, the most important being the *PDO communication parameter* and the *PDO mapping parameter*.

Details about the way each PDO is exchanged over the network are defined through the PDO communication parameter. It includes two mandatory items:

1. The ID used for the CAN frame that embeds the PDO (COB-ID)
2. The transmission type, as specified earlier

Optionally, it can also specify the following information:

- An *inhibit time* (expressed as a multiple of 100 µs), which is the shortest time that must elapse between any two subsequent transmissions of the PDO. This is useful to prevent high-priority messages from hogging the network, thus ruling out (or delaying excessively) lower-priority communications. The value 0 means that the inhibit time is disabled.
- An *event timer* (expressed as a multiple of 1 ms), which is the maximum time allowed between any two subsequent transmissions of the same PDO. In the case of TPDOs, when the timer expires, a message is sent automatically. This parameter can be used to enforce a minimum refresh rate for slowly changing values. For RPDOs, instead, the timer may be used for monitoring message deadlines. In this case, time-outs are notified to the local application. The value 0 means that the event timer is disabled.
- A *SYNC start* value, which is used as a displacement for multiplexing synchronous TPDOs whose periodicity is larger than the cycle time. When in the range 1–240, this parameter is checked against the counter field optionally included in SYNC messages. The SYNC message for which equality holds shall be regarded as the first one, on which the TPDO is sent. Following transmissions are then spaced according to the value of the transmission type.

Communication parameters for RPDOs and TPDOs are stored in the OD in the entries  $1400_h$ - $15FF_h$  and  $1800_h$ - $19FF_h$ , respectively.

The PDO mapping parameter specifies how information concerning application objects (and stored in the OD) has to be combined to build the payload of a TPDO or, equivalently, how it has to be decoded from an incoming RPDO. PDO mapping is also useful to improve the protocol efficiency: in fact, it enables the collection of several device signals (either input or output) in the payload of the same CAN frame. Obviously, information that is gathered in the PDO must have the same direction (transmission/reception) and triggering mode (including periodicity). The overall size is not allowed to exceed 8 bytes.

Basically, every PDO mapping parameter is made up of a number of 4-byte subentries. In turn, each subentry encodes three elements, namely, the index and subindex of the application object that will be mapped in the PDO (3 bytes) as well as its length in bits (1 byte).

Two kinds of PDO mapping are provided, that is, static and dynamic. Static mapping is built-in in the device and cannot be changed, whereas dynamic mapping can be freely configured by accessing the relevant items in the OD. A procedure is defined to this extent in order to avoid inconsistencies. Mapping parameters for RPDOs and TPDOs are stored in the OD in the entries  $1600_{\text{h}}\text{--}17FF_{\text{h}}$  and  $1A00_{\text{h}}\text{--}1BFF_{\text{h}}$ , respectively.

## 52.7.4 Service Data Objects

SDOs provide direct access for reading and writing the entries of the OD remotely. They are used in CANopen for parameterization activities, which usually take place during the configuration phase. Since SDOs are not considered real-time exchanges, they have a lower priority than PDOs. On the other hand, confirmed transmission services are required for them, which ensure a reliable exchange of information between end devices. SDOs rely on a client/server protocol and require a peer-to-peer connection (multicasting is not allowed) where the client is the accessing device, while the server is the device that owns the OD being accessed.

Since information to be exchanged may be of any size (in theory, at least), a fragmentation protocol was defined for SDOs, which derives from the domain transfer services of CAL. This means that information has to be split by the sender in smaller chunks (fragments or *segments* according to the CANopen specification) able to fit in the data field of CAN frames. Fragments must be reassembled on the receiver's side, and this requires that suitable information is included in every segment by the fragmentation protocol, along with the chunk of data. Indeed, the communication efficiency is negatively affected and transmissions are slowed down, but as SDOs are seldom used for the real-time control of the system, this is typically not perceived as a problem.

SDOs are used to access the entries of the OD by applications and/or configuration tools. From a practical point of view, two services are provided, which are used to *upload* and *download* the content of a subentry of the OD, respectively. SDO transfers are always initiated on the client side of the connection, and the protocol involves exchanging one or more pairs of CAN frames with an 8-byte payload. Specifically, one frame in the pair encodes the request from the client to the server, while the other carries the response from the server back to the client, and a separate ID is needed for each direction.

### 52.7.4.1 SDO Transfer Types

Three kinds of transfers are envisaged for SDOs, namely, *expedited*, *normal* (or *segmented*), and *block*. They basically differ for communication efficiency and implementation complexity. Higher-complexity communication modes are advantageous when large pieces of information have to be transferred:

- Expedited transfer is a particular (simplified) case of SDO that only requires two frame exchanges between the client and the server (i.e., one *SDO download/upload initiate* request and the related response). As a consequence, only up to 4 bytes of data can be exchanged.
- Normal transfer is based on a segmented approach. In this case, following the *SDO download/upload initiate* message pair, a variable number of segments are sent. Each segment requires a separate *SDO download/upload request/response* pair and can carry up to 7 bytes of data. For this reason, the communication efficiency is quite low.
- Block transfer is an optional mode where information is exchanged as a sequence of blocks, each one consisting of a sequence of up to 127 segments. Every SDO block transfer is required to be both initiated and concluded explicitly (*SDO block download/upload initiate/end* services). Each block is transferred using the *SDO block download/upload subblock* service. A *go-back-n* strategy is adopted in this case to confirm the correct delivery of each block and to improve the efficiency in transferring large amounts of data.

An unconfirmed SDO *abort transfer* service is also provided, which employs only one frame and can be issued on both the client and the server sides, in order to terminate the transfer sequence when some error is detected.

Each CANopen node must provide SDO server functionalities. This means that it has to offer a pair of COB-IDs to support remote access to its OD, one for each transfer direction. Generally speaking, only one SDO client at a time is allowed in the network. In practice, only one SDO client is enabled to connect to any given SDO server, and this is implicitly guaranteed with the static allocation of IDs in the predefined connection set. Optionally, the dynamic establishment of additional SDO connections can be supported by means of a network entity called the *SDO manager*.

## 52.7.5 Other Objects

Besides PDOs and SDOs, a number of other COBs can be optionally defined in CANopen. They are intended to support specific functions, related to either application (and time) synchronization or error notification.

### 52.7.5.1 Synchronization Object

The SYNC is periodically broadcast over the network by the *SYNC producer* to enable synchronous operation. The time elapsing between any two subsequent generations of the SYNC message can be configured (as a multiple of 1  $\mu$ s) through the *communication cycle period*.

Despite its high priority (SYNC is assigned the ID 080<sub>h</sub>), the SYNC object may be delayed nevertheless by lower-priority messages and suffer from the blocking time because CAN is not preemptive. The resulting jitters (in the order of hundreds of  $\mu$ s) are much lower than for asynchronous exchanges, but they are not usually negligible. Hence, the synchronization might not be as accurate as high-precision applications demand.

In the initial CANopen specification (as well as in many existing devices), the SYNC object was mapped onto an empty data frame, since it has to provide a sort of *network clock* that ticks for applications, and only the SYNC reception instants are really meaningful. The most recent specification, however, defines an additional format for the SYNC message, which extends the previous one and can now include a 1-byte payload. In this case, the data field contains a counter (initially set to 1), which is increased by 1 on every SYNC transmission. When the counter reaches its maximum value (*synchronous counter overflow*), it is reset (i.e., it is set back to 1). This allows devices to arrange the transmissions of synchronous PDOs with periods greater than the communication cycle, so that the overall traffic is spread evenly over different cycles. As a side effect, this also helps in reducing jitters and latencies.

### 52.7.5.2 Emergency Object

The EMCY is sent asynchronously by devices as a consequence of internal error conditions. It can be considered as a sort of interrupt, which is raised for notifying urgent alarms so as to provide, for instance, prompt diagnostics. Its implementation is not mandatory. Unlike the error mechanisms provided by CAN, which copes with communication errors, this object is meant to deal with errors at the application level (e.g., a short circuit on an output channel, a low voltage on line power, or an excessive internal temperature).

Only one EMCY shall be sent for each error event. A state machine is then defined that describes the current error condition of the device. As soon as all errors have been repaired, the device returns to the error-free state.

EMCYs are encoded on CAN data frames having an 8-byte data field. Their payload is made up by three elements:

1. The *emergency error code*, encoded on 2 bytes. A number of standardized error code classes are defined in the CANopen communication profile, and others can be added by device profiles.

2. The *error register* (object  $1001_h$  of the OD). This is a 1-byte field that identifies errors that are still pending. Every bit concerns a specific error class, namely, generic, current, voltage, temperature, communication, device profile specific, and manufacturer specific.
3. The *manufacturer-specific error* field, which may include additional information about the error as for the device vendor.

## 52.7.6 Network Management

CANopen NMT relies on a master/slave approach, where one NMT master controls a number of NMT slave devices. In general, all CANopen devices are considered NMT slaves and are identified by means of a *node-ID*, encoded as an integer in the range from 1 to 127. NMT requires that one specific device in the network carries out the function of the NMT master.

Two kinds of services concern NMT, that is, *node control* and *error control*. Node control services, as the name suggests, are used to control the operation of nodes. For example, they can be used to start/stop nodes, to reset them to a predefined state, or to put them in the configuration (preoperational) mode. Error control services, instead, are aimed at verifying if every device is alive and operating properly.

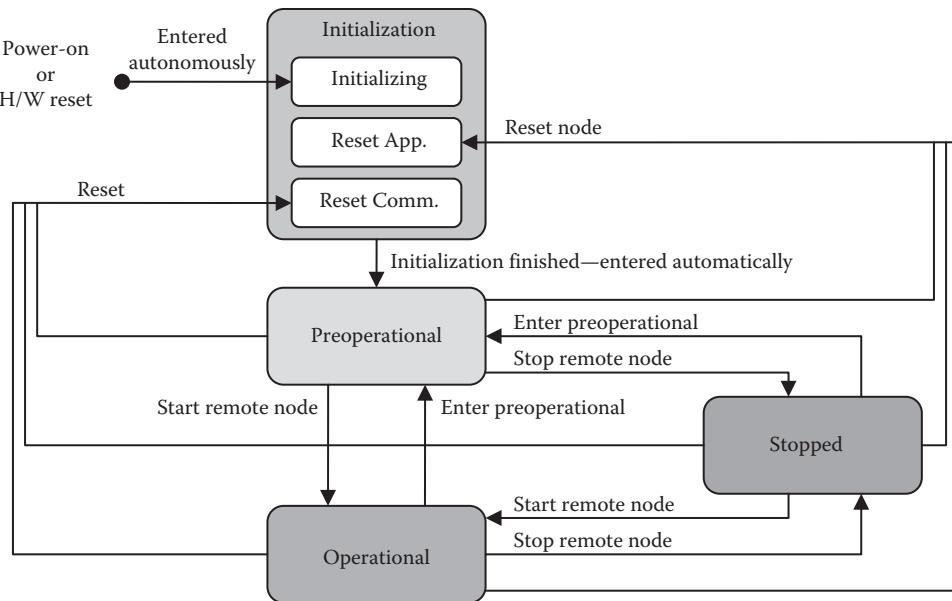

### 52.7.6.1 Node Control Services

From the point of view of NMT, each device is described through an NMT state machine. At any time, a node can be in one of the following four NMT states, which define its current behavior and allowed operations:

1. *Initialization*: This state actually consists of three substates, whose operations are executed in sequence. The first one (*initializing*), entered autonomously after either power-on or hardware reset, is where basic initialization activities are performed. Parameters of both the manufacturer-specific and the standardized device profile areas are loaded with power-on values in the *reset application* state, whereas in the *reset communication* state, parameters of the communication profile area are set. If the device is equipped with a nonvolatile storage area, power-on values are the last stored parameters; if not, default values are used. After initialization has finished, a boot-up message is sent and the preoperational state is entered automatically.
2. *Preoperational*: This state is used for configuring the device. Communication through SDOs is available and entries of the OD can be remotely accessed (and changed) by the configuration applications and tools. Communication through PDOs, instead, is not allowed yet.
3. *Operational*: In this state, all communications are enabled, and this usually corresponds to a fully functional behavior for the device. Besides PDO communications, which are used to exchange set points and measured values, also SDOs are allowed. However, the access to the OD might be somehow restricted, so as not to alter the system behavior accidentally or leave it in an inconsistent state.
4. *Stopped*: In this state, all communications are completely stopped except for NMT services. Furthermore, a specific behavior (which usually corresponds to a stopped device) can be enforced, as described by the corresponding device profile. Requirements concerning functional safety may also apply.

The resulting behavior of the device can be described by means of the state diagram in Figure 52.17. Transitions are labeled through the following NMT services, whose meaning is self-explanatory:

- Start remote node
- Stop remote node
- Enter preoperational
- Reset node
- Reset communication

**FIGURE 52.17** NMT state machine.

NMT commands are definitely time critical, and hence they use the highest-priority frames available in CAN (i.e., CAN-ID is set to 0). The data field in such frames is 2 bytes long; the first byte (*command specifier*) encodes the service, whereas the second (*node-ID*) identifies the target node(s). The NMT master can invoke these services for either one slave at a time or all of them at the same time. This is useful for starting/halting all devices in the network simultaneously. In the latter case, the node-ID field in NMT messages is set to  $00_h$ .

The way the NMT state machine is actually coupled to the state machine governing the application task(s) depends on the specific device taken into account and falls in the scope of the device profiles.

### 52.7.6.2 Error Control Services

Error control services are used to detect possible failures by monitoring the correct operation of the network. Two mechanisms are available, that is, *node guarding* and *heartbeat*. In both cases, low-priority messages are periodically exchanged in background, and suitable watchdogs are defined, both in the NMT master and NMT slaves. If a node ceases sending these messages, the NMT entity is made aware of the problem after a short amount of time and can take the appropriate actions.

The main difference between the two mechanisms is that, in the node guarding protocol, the NMT master polls the NMT slaves explicitly at regular intervals (the period is called the *guard time*) by means of suitable requests implemented as CAN remote frames. If a slave does not respond within a predefined time (*lifetime*), whose duration is evaluated as an integer multiple (*lifetime factor*) of the guard time, or the state of the slave has changed unexpectedly, the master application is notified (a *node guarding event* is issued). In this case, *life guarding* is supported as well, that is, slave devices may guard the correct behavior of the NMT master. If a slave is not polled during its lifetime, a *life guarding event* is issued locally.

The heartbeat protocol, instead, foresees that heartbeat messages are produced autonomously and periodically by nodes, which can be monitored by other nodes in the network. If a heartbeat consumer does not hear a heartbeat message from a producer within a given time (*heartbeat consumer time*),

the local application is notified. The advantage is that remote frames are not required in this case, so that the network load is reduced and the implementation made easier on some controllers.

Messages sent by these two protocols are very similar. They are encoded in 1-byte data frames and use the very same CAN-IDs. Basically, the NMT state of the transmitting device is included in the seven least significant bits of the payload. In the case of node guarding, a toggle bit is also included as the first bit to improve reliability.

The same kind of messages is also adopted by the *boot-up* protocol, which is used by slave nodes to notify that they have entered the preoperational state after initialization. It is worth noting that the implementation of either node guarding or heartbeat is mandatory.

### 52.7.6.3 Predefined Connection Set

In order to reduce the efforts involved in setting up a CANopen system, a default allocation scheme can be used to map COBs directly onto CAN-IDs. Such an allocation is made available just after initialization, provided that no modification was stored in the device nonvolatile memory. In many cases, such a scheme is more than adequate and does not need changes, as in the case of simple applications that consist of a single master controlling several slave devices.

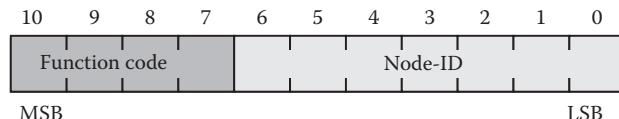

According to the *generic predefined connection set*, the CAN-ID of frames used to encode COBs includes two parts: the first one is the *function code* (FC), which takes the four most significant bits of the ID, while the second is the *node-ID* and is encoded in the seven least significant bits, as shown in Figure 52.18. Basically, the FC specifies the type of the COB (SYNC, PDO, SDO, EMCY, NMT, etc.) and is the element that mostly affects the priority of the frame. The inclusion of the node-ID in the CAN-ID, besides providing a very simple allocation scheme, implicitly ensures that no two nodes in the network can send a frame with the same ID (as discussed previously, this could lead to unsolvable collisions on the bus).

Some COBs in the predefined connection set, such as NMT node control, SYNC, and TIME, are intended for transmission to all devices simultaneously (broadcast). The CAN-IDs, in this case, can be easily singled out, as the node-ID field is set to 0. Generally speaking, it is worth noting that the particular format chosen for IDs makes the configuration of the filtering masks easier in CAN controllers.

The scheme for peer-to-peer (and multipeer) communications basically provides each slave device with up to four TPDOs and up to four RPDOs for sending/receiving real-time process data, one EMCY object for asynchronous alarm notification, one SDO to make the OD accessible via the network, and one low-priority message to be used by either the heartbeat or the node guarding error control mechanism. In these cases, the slave device can be either the source or the destination node, depending on the specific COB. The generic predefined connection set is shown in Table 52.1.

CAN-IDs assigned to the SYNC, TIME, and EMCY objects, as well as to any PDO, can be changed through a suitable reconfiguration, if this kind of parameterization is supported by the device.

The generic predefined connection set applies to devices that comply with a certain device profile. Conversely, devices that comply with an application profile must use a *specific predefined connection set*. In this case, the allocation scheme for IDs is defined in the relevant profile specification. COBs concerning NMT and SDO services, however, cannot be redefined.

**FIGURE 52.18** CAN-ID in the predefined connection set.

## 52.8 Interoperability between Devices

Sharing a common communication protocol is a prerequisite for achieving device interoperability, but it is not a sufficient condition. In fact, besides the rules for exchanging data over the network, also the meaning of data themselves and their impact on the device behavior have to be specified. The vast majority of industrial communication systems introduced in the past two decades (both fieldbuses and RTE solutions) adopt the concept of device profile. Basically, this is an abstract model describing the device behavior, which enables interoperability and interchangeability of equipment coming from different manufacturers. In fact, as long as a device conforms to a given profile, it can be used to replace any other device compliant to the same profile.

CAN-based application protocols are no exception. Popular solutions such as CANopen and DeviceNet define their own device profiles, which are sometimes said to belong to the *user layer* (the user layer is located above the top communication layer in the protocol stack). Though the purpose of profiles is basically the same, irrespective of the different solutions, exact definitions may vary. In particular, DeviceNet relies on a hierarchical model, defined in the *common industrial protocol* (CIP), which is based on the object-oriented paradigm, whereas CANopen is simpler and exploits the OD directly.

It is worth pointing out that device profiles for CAN-based solutions, as well as most part of their communication profiles and application layer services, have been reused in some popular RTE solutions. This is the case, for instance, of both EtherCAT and Ethernet POWERLINK, which rely on CANopen, and EtherNet/IP, which, as DeviceNet, is based on CIP.

### 52.8.1 Profiles in CANopen

CANopen specifications include a common and agreed communication stack (which includes the physical, data link, and application layers), a standard mechanism to configure the relevant parameters (communication profile area in the OD), and a number of profiles to ensure interoperability among devices.

In particular, *device profiles* can ease the task of system integrators in the design and deployment of CANopen systems, by providing off-the-shelf devices with true plug-and-play capabilities. Each profile concerns the interface of a logical device and is usually described in a separate document. In practice, the common behavior of a particular class of devices is considered. At present, about 20 device profiles have already been defined, including the following:

- The *device profile for generic I/O devices* (CiA 401) deals with both digital and analog I/O devices.
- The *device profile for drives and motion control* (CiA 402), used to describe products for digital motion, such as frequency inverters, stepper motor controllers, and servo controllers.
- The *device profile for measuring devices and closed-loop controllers* (CiA 404) is adopted for measuring and controlling physical variables.
- The *device profile for encoders* (CiA 406) defines the behavior of incremental/absolute linear and rotary encoders for measuring position, velocity, and so on.

Profiles listed earlier have been introduced mainly for general-purpose applications. This means they were not designed to fulfill the requirements of any specific application domain. Compliant devices are typically used, for instance, for assembling automated production lines in factory automation systems.

An additional set of profiles, known as *application profiles*, can be also found in CANopen. They are aimed at fulfilling requirements that are peculiar to a particular application domain and are able to describe a set of virtual device interfaces. This is the case, for example, of the *application profile for special-purpose car add-on devices* (CiA 447). It was defined explicitly for the automotive domain and specifies interfaces for add-on devices to be used in special-purpose cars. Devices for police cars (e.g., the roof bar and digital radio), taxi/cabs (e.g., taximeter), and disabled drivers are included in this profile.

Finally, some *interface profiles*, such as the *interface profile for AS-interface gateways* (CiA 446), are provided for devices without application functionality (e.g., nontransparent gateways).

In the following, the CANopen device profile for generic I/O modules (CiA 401) is described in more detail, to give the reader a flavor of the typical profile content and to show how it can help designers to build up a networked system.

### 52.8.2 Device Profile for Generic I/O Modules

The device profile for generic I/O modules [CiA401] is certainly one of the most popular profiles defined in CANopen. Generic I/O modules provide digital/analog inputs and/or outputs. This means that they are not bound to any application-specific context, such as measuring the temperature of an engine or switching the lights of a car on and off.

Many optional configuration parameters are specified by this profile, as well as a number of PDOs for transmission and reception. For instance, the polarity of each digital I/O port can be defined, or a filtering mask can be applied to selected channels. For analog devices, either raw or converted values can be used (in the latter case, a scaling factor and an offset are applied). In the same way, triggering conditions can be defined when specific thresholds are exceeded. The generic I/O module profile supports different access granularities for digital I/Os and several resolutions (and formats) for analog I/Os.

Input values are sent as TPDOs by sensors over the CAN and their transmission defaults to the asynchronous (i.e., event-driven) triggering. However, also the synchronous or remotely requested triggering schemes can be optionally enabled when supported by the device. In the same way, output values are provided to actuators via asynchronous RPDOs.

I/O values may be accessed by remote applications through SDOs in the OD. However, this is not recommended in control loops, as it leads to reduced communication efficiency and generally higher delays.

### 52.8.2.1 Profile Predefinitions

Several OD entries are standardized by this profile. One of the most significant objects in the communication profile area is the *device-type* object (entry 1000<sub>h</sub> in the OD), which defines both the type of the device and its functionality. In particular, the type is specified through the *device profile number* (which is typically set to the number of the standard document related to the class of device, in this case the value 401), whereas the functionality is encoded in the *additional information* field and reminds what kind of channels (e.g., input vs. output, digital vs. analog) are actually included in the device.

I/O modules compliant to the device profile for generic I/O modules specify OD entries in the standardized device profile area to store process data. Different objects in the OD, concerning digital I/O modules, provide access to process data organized on either 1, 8, 16, or 32 bits. It is worth noting, however, that only the 8-bit access scheme is mandatory, whereas the other lengths are optional. All entries refer to exactly the same value, the only difference being the access granularity. In particular, objects 6000<sub>h</sub> and 6200<sub>h</sub> are used for 8-bit access to digital input and output modules, respectively.

When analog modules are considered, values encoded as integers on 8, 16, and 32 bits are available. In addition, floating-point and manufacturer-specific formats can be used. Only 16-bit data are mandatory, and objects 6401<sub>h</sub> and 6411<sub>h</sub> are used for accessing 16-bit analog input and output values, respectively.

The standardized device profile area also includes OD entries that are needed to configure the behavior of the device. A number of default PDOs are defined as well, together with their default mapping:

- *RPDO1 (digital outputs)*: Up to 64 digital outputs can be received from the network through this RPDO, which are actuated immediately.
- *TPDO1 (digital inputs)*: Up to 64 digital inputs can be sent over the network through this TPDO, according to an event-driven scheme. This means that the PDO is transmitted as soon as at least one of the digital inputs changes its value (provided it is not disabled via the interrupt mask).
- *RPDO2 (analog outputs)*: Up to four analog outputs, each one encoded on 16 bits, can be received from the network through this RPDO.
- *TPDO2 (analog inputs)*: Up to four analog inputs, each one encoded on 16 bits, can be sent on the network through this TPDO, according to an event-driven scheme.

Only PDOs concerning the supported functionalities have to be provided by the device. For instance, a digital input module is only required to define TPDOs (and, for simple devices, just TPDO1). However, additional manufacturer-specific PDOs could be included in the module.

### 52.8.3 Device Behavior

The behavior of devices is formally defined in the profile specification. In the case of generic I/O modules, block diagrams are provided that describe how information is exchanged between the CANopen network and the real world and how sampling and actuation are carried out. Configuration takes place through a set of parameters, which are stored in the OD.

#### 52.8.3.1 Digital Input Devices

In Figure 52.19, the sequence of steps involved in the processing chain of a digital input is shown. Details on the way each operation is carried out can be changed by configuring the appropriate entries in the OD. A filter constant can be activated separately (2) on each single digital input channel (1) by means of object 6003<sub>h</sub>. This can be useful, for instance, to suppress undesirable signal fluctuations. Moreover, the

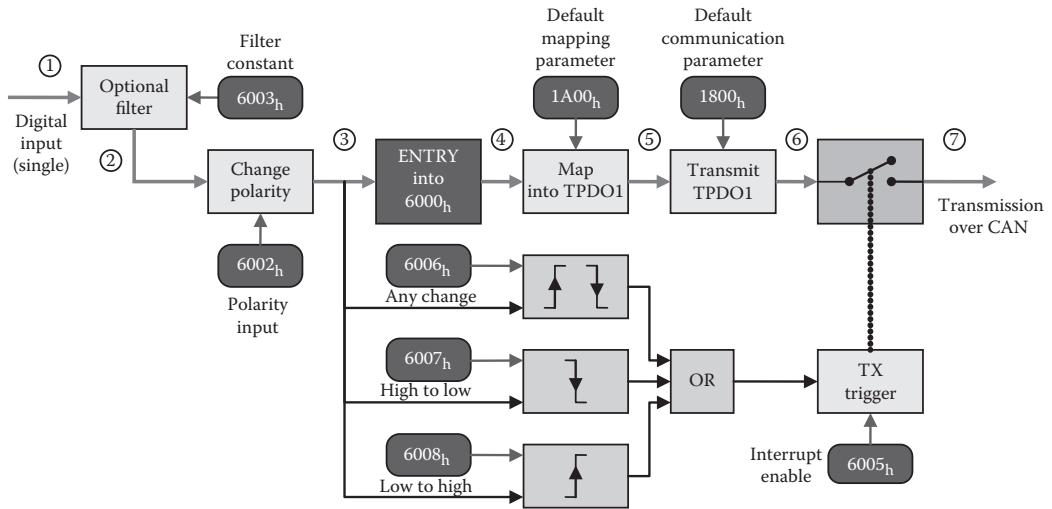

FIGURE 52.19 Abstract model of digital inputs.

channel polarity (normal/inverted) can be optionally changed (3) through object 6002<sub>h</sub>. Then, all bits associated to the different input channels are gathered together and stored in the relevant entries of the OD (object 6000<sub>h</sub>), from where they will be subsequently extracted and sent over the network (4). In this case, values are first mapped in the payload of a PDO through the PDO mapping mechanism (5); then the correct CAN-ID is selected (6) by means of the PDO communication parameter.

The actual transmission on the CAN bus (7) is driven by the trigger block. By default, the asynchronous mode is enabled, which triggers the transmission as soon as any of the input channels changes its logical value. However, this behavior can be changed through objects 6006<sub>h</sub>, 6007<sub>h</sub>, and 6008<sub>h</sub>. Moreover, triggering can be globally enabled and disabled through the (Boolean) object 6005<sub>h</sub>.

It is clear that, by writing into the relevant entries of the OD, a control application (or a configuration tool) can easily customize the behavior of each single digital input channel, as well as decide how these information are sent over the CAN.

### 52.8.3.2 Digital Output Devices

Figure 52.20 shows the steps involved in the processing chain affecting the operation of a digital output device. Frames received from the CAN bus (1) are first filtered according to the information stored in the RPDO communication parameter (2). Whenever the ID field in the received frame corresponds to the value configured for RPDO1 in this device, its payload is decoded according to the PDO mapping parameters and the related values are stored (and possibly scattered) (3) through the relevant entries of the OD (object 6200<sub>h</sub>). After an optional change of polarity (5), configured through the object 6202<sub>h</sub>, each output value is made available on the related output channel (7). A block is also provided (6) through object 6208<sub>h</sub> that acts as a filter mask. When disabled, the previous value is retained on the output channel.

The lower part of Figure 52.20 describes the behavior of the actuator in the case a device internal failure (including heartbeat or life guarding events) is detected. In order to improve the functional safety, two objects (6206<sub>h</sub> and 6207<sub>h</sub>) are provided that specify the value each digital output channel should assume in the case of failure. In particular, each output can be set separately to 0, 1, or its own value before the failure was detected. Whenever a failure is detected, the output is automatically switched (4) to such a value.

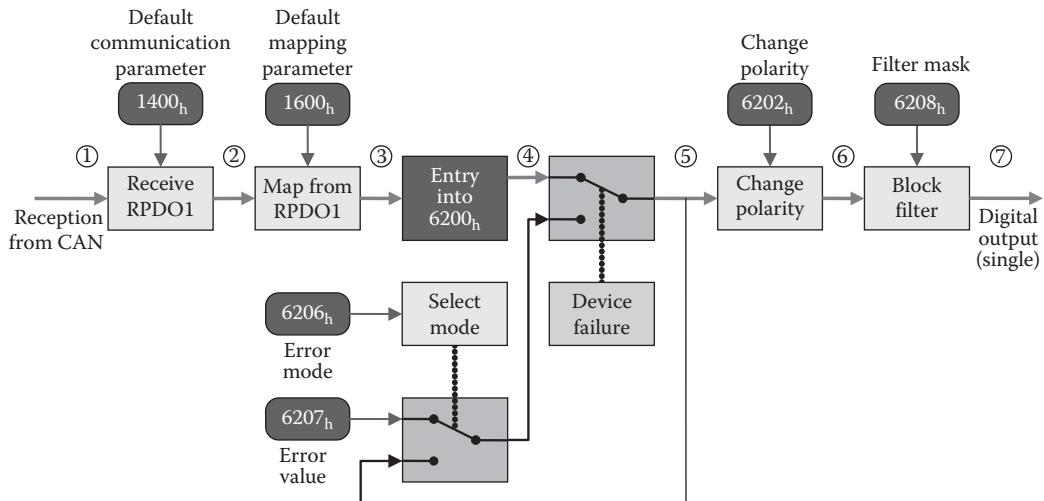

FIGURE 52.20 Abstract model of digital outputs.

### 53.1 Introduction

---

New electronic technologies have dramatically changed cars and the way we experience driving. Anti-lock braking system (ABS), electronic stability program (ESP), air bags, and many more applications have made cars a lot more convenient, comfortable, and, above all, safer. This trend of the past decade has been rather pleasant for the consumer and a tedious task for the automotive industry. The reasons for this drawback have not to do with the need of higher integration of the involved technologies. The very nature of the deployed communication technologies makes the task of integration itself a lot more complex as well as the design of fault-tolerant systems on top of these communication technologies rather difficult.

These limitations on the one hand as well as requirements and anticipated challenges of future automotive applications on the other hand motivated OEMs and suppliers to join forces. The goal of the 2001 founded FlexRay Consortium [1]: to establish one standard for a high-performance communication technology in the automotive industry.

### 53.2 Automotive Requirements

---

Since OEMs and suppliers were the founding members of the FlexRay Consortium, it was clear from the very beginning of the work on the new de facto communication standard that FlexRay has to meet the requirements of the automotive industry. Therefore, two key issues have driven the development work for the communication protocol: the need for a technological basis and solution for future safety-related applications and the need to keep costs down.

### 53.2.1 Cutting Costs

The cost factor is a key driver for many requirements for the communication system as the push for systematic reuse of existing components in multiple car platforms proves. Due to this approach, subsets of components related to a specific function can be reused in multiple platforms without changes inside the components. This elegant and cost-saving solution, however, is possible only if the communication system offers two decisive qualities:

1. It must be standardized and provide a stable interface to the components.
2. The communication system has to provide a deterministic communication service to the components.

This communication determinism is the solution for the problem of interdependencies between components, which is a major issue and cost factor in today's automotive distributed systems. Since any change in one component can change the behavior of the entire system, integration and testing is of utmost importance in order to ensure the needed system reliability. At the same time, testing is extremely difficult and expensive. A deterministic communication system significantly reduces this integration and test effort as it guarantees that the cross-influence is completely under control of the application and not introduced by the communication system. This property is often referred to as *composability*, meaning that each component of a system can be tested in isolation, and integration of these components does not have any side effects.

#### 53.2.1.1 Migration

A new technology, such as FlexRay, does not make all predecessors obsolete at once. It rather replaces the traditional systems gradually and builds on proven solutions. Therefore, existing components and applications have to be migrated into new systems. In order to create this migration path as smooth and efficient as possible, FlexRay has integrated some key qualities of existing communication technologies, for example, dynamic communication.

#### 53.2.1.2 Scalability

Communication determinism and reuse are also key enablers for scalability, which obviously is yet another cost-driven requirement. Scalability, however, calls for not only communication determinism and reuse but also the support of multiple network topologies and network architectures as well as the applicability of the communication technology in different application domains like power train, chassis control, backbone architectures, or driver assistance systems.

#### 53.2.1.3 Future Proof

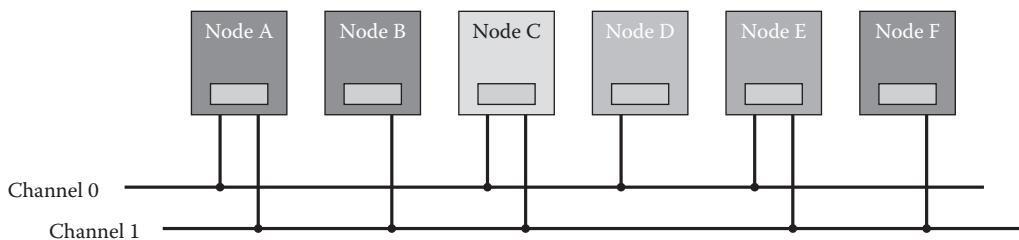

Keeping costs down is only one side of the coin. The automotive industry has visions of the future car and applications. The most obvious developments are active safety functions like electronic braking systems, driver convenience functions like active rear steering for parking, or the fast-growing domain of driver assistance systems like active cruise control or the lane departure warning function. These automotive applications demand a high level of reliability and safety from the network infrastructure in the car in order to provide the required level of safety at the system level. Therefore, the communication technology has to meet requirements such as redundant communication channels, deterministic media access scheme, high robustness in case of transient faults, distributed fault-tolerant agreement about the protocol state, and extensive error detection and reporting toward the application. The most stringent particular requirement arises from the deterministic media access scheme. In time division multiple access (TDMA) schemes for networks, all participating communication partners need a common understanding of the time used in order to control the access to the communication medium. Typically, a fault-tolerant distributed mechanism for clock synchronization is required. Additionally, the safety requirement introduces the need to protect individual communication partners from faults of other partners by means of so-called guardians. Otherwise, errors of one partner could cross-influence other partners, thus violating safety demands.

Specific automotive issues complete the broad range of requirements forming the framework for and of FlexRay. These issues range from the use of automotive components like x-tals, automotive electromagnetic compatibility requirements, support for power management to conserve battery power, support for electrical and optical physical layers, to a high bandwidth demand of at least two times 10 Mbps.

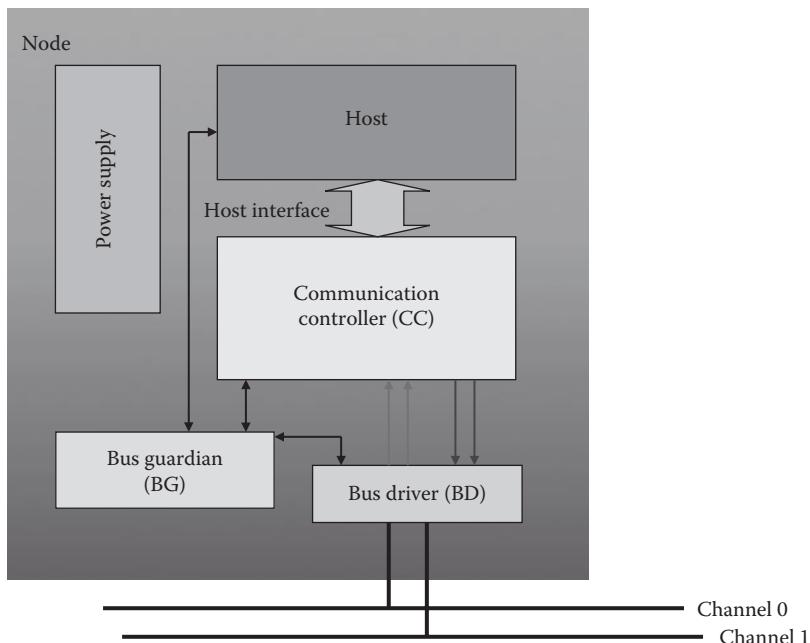

### 53.3 What Is FlexRay?

Before the development of FlexRay was started, a comprehensive evaluation of the existing technologies took place. The results showed that none of the existing communication technologies could fulfill the requirements to a satisfactory degree. Thus, the development of a new technology was started. The resulting communication protocol FlexRay is an open, scalable, deterministic, and high-performance communication technology for automotive applications.

A FlexRay network consists of a set of electronic control units (ECUs) with integrated communication controllers (CCs) (Figure 53.1). Each CC connects the ECU to one or more communication channels via a communication port, which in turn links to a bus driver (BD). The BD connects to the physical layer of the communication channel and can contain a guardian unit that monitors the TDMA access of the controller (the architecture of an ECU is depicted in Figure 53.2). A communication channel can be as simple as a single bus wire but also be as complex as active or passive star configurations.

**FIGURE 53.1** FlexRay network.

**FIGURE 53.2** ECU architecture.

FlexRay supports the operation of a CC with single or redundant communication channels. In case of single communication channel configuration, all controllers are attached to the communication channel via one port. In case of redundant configuration, controllers can be attached to the communication channels via one or two ports. Controllers that are connected to two channels can be configured to transmit data redundantly on two channels at the same time. This redundant transmission allows the masking of a temporary fault of one communication channel and thus constitutes a powerful fault-tolerance feature of the protocol. A second fault-tolerance feature related to transient faults can be constructed by the redundant transmission of data over the same channels with a particular time delay between the redundant transmissions. This delayed transmission allows tolerating transient faults on both channels under particular preconditions.

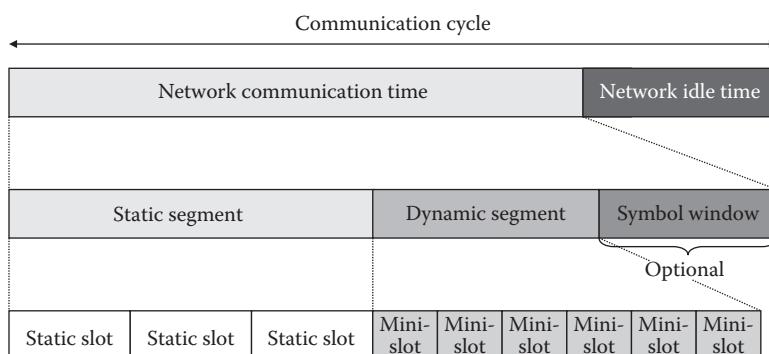

If the fault-tolerance property of two independent channels is not required for a specific application, the channels can be used to transfer different data, thus effectively doubling the transmission bandwidth.

### 53.3.1 Media Access

The media access strategy of FlexRay is basically a TDMA scheme with some very specific properties. The basic element of the TDMA scheme is a communication cycle. A communication cycle contains a static segment, a dynamic segment, and two protocol segments called symbol window and network idle time (Figure 53.3). Communication cycles are executed periodically from start-up of the network until shutdown. Two or more communication cycles can form an application cycle.

The static segment consists of slots with fixed duration. The duration and the number of slots are determined by configuration parameters of the FlexRay controllers. These parameters must be identical in all controllers of a network. They form a so-called global contract. Each slot is exclusively owned by one FlexRay CC for the transmission of a frame. This ownership only relates to one channel. On other channels, in the same slot, either the same or another controller can transmit a frame. The identification of the transmitting controllers in one slot is also determined by configuration parameters of the FlexRay controllers. This piece of information is local to the sending controller. The receiving controllers do not possess any knowledge on the transmitter of a frame nor on its content; they are configured solely to receive in a specific slot. Hence, the content of a frame is determined by its positions in the communication cycle.

Alternatively, a message ID in the payload section of the frame can be used to identify a message. The message ID uniquely tells the receivers which information is contained in a frame. By providing a filter mechanism for message IDs, a controller can pick specific data.

**FIGURE 53.3** FlexRay communication cycle.

The static segment provides deterministic communication timing, since it is exactly known when a frame is transmitted on the channel, giving a strong guarantee for the communication latency. This strong guarantee in the static segment comes for the trade-off of fixed bandwidth reservation.

The dynamic segment has fixed duration, which is subdivided into so-called minislots. A minislot has a fixed length that is substantially shorter than that of a static slot. The length of a minislot is not sufficient to accommodate a frame; a minislot only defines a potential start time of a transmission in the dynamic segment. Similar to static slots, each minislot is exclusively owned by one FlexRay controller for the transmission of a frame. During the dynamic segment, all controllers in the network maintain a consistent view about the current minislot. If a controller wants to transmit in a minislot, the controller accesses the medium and starts transmitting the frame. This is detected by all other controllers, which interrupt the counting of minislots. Thus, the minislot is *expanded* to a real slot, which is large enough to accommodate a frame transmission. It is only after the end of the frame transmission that counting of the minislots continues. The expansion of a minislot reduced the number of minislots available in this dynamic segment. The operation of the dynamic segment is illustrated in Figure 53.4: Figure 53.4a shows the situation before minislot 4 occurs. Each of the channels offers 16 minislots for transmission. The owner of minislot 4 on channel 0—in this case controller D—has data to transmit. Hence, the minislot is expanded as shown in Figure 53.4b. The number of available minislots on channel 0 is reduced to 13.

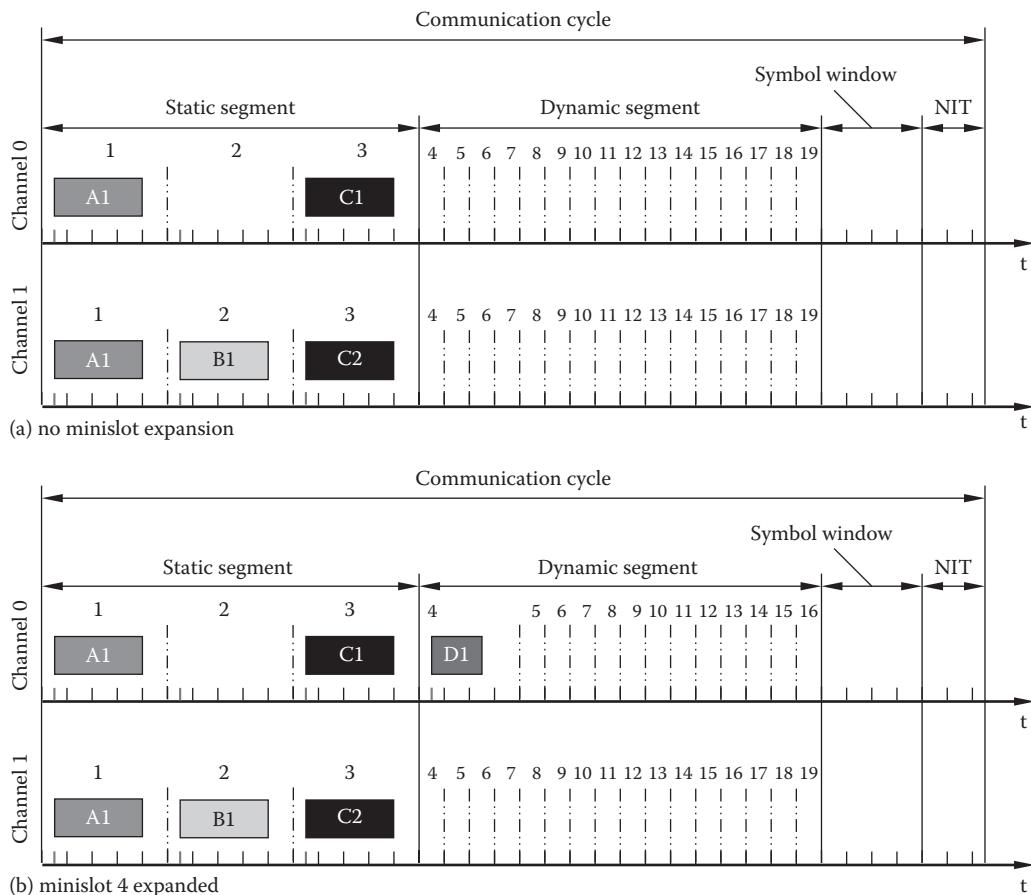

FIGURE 53.4 FlexRay dynamic segment.

If there are no data to transmit by the owner of a minislot, it remains silent. The minislot is not expanded, and slot counting continues with the next minislot. As no minislot expansion occurred, no additional bandwidth beyond the minislot itself is used; hence, other lower-priority minislots that are sequenced later within the dynamic segment have more bandwidth available.

This dynamic media access control scheme produces a priority and demand-driven access pattern that optimally uses the reserved bandwidth for dynamic communication. A controller that owns an *earlier* minislot, that is, a minislot, which has a lower number, has higher priority. The further a minislot is situated in the dynamic segment, the higher is the probability that it will not be in existence in a particular cycle due to the expansion of higher-priority slots. A minislot is only expanded and its bandwidth used if the owning controller has data to transmit. As a consequence, the local controller configuration has to ensure that each minislot is configured only once in a network. The minimum duration of a minislot is mainly determined by physical parameters of the network (delay) and by the maximum deviation of the clock frequency in the controllers. The duration of a minislot and the length of the dynamic segment are global configuration parameters that have to be consistent within all controllers in the network.

The symbol window is a time slot of fixed duration, in which special symbols can be transmitted on the network. Symbols are used for network management purposes.

The network idle time is a protocol-specific time window, in which no traffic is scheduled on the communication channel. The CCs use this time window to execute the clock synchronization algorithm. The offset correction (see the following text) that is done as a consequence of clock synchronization requires that some controllers correct their local view of the time forward and others have to correct backward. The correction is done in the network idle time. Hence, no consistent operations of the media access control can be guaranteed, and thus, silence is required. Since this duration has to be subtracted from net bandwidth, this duration is kept as small as possible. The minimum length is largely determined by the maximum deviation between the local clocks after one communication cycle. The duration of the network idle time is a global parameter that has to be consistent between all controllers in a network.

While at least a minimal static segment and the network idle time are mandatory parts of a communication cycle, the symbol window and the dynamic segment are optional parts. This results in basically three reasonable configurations (see Figure 53.5):

- Pure static configuration, which contains only static slots for transmission. In order to enable clock synchronization, the static segment must consist of at least two slots, which are owned by different controllers. If fault-tolerant clock synchronization should be maintained, the static segment must comprise at least four static slots.

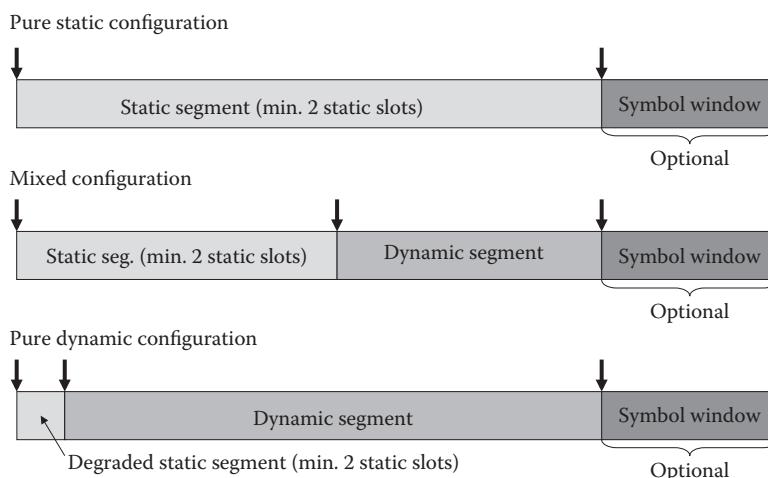

FIGURE 53.5 FlexRay configurations.

- Mixed configuration with a static segment and a dynamic segment, where the ratio between static bandwidth and dynamic bandwidth can vary in a broad range.
- Finally, a pure dynamic configuration with all bandwidth assigned to dynamic communication. This configuration also requires a so-called degraded static segment, which has two static slots.

Considering the most likely application domains, mixed configurations will be dominant. Depending on the actual configuration, FlexRay can achieve a best-case bandwidth utilization of about 70% with the average utilization ranging around 60%.

### 53.3.2 Clock Synchronization

The media access scheme of FlexRay relies on a common and consistent view about time that is shared between all CCs in the network. It is the task of the clock synchronization service to generate such a time view locally inside each CC. For the detailed description of the clock synchronization, first the representation of time inside a CC is described. The physical basis for each time representation is the tick of the local controller oscillator. This clock signal is divided by an integer to form a clock signal called microtick. This is often done by a frequency divider implemented in hardware. An integer number of microticks form a time unit called macrotick. Minislots and static slots are set up as integer multiple of macroticks. The number of microticks that constitute a macrotick is statically configured. However, for adjustment of the local time, the clock synchronization service can temporarily adjust this ratio in order to accelerate or decelerate the macrotick clock. If, for instance, a clock is too fast, microticks are added to a macrotick in order to slow down the counting.

The clock synchronization service is a distributed control system that produces local macroticks with a defined precision in relation to the local macroticks of the other controllers of a network. The control system takes some globally visible reference events that represent the global time ticks, measures the deviation of the local time ticks to these global ticks, and computes the local adjustments in order to minimize the deviation of the local clock from the global ticks. Due to the distributed nature of the FlexRay system, no explicit global reference event exists. The only event, which is globally observable, is a frame transmission on the communication channel. The start of a transmission is triggered by the local time base of the sending controller. Each controller can collect these reference events to form a virtual global time base by computing a fault-tolerant mean value of the deviation between the local time and the perceived events.

The reasoning behind this approach is based on the assumption that a majority of local clocks in the network is correct. Correctness of a local clock is given, when the local clock does not deviate from every other by more than the precision value. A controller with locally correct clock sees only deviation values within the precision value. By computing the median value of deviations, the actual temporal deviation of the local clock to the virtual reference tick is formed. Next, the local clock is adjusted such that the local deviation is minimized. Since all nodes in the network perform this operation, all local clocks move their ticks toward the tick of the virtual global time. The operation of observation, computing, and correction is performed in every communication cycle.

In case of wrong transmission times of faulty controllers on the communication channel, things get more complicated. Here, a special part of the fault-tolerant median value algorithm takes over. This algorithm uses only the best of the measured deviation values. All other values are discarded. This algorithm ensures that the maximum influence of a faulty controller to the virtual global time is strictly bound. Additionally, the protocol requires the marking of particular synchronization frames that can be used for deviation measurement. The reasoning behind this mechanism is twofold. The first reason is that it is used to pick exactly one frame from a controller in order to avoid monopolization of the global time by one controller with many transmit frames. The second reason is that particular controllers can be excluded from clock synchronization, either because the crystal is not trustworthy or more likely because there are system configurations in which a controller is not available.

In case of a faulty local clock, the faulty controller perceives only deviation values that exceed a particular value. This value is given by the precision value. This condition is checked by the synchronization service, and an error is reported to the application. A specific extension of the clock synchronization services handles the compensation of permanent deviations of one node. In case such a permanent deviation is detected, a permanent correction is applied. The detection and calculation of such permanent deviations is executed less frequently than the correction of temporal deviations.

The error handling of the protocol follows a strategy, which identifies every problem as fast as possible, but keeps the controller alive as long as possible. Problem indicators are frames that are received outside their expected arrival intervals or when the clock synchronization does not receive a sufficient number of synchronization frames. The automatic reaction of the controller is to degrade the operation from a sending mode to a passive mode where reception is still possible. At the same time, the problem is indicated to the application. The application can react in an application-specific manner to the detected problem. This strategy gives the designer of a system a maximum of flexibility for the design of the safety required by the application.

### 53.3.3 Start-Up

The preceding protocol description handled only the case of an already running system. To reach this state, the start-up service is part of the protocol. Its purpose is to establish a common view on the global time and the position in the communication cycle.

Generally, the start-up service has to handle two different cases. The coldstart case is a start-up of all nodes in the network, while the reintegration case means to integrate a starting controller into an already running set of controllers (see Figure 53.6).

During coldstart, the algorithm has to ensure that really a coldstart situation is given. Otherwise, the starting controller might disturb an already running set of controllers. For this reason, the starting controller has to listen for the so-called listen time-out for traffic on the communication channel. In case no traffic is detected, the controller assumes a coldstart situation and starts to transmit frames for a limited number of rounds. In case another controller responds with frames that fit to the slot counter of the coldstart node, start-up was successful.

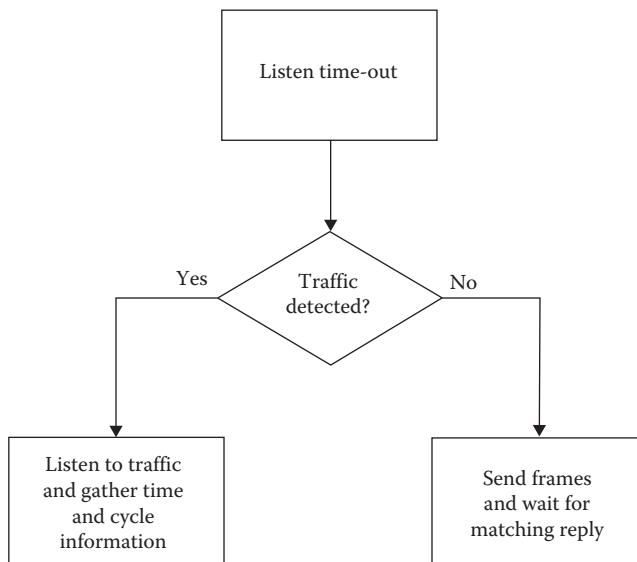

FIGURE 53.6 Start-up process.

In case traffic is detected during the observation period, the controller changes into the reintegration mode. In this mode, the controller has to synchronize the slot counter with the frames seen on the channel. Therefore, the controller receives frames from the channel and sets the slot counter accordingly. For a certain period of time, the controller checks the plausibility of the received frames in relation to the internal slot counter. If there is a match, the controller enters the normal mode, in which active transmission of frames is allowed.

### 53.3.3.1 Coding and Physical Layer

The frame format for data transmission contains three sections: the header section, the payload section, and the trailer section (see Figure 53.7). The header contains protocol control information like the synchronization frame flag, the frame ID, a null frame indicator and the frame length, and a cycle counter. The payload section contains up to 254 bytes of data. In case the payload does not contain any data, the null frame indicator is set. A null frame is thus a valid frame that does not contain any payload data. It can, however, serve as an alive signal or can be used for clock synchronization purposes.

Optionally, the data section can contain a message ID, which identifies the type of information transported in the frame. The trailer section contains a 24-bit CRC that protects the complete frame.

The existing FlexRay CCs support communication bit rates of up to 10 Mbps on two channels over an electrical physical layer. The physical layer is connected to the controller via a transceiver component.

This physical layer supports bus topologies, star topologies, cascaded star topologies, and bus stubs connected to star couplers as shown in Figure 53.8. This multitude of topologies allows a maximum of scalability and flexibility of electronic architectures in automotive applications.

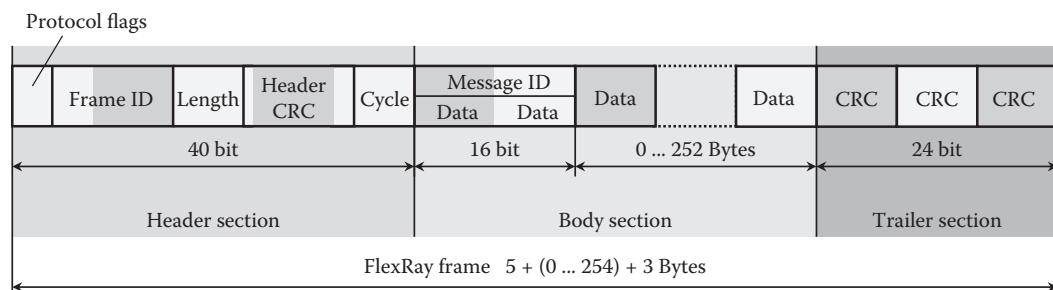

FIGURE 53.7 FlexRay frame format.

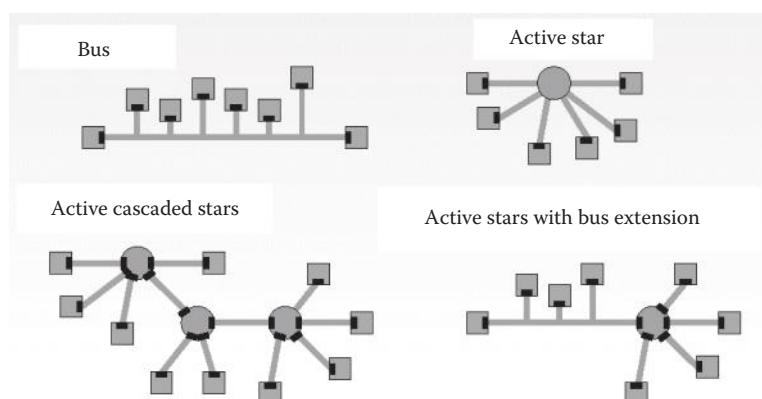

FIGURE 53.8 Topologies.

Besides the transformation of bit streams between the CC and the physical layer, the transceiver component also provides a set of very specific services for an automotive network. The major services are alarm handling and wakeup control. Alarm signals are a very powerful mechanism for diverse information exchange between a sender controller and receiver controllers. A sender transmits an alarm symbol on the bus parallel to alarm information in a frame. A receiver ECU receives the alarm information in the frame like normal data. Additionally, the CC receives the alarm symbol on the physical layer and indicates this symbol to the ECU. Thus, the ECU has two highly independent indicators for an alarm to act on. This scheme can be used for the validation of critical signals like an air-bag fire command.

The second type of service provided by the symbol mechanism is the wakeup function. A wakeup service is required in automotive applications where electronic components have a sleep mode, in which power consumption is extremely reduced. The wakeup service restarts normal operation in all sleeping ECU components. In a network, the wakeup service uses a special signal that is transmitted over the network. In FlexRay, this function relies on the ability of a transceiver component to identify a wakeup symbol and to signal this event to the CC and the remaining components of the ECU to wake these components up.

### 53.3.4 Bus Guardian

The media access strategy completely relies on the cooperative behavior of every CC in a network. The protocol mechanisms inside a controller ensure this behavior to a considerable high level of confidence. However, for safety-relevant applications, the controller internal mechanisms do not provide a sufficiently high level of safety. An additional and independent component is required to ensure that no controller can disturb the media access mechanism of the network. This additional component is called bus guardian (BG).

In FlexRay, the BG is a component with an independent clock and is constructed such that an error in the controller cannot influence the guardian and vice versa. The BG is configured with its own set of parameters. These are independent of the parameters of the controller, although both parameter sets represent the same communication cycle and slot pattern. During runtime, the BG receives synchronization signals from the controller in order to keep track with the communication cycle. Using its own clock the BG verifies those synchronization signals to avoid being influenced by a faulty controller.

Typically, the BG will be combined with the transceiver component. Optionally, a central BG located inside a star coupler can be used.

### 53.3.5 Protocol Services

Application information is transmitted by the CC inside of frames. A frame contains one or more application signals. A controller provides an interface for frame transmission and reception that consists of buffers. A buffer consists of a control/status section and the data section. These sections have different semantics for receive and transmit frames and for static and dynamic slots.

The control section of transmit buffers for frames in the static segment contains the slot ID and the channel, in which the frame is transmitted. Once a buffer of this type is configured and the communication is started, the controller periodically transmits the data in the data section in the slot configured in the slot ID. When the application changes the data in the buffer, the subsequent transmission contains the new data. A special control flag allows modifying this behavior such that in case the application does not update the data in the buffer, a null frame is transmitted, signaling the failure to update other controllers. The control section of a receive buffer for frames in the static segment defines the slot ID and the channel from which the frame should be loaded into the buffer. The status section contains the frame receive status and the null frame indicator. One special flag indicates that a new frame has been received. It is important to note that the slot ID and the channel selection for slots in the static segment cannot be changed during operation.

Buffer status and control section for frames in the dynamic segment are similar to the buffers in the static segment. Differences result from the fact that the slot ID and the channel can be changed during normal operation and that multiple buffers can be grouped together to form a FIFO for frame reception from the dynamic section.

The CC provides a set of timers that run clocked by the synchronized time of the network. Several different conditions can be used to generate interrupts based on these timers. These interrupts are efficient means to synchronize the application with the timing on the bus.

### 53.3.6 FlexRay Current State

By the end of 2006, the FlexRay technology was introduced in a passenger car, proving the readiness of the technology for use in series production. Already in 2008, five silicon vendors provided or announced microcontrollers with FlexRay interfaces for 16- and 32-bit architectures (Freescale, Fujitsu, NEC, TI, and Renesas). Three silicon vendors provide physical layer chips (NXP, AMS, and Elmos). Another important milestone was the introduction of FlexRay in the first mass production car below the premium segment in 2011 (BMW 3 series), thus proving the economic validity of the technology.

The version of the implemented protocol specification is 2.1 rev A. As a result of the experience gained from the first series projects, the FlexRay Consortium continued to improve the FlexRay specification. Those improvements resulted in the FlexRay standard 3.0, which was handed over to the ISO standardization body. In 2013, the standardization process is almost completed (ISO 10681-1,2 and ISO 17458-1,5). However, currently no silicon vendor has FlexRay 3.0 on the roadmap.

Feedback from carmakers and suppliers does not indicate any significant problems with FlexRay observed in the field. Compared to CAN, a high level of robustness was reached by FlexRay much faster. One concern related to FlexRay in automotive applications is the complexity of configuration. The fine-segmented distribution of responsibilities over many parties and suppliers makes the planning process a burden that needs to be overcome. However, the current automotive open system architecture (AUTOSAR) methodology supports this process in many ways.

In the recent years, two alternative technologies got into the focus of the carmakers, Ethernet and CAN FD [2]. Both technologies root in requirements outside the scope of FlexRay, yet they will reduce the scope of application for FlexRay. CAN FD will prolong existing CAN-based architectures without the need to upgrade to FlexRay, and Ethernet can take over areas where the complex configuration of FlexRay is a hindering factor (e.g., backbone networks).

## 53.4 System Configuration

---

With the advent of the TDMA communication technologies and especially in the automotive application domain, the off-line configuration of networks gets increasingly important. Off-line configuration means that the configuration parameters of the CCs are not generated during the runtime of the system but are determined throughout the development time of the system. The processes for system development are not only mainly determined by the applied technology, but also driven by industry-specific technical or organizational constraints. In the following section, the background for such a design process is described by first defining a model for the used information (Figure 53.9) and second explaining the information processing.

The functional domain defines entities called functions and the communication relations between them. Functions describe the functionality of the entire system, creating a hierarchy from very abstract high-level functions down to specific tailored functions. A system normally comprises more than one function. In a vehicle, for example, the functional hierarchy would feature *chassis functions* on the top level like *steering functions* and *braking functions*, the latter being even more detailed into *basic braking function*, *antilock brake functions*, and so on. A communication relation between functions or within a function starts at a sender function, connects the sender function with receiver functions, and has an assigned signal.

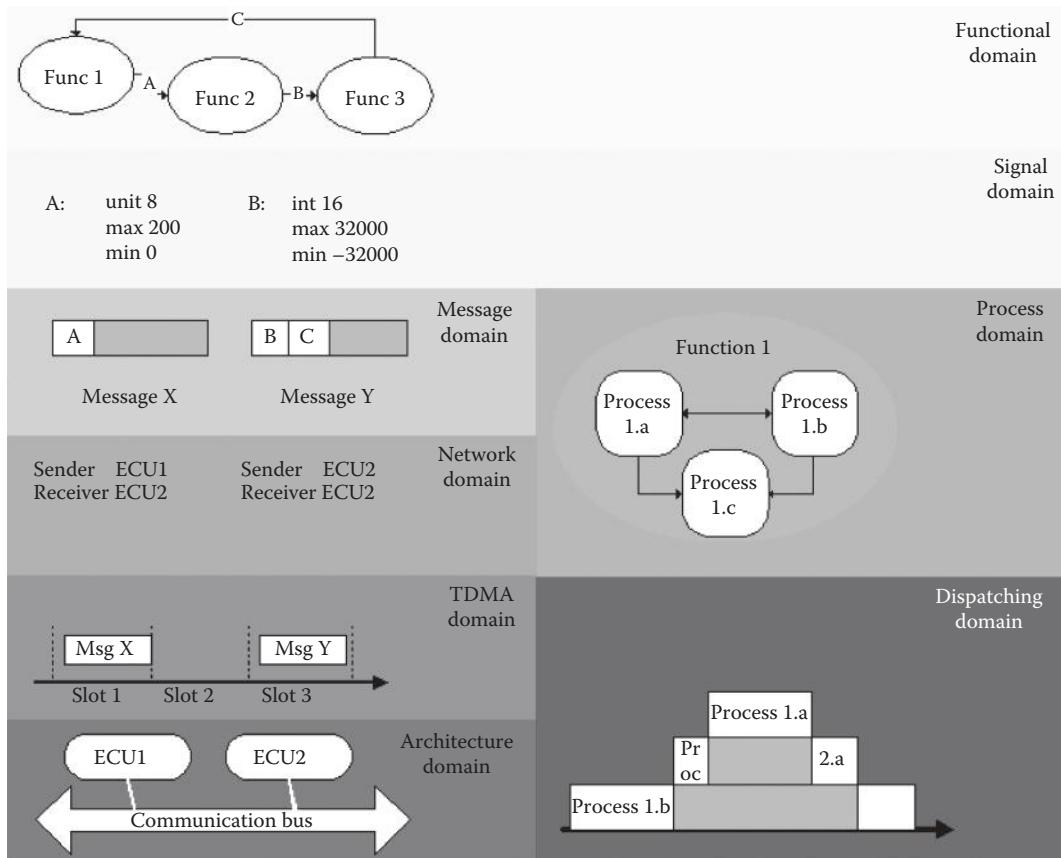

FIGURE 53.9 Information domains.

Signals are defined in the signal domain. A signal definition contains a signal name, the signal semantics, and the value range. Signals are assigned to messages. The message domain defines messages, that is, packages of signals that should be transmitted together. A message has a name and a fixed setup of the signals it contains. The network domain determines which ECU will send a frame containing a message as well as which ECUs should receive this frame. The TDMA domain establishes the exact points in time when frames are transmitted. Finally, the architecture domain defines the physical structure of a system, with all ECUs, communication systems, and the connections of the ECUs to them.

The six information domains provided earlier are of importance for the entire system, that is, for all ECUs of the systems. Hence, they are considered *global information*.

Two additional domains complement the message, network, TDMA, and architecture domains. These two domains are the process domain and the dispatching domain. The process domain describes the software architecture of the system. It lists all processes and their interactions like mutual exclusion, as well as the assignment of processes to functions. Processes are information processing units of an application. They have timing parameters assigned to them that define the period and the time offset of their execution. The dispatching domain is the ECU counterpart of the TDMA domain. It determines the application timing, that is, which process is executed at which point in time. Implicitly, this also defines the preemption of processes, that is, when a process is interrupted by the execution of another process. The latter two information domains feature information that is relevant for only one ECU. Hence, they are considered to be *local information* (local referring to one ECU rather than the entire system).

The categorization of information given by the information domain model leads the way to the development process. It is an organizational constraint in the automotive development processes that the knowledge related to the system to be developed is distributed among the process participants. These participants are typically the automobile manufacturer (OEM) and one or more suppliers. The OEM possesses the information on the intended system functions, the envisioned system architecture, and the allocation of functions to architectural components, that is, to ECUs. Thus, the OEM's knowledge covers three of the six global information domains.

The supplier, on the other hand, is the expert on function implementation and ECU design. This means he provides the knowledge on the process domain, that is, the software architecture underlying the function implementation. Each function of the system or each part thereof is implemented by a set of interacting processes. The functionality of the ECU does rely not only on the software architecture but also on the execution pattern. The supplier has to define the timing of each process executed in his developed ECU. Hence, the dispatching domain is the supplier knowledge as well.

With five of the eight information domains assigned, the open question is whose responsibility are the three remaining information domains. As described in the previous section, these domains—the message, the network, and the TDMA domain—define the communication behavior on the system level. They specify at which point in time, which message is transferred from which sending ECU to which receiving ECUs. These domains obviously affect all ECUs of the system; hence, no single supplier should be able to define these domains. For this reason, the DECOMSYS development process for collaborative system development between an OEM and several suppliers assigns the message, the network, and the TDMA domain to the OEM.

So far, each piece of development information has been assigned to a process participant, which results in a static structure. In the following appropriate dynamic structure, the development process will be described in brief.

The proposed OEM-supplier development process (Figure 53.10) takes a two-phase approach. In the first phase, the OEM has to cover all global aspects; subsequently, supplying companies deal with the local aspects.

The process builds on the functional model of the system, which belongs to the functional domain and the signal domain, and the architectural model belonging to the architecture domain. The functional model describes the functions of the system and their structure consisting of subfunctions. As subfunctions have to exchange information in order to provide the intended function output, the functional

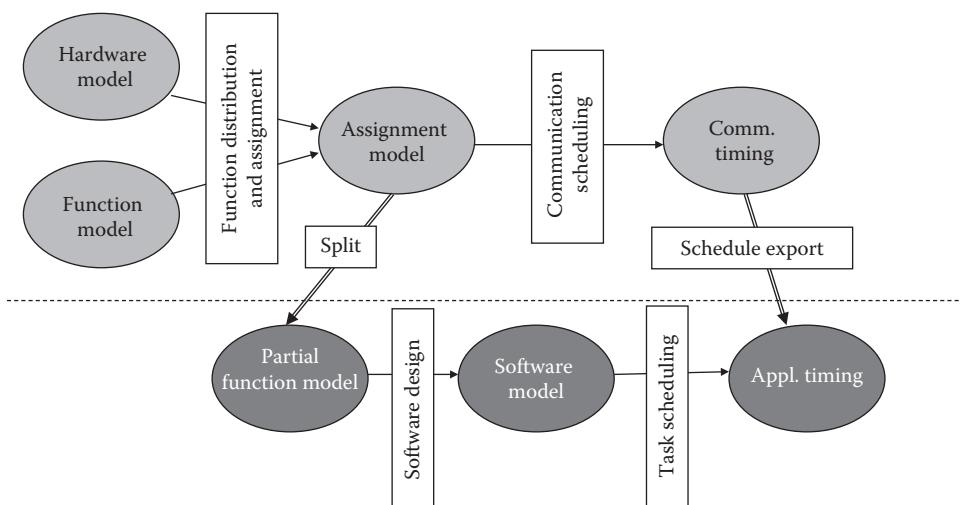

FIGURE 53.10 OEM-supplier development process.

model inherently also defines the signals that are transferred from one subfunction to others. The functional model is complemented by the architectural model, which defines the system topology and the ECUs that are present in the system. The mapping between these two models results in a concrete system architecture for a particular system in a particular vehicle. This is described in the distributed functional model.

Based on the distributed functional model, the OEM performs communication scheduling. During this operation, signals are packed to messages, which in turn are scheduled for transmission at a specific point in time. Communication scheduling concludes the global design steps and thus the OEM's tasks.

The suppliers base their local design steps on the global information given by the OEM. The so-called split of the distributed functional model tells the supplier which functions or subfunctions the ECU has to perform, that is, his responsibility. The supplier conducts software architecture design and creates the software model for each function or subfunction. The resulting list of processes is scheduled for the ECU taking into account local constraints as well as the global constraints defined in the communication schedule.

Note that for performing the local design, the supplier solely requires parts of the global information created by the OEM as well as his own knowledge on the ECU. In principle, the suppliers do not influence each other.

### 53.4.1 Development Models

The use of development models with a clear purpose and information content is the answer to the challenge of reuse of components for different car lines. Each model focuses on a certain type of information. The full picture of the system consists of these individual models and the mappings between them.

When developing a new car, only those models affected by the differences between the previous version and the new vehicle have to be adapted while the other models remain unchanged. To be more specific, the reuse of system parts calls for the separation of the architectural and the functional models. The functional model, that is, the functions to be executed by the distributed system, is primarily independent of a specific car model and can be reused in different model ranges. The architectural model on the other hand, that is, the concrete number of ECUs and their properties in a certain car, vary between model ranges.

It is decisive for a useful development process to allow the separate development of the functional model and the architectural model. At the same time, the process must support the mapping of the functions to concrete hardware architecture elements.

## 53.5 Standard Software Components

---

Standard software components within an ECU deliver a set of services to the actual application. The application itself can make use of these services without implementing any of them. For example, if a transport layer is part of the standard software components used in a project, the application does not need to take into account the segmentation and reassembly of data that exceed the maximum message size.

In order to reuse the application code in another project, the services offered by the standard software in the new project should be the same. If the standard software provides less functionality, the code has to be changed, as missing services have to be added.

In the optimal case, the standardization effort covers all OEMs and suppliers. Only then, reuse of existing code can be guaranteed, thus creating a win-win situation for all participants: The OEMs can purchase tested software that has proven its function and reliability in other projects—suppliers on the other hand have the possibility to sell this software, which they have created with considerable effort, to other OEMs.

### 53.5.1 Standardized Interfaces

Standard software components are not the only answer to the challenge of reuse. The standard software components and their standardized services must be complemented by standardized interfaces, through which the application software can access these services. Standardizing interfaces for software means to provide one operating system API for the software to access communication as well as other resources like analog-to-digital converters (ADCs). Similarly, standardized network interfaces allow the reuse of entire ECUs in different networks. The hardware of a distributed system can have a standardized interface represented by an abstract description of the network communication.

Standardization of software components as well as interfaces and thus a system architecture is not a competitive issue. Depending on where the interfaces are set, there is ample room for each participating company to use its strengths effectively to achieve its purpose. In our opinion, the real competitive issues are the functions in an ECU or the overall system functionality that is realized by the interaction of ECU functions. The special behavior of an electronic power-steering system as perceived by the car driver is mainly determined by the control algorithms and their application data, rather than by the type of communication interface used for integration.

With respect to standardization efforts, the industry is currently moving in the right direction. Initiatives like the open systems and the corresponding interfaces for automotive electronics (OSEK/VDX) Consortium [3], HIS [4], and many others attempt to standardize certain software components and interfaces. The field bus data exchange format (FIBEX) group that is now part of the Association for standardization of automation and measuring systems Consortium [5] develops a standardized exchange format between tools based on XML, which is able to hold the complete specification of a distributed system. Many of these initiatives and projects are now united in the AUTOSAR development partnership [6] with the goal to generate an industry-wide standard for the basic software infrastructure.

### 54.1 Introduction

---

Local interconnect network (LIN) is much more than *just another protocol!* LIN is defining a straightforward design methodology and provides definition of tool interfaces and a signal-based application programming interface (API) in a single package.

LIN is an open communication standard, enabling fast and cost-efficient implementation of low-cost multiplex systems. It supports encapsulation for model-based design and validation, leading to front-loaded development processes that are faster and more cost efficient than traditional development methods.

The LIN standard not only covers the definition of the bus protocol but expands its scope into the domain of application and tool interfaces, reconfiguration mechanisms, and diagnostic services—thus offering a holistic communication solution for automotive, industrial, and consumer applications. In other words, systems engineering at its best enables distributed and parallel development processes.

Availability of dedicated tools to automate the design and system integration process is a key factor for the success of LIN.

## 54.2 Need

---

The car industry today is implementing an increasing number of functions in software. Complex electrical architectures using multiple networks with different protocols are the norm in modern high-end cars. The software industry in general is handling software complexity through *best practices* such as the following:

- *Abstraction*: Hiding the unnecessary level of detail.
- *Composability*: Partitioning a solution into a set of separately specified, developed, and validated modules, easily combined into a larger structure inheriting the validity of its components—without the need for revalidation.
- *Parallel processes*: State-of-the-art development processes such as the Rational Unified Process (RUP) are based on parallel and iterative development where the most critical parts are developed and tested in the first iterations.

The automotive industry is under constant pressure to reduce cost and lead time while still providing increasing amount of functionality. This must be managed without sacrificing quality. It is not uncommon today for a car project to spend half a billion US dollars on development and perhaps as much as 150 million on prototypes. By shortening lead time, the carmaker creates benefits in several ways; typically, both development cost and capital costs are reduced. At the same time, an earlier market introduction creates better sales volumes and therefore better profit. One way of reducing lead time is by eliminating traditional prototype loops requiring full-size cars, rather than relying on *virtual development*, replacing traditional development, and testing methods by Computer aided engineering (CAE).

To reduce development time while maintaining quality, a reduction in lead time must occur in a coordinated fashion for all major subsystems of a car such as body, electrical, chassis, and engine. With improved tools and practices for other subsystems and increasing complexity of the electrical system, more focus must be placed on the electrical development process, as it may determine the total lead time and quality of the car. These two challenges—lead time reduction and handling of increased software complexity—will put growing pressure on the industry to handle development of electrical architectures in a more purposeful manner. (Specks and Rajnák [1998, 2000]).

## 54.3 History

---

The LIN Consortium started in late 1998 initiated by five car manufacturers Audi, BMW, DaimlerChrysler, Volvo, and Volkswagen, the tool manufacturer Volcano Communications Technologies (VCT), and the semiconductor manufacturer Motorola. The workgroup focused on specification of an open standard for low-cost LINs in vehicles where the bandwidth and versatility of Control Area Network (CAN) are not required. The LIN standard includes the specification of the transmission protocol, the transmission medium, the interface between development tools, and the interfaces for application software programming. LIN promotes scalable architectures and interoperability of network nodes from the viewpoint of hardware and software and a predictable EMC behavior. LIN complements the existing portfolio of automotive multiplex networks. It will be the enabling factor for the implementation of hierarchical vehicle networks, in order to gain further quality enhancement and cost reduction of vehicles. It addresses the needs of increasing complexity, implementation, and maintenance of software in distributed systems by providing a highly automated tool chain.

The main properties of the LIN bus are

- Single master multiple slaves structure
- Low-cost silicon implementation based on common universal asynchronous receiver/transmitter/serial communications Interface (UART/SCI) interface hardware, an equivalent in software, or as pure state machine

- Self-synchronization without a quartz or ceramics resonator in the slave nodes
- Deterministic signal transfer entities, with signal propagation time computable in advance
- Signals-based API

A LIN network comprises one master and one or more slave nodes. The medium access is controlled by a master node—no arbitration or collision management in the slaves is required. Worst-case latency of signal transfer is guaranteed.

The LIN consortium ended its operation in 2010 after 12 years of development of the LIN standard. After 2010, the LIN standard was considered stable for several years and it was difficult to justify continued operation of a consortium maintaining the LIN standard. The last LIN standard released by the LIN consortium by the end of 2010 was the LIN 2.2A. The LIN consortium requested the International Organization for Standardization (ISO) to take over the standard—following the example of the FlexRay specification.

The LIN standard was accepted as an ISO standard and is currently (2013) under continued development. The identification of the specification is ISO/CD 17987, parts 1–7. The diagnostic part is moved to ISO/CD 14229-7.

## 54.4 Some LIN Basics

---

LIN is a low-cost, single-wire network. The starting point of the physical layer design was the ISO 9141 standard. In order to meet EMC requirements, the slew rates are controlled. The protocol is a simple master slave protocol based on the common UART format. In order to enable communication between nodes clocked by low-cost RC oscillators, synchronization information is transmitted by the master node on the bus. Slave nodes will synchronize with the master clock, which is regarded to be accurate. The speed of the LIN network is up to 20 kbps, and the transmission is protected by a checksum. The LIN protocol is message identifier based. The identifiers do not address nodes directly, but denote the meaning of the messages. This way any message can have multiple destinations (multicasting). The master sends out the message header consisting of a synchronization break (serving as a unique identifier for the beginning of the frame), a synchronization field carrying the clock information, and the message identifier, which denotes the meaning of the message.

Upon reception of the message identifier, the nodes on the network will know exactly what to do with the message. One of the nodes sends out the message response and the others either listen or do not care. Messages from the master to the slave(s) are carried out in the same manner—in this case, the slave task incorporated into the master node sends the response.

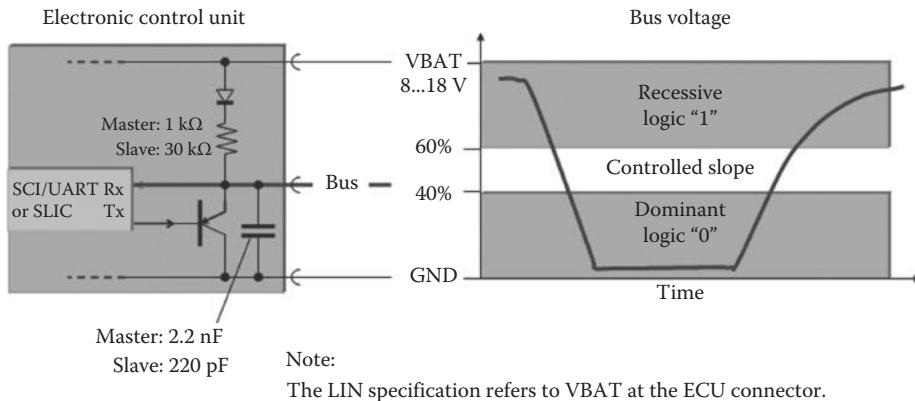

LIN messages are scheduled in a time-triggered fashion. This provides a model for the accurate calculation of latency times—thus supporting fully predictable behavior. Since the master sends out the headers, it is in complete control of the scheduling and is also able to swap between a set of predefined schedule tables, according to the specific requirements/modes of the applications running in the subsystem.

## 54.5 LIN Physical Layer

---

The transport medium is a single-line, wired-AND bus being supplied via a termination resistor from the positive battery node ( $V_{BAT}$  nominally 12 V). The bus line transceiver is an enhanced ISO 9141 implementation. The bus can take two complementary logical values: the dominant value with an electrical voltage close to ground and representing a logical “0” and the recessive value, with an electrical voltage close to the battery supply and representing a logical “1” (Figure 54.1).

The bus is terminated by a pull-up resistor with a value of  $1\text{ k}\Omega$  in the master node and  $30\text{ k}\Omega$  in a slave node. A diode in series with the resistor is required to prevent the electronic control unit (ECU) from being powered by the bus in case of a local loss of battery. The termination capacitance is typically  $C_{Slave} = 220\text{ pF}$  in the slave nodes, while the capacitance of the master node is higher in order to make the total line capacitance less dependent from the actual number of slave nodes in a particular network.

**FIGURE 54.1** LIN physical layer.

The maximum signaling rate is limited to 20 kbps. This value is a practical compromise between the conflicting requirements of high slew rates for the purpose of easy synchronization and for slower slew rates for electromagnetic compatibility. The minimum baud rate is 1 kbps—helping to avoid conflicts with the practical implementation of time-out periods.

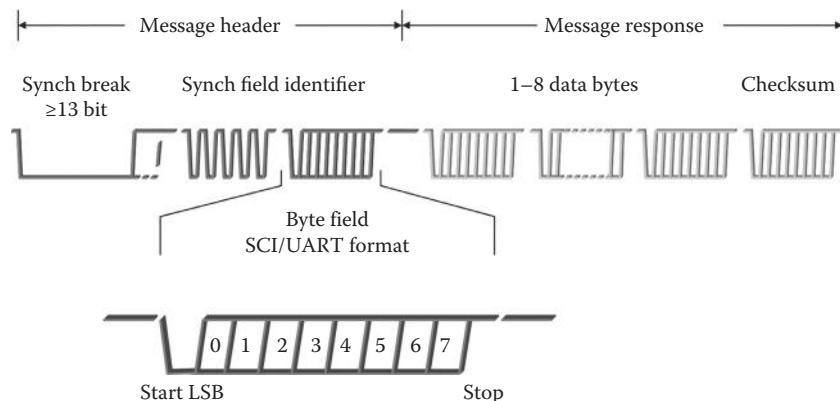

In addition to the 12 V LIN bus, there is also a specification for a 24 V LIN variant, driven by demand from the truck original equipment manufacturers (OEMs).

## 54.6 LIN Protocol

The entities that are transferred on the LIN bus are frames. One message frame is formed by the header and the response (data) part. The communication in a LIN network is always initiated by the master task sending out a message header, which comprises the synchronization break, the synchronization byte, and the message identifier. One slave task is activated upon reception and filtering of the identifier and starts the transmission of the message response. The response comprises one to eight data bytes and is protected by one checksum byte.

The time it takes to send a frame is the sum of the time to send each byte, plus the response space, and the interbyte space. The interbyte space is the period between the end of the stop bit of a byte and the start bit of the following byte.

The interframe space is the time from the end of a frame until the start of the next frame. A frame is constructed of a break followed by 4–11 byte fields. The structure of a frame is shown in Figure 54.2.

**FIGURE 54.2** Frame structure.

In order to allow the detection of signaling errors, the sender of a message is required to monitor the transmission. After transmission of a byte, the subsequent byte may only be transmitted if the received byte was correct. This allows a proper handling of bus collisions and time-outs.

Signals are transported in the data field of a frame. Several signals can be packed into one frame as long as they do not overlap each other. Each signal has exactly one producer, that is, it is always written by the same node in the cluster. Zero, one, or multiple nodes may subscribe to the signal. A key property of the LIN protocol is the use of schedule tables. Schedule table makes it possible to assure that the bus will never be overloaded. They are also the key component to guarantee timely delivery of signals to the subscribing applications. Deterministic behavior is made possible by the fact that all transfers in a LIN cluster are initiated by the master task. It is the responsibility of the master to assure that all frames relevant in a certain mode of operation are given enough time to be transferred.

## 54.7 LIN Conformance Test

---

In addition to the LIN specification, the LIN consortium also developed a LIN conformance test specification. The OEMs need an assurance that the LIN nodes that are developed by suppliers do fully conform to the specification. It covers both the physical and the protocol layers. Pre-2010 accredited test houses performed certification of the LIN node implementations. Today, the accredited test houses are typically governed by the OEMs.

## 54.8 Design Process and Workflow

---

Regardless of the protocol, a network design process comprises of three major elements:

1. Requirement capturing (signal definitions and timing requirements)
2. Network configuration/design
3. Network validation

The holistic concept of LIN supports the entire development, configuration, and validation of a network by providing definition of all necessary interfaces.

The LIN workflow allows for the implementation of a seamless chain of design and development tools enhancing speed of development and the reliability of the resulting LIN cluster.

The LIN configuration language allows description of a complete LIN network and also contains all information necessary to monitor the network. This information is sufficient to make a limited emulation of one or multiple nodes if it/they are not available. The LIN description file (LDF) can be one component used to generate software for an ECU, which shall be part of the LIN network. An API has been defined by the LIN standard to provide a uniform, abstract way to access the LIN network from applications. The syntax of an LDF is simple and compact enough to be handled manually, but the use of computer-based tools is encouraged. Node capability files (NCFs), as described in LIN node capability language specification, provide one way to (almost) automatically generate LDFs.

## 54.9 System Definition Process

---

Defining optimal signals packing and schedule table(s) fulfilling signaling needs in varying modes of operation, with consideration of capabilities of the participating nodes, is called the system definition process. Typically, it will result in generation of the LDF, written by hand for simple systems or generated by high-level network design tools.

However, reusing existing, preconfigured slave nodes to create a cluster of them, starting from scratch, is not that convenient. This is especially true if the defined system contains node address conflicts or frame identifier conflicts. The LIN node capability language, which is a new feature in LIN 2.0, provides

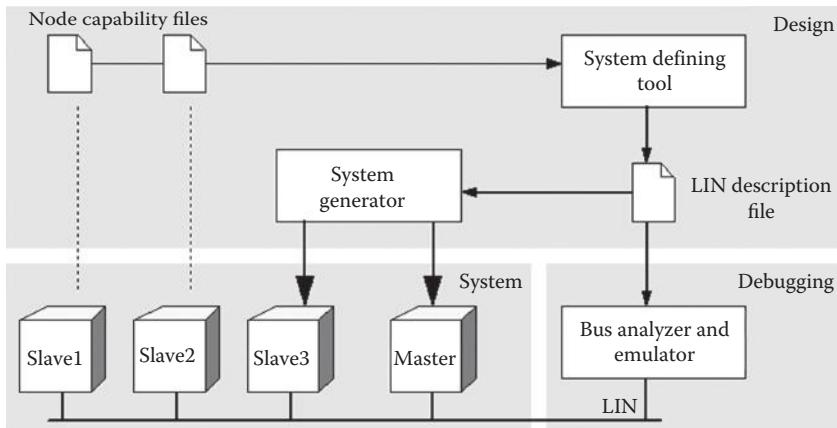

FIGURE 54.3 Workflow.

a standardized syntax for specification of off-the-shelves slave nodes. This will simplify procurement of standard nodes as well as provide possibilities for tools that automate cluster generation. The availability of such nodes is expected to grow rapidly. If accompanied by an NCF, it will be possible to generate both the LIN configuration file and initialization code for the master node. Thus, true plug and play with nodes in a cluster will become a reality.

By receiving an NCF with every existing slave node, the system definition step is automatic: just add the NCF to your project in the system definition tool and it produces the LDF together with C code to configure a conflict free cluster. The configuration C code shall, of course, be run in the master node during start-up of the cluster.

If you want to create new slave nodes as well, the process becomes somewhat more complicated. The steps to perform will depend on the system definition tool being used, which is not part of the LIN specification. A useful tool will allow for entering of additional information before generating the LDF. (It is always possible to write a fictive NCF for the nonexistent slave node, and thus, it will be included.)

An example of the intended workflow is depicted in Figure 54.3.

The slave nodes are connected to the master forming a LIN cluster. The corresponding NCFs are parsed by the system defining tool to generate an LDF in the system definition process. The LDF is parsed by the system generator to automatically generate LIN-related functions in the desired nodes (the Master and Slave3 in the example shown in the picture previously). The LDF is also used by a LIN bus analyzer/emulator tool to allow for cluster debugging.

If the setup and configuration of any LIN cluster is fully automatic, a great step toward plug-and-play development with LIN will be taken. In other words, it will be just as easy to use distributed nodes in a LIN cluster as using a single node with the physical devices connected directly to the node.

It is worth noticing that the generated LDF reflects the configured network; any preexisting conflicts between nodes or frames must have been resolved before activating cluster traffic.

## 54.10 Debugging

Debugging and node emulation are based on the LDF produced during system definition. Emulation of the master adds the requirement that the cluster must be configured to be conflict free. Hence, the emulator tool must be able to read reconfiguration data produced by the system definition tool.

One example of a comprehensive tool chain built around the open interface definitions of the LIN standard is presented in the following sections of this chapter.

## 54.11 AUTOSAR and LIN

The Automotive Open System ARchitecture (AUTOSAR) standard partially covers the LIN protocol, covering the master node only. The slave node is not addressed based on the argument that LIN slave nodes do not make use of the AUTOSAR platform. Seen from the bus, the AUTOSAR LIN protocol is identical with the LIN specification. The AUTOSAR LIN software requirements are however different from the original LIN specification. Due to the specific software architecture of AUTOSAR, the LIN interface specifications are not used. Consequently, the configuration API is not used either by AUTOSAR. However, configuration using schedule tables is supported in AUTOSAR.

The relevant AUTOSAR LIN specifications are the following:

*LIN interface software specification (SWS)*: Covers the specification of the master node behavior and its interfaces in the AUTOSAR architecture.

*LIN network manager*: This is today an empty template, since LIN lacks the complex network management defined for CAN.

*LIN state manager*: Handles the mode change mechanism of the LIN bus.

*LIN driver*: Handles the  $\mu$ -controller abstraction to make the other LIN documents  $\mu$ -controller independent.

*LIN transceiver driver*: To handle complex LIN transceivers.

## 54.12 Future

The driving ideas and the resulting technology behind the success of LIN—the structured approach toward the system design process—will most likely migrate to other areas of automotive electronics. LIN itself will find its way to applications outside of the automotive world due to its low cost and versatility. The LIN specification will evolve further to cover upcoming needs. There will be a broad supply of components that are made for LIN. Because of high production volumes, these products can be used cost effectively in many applications, enhancing the functionality of vehicles in a more cost-effective manner.

Fifteen years after the LIN consortium was founded, the number of LIN nodes manufactured has been increasing steadily. Due to the holistic concept that the LIN specifications realize, LIN has gained wide acceptance in the automotive industry.

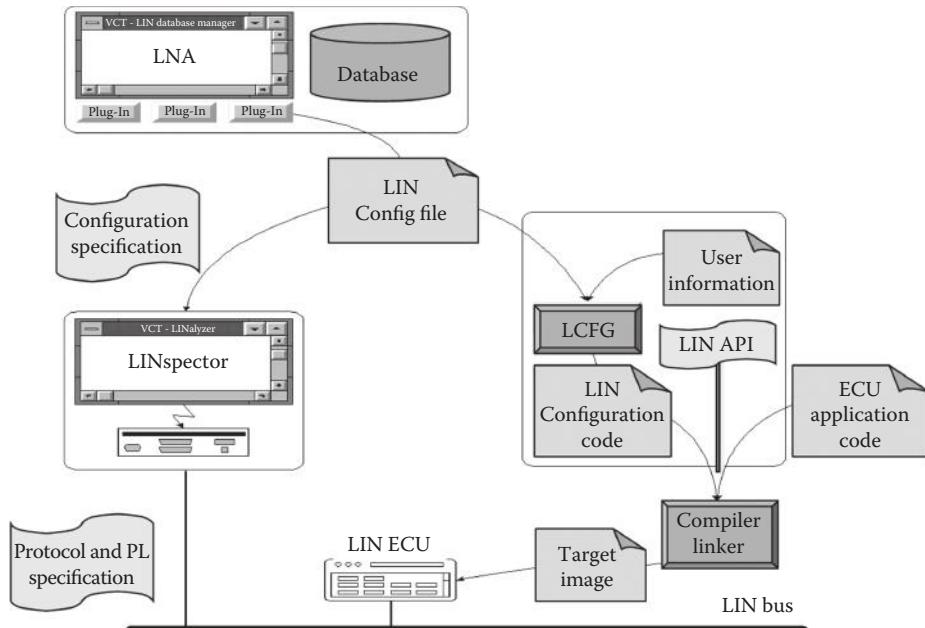

## 54.13 Volcano LIN Tool Chain

Process description (Figure 54.4):

1. LIN network requirements are entered into LNA.
2. Automatic frame compilation and schedule table generation by LNA.
3. LDF is generated by LNA.
4. LIN configuration generator tool converts the LDF and private file to target-dependent ".c" and ".h" code.
5. Application code is compiled with target-dependent configuration code and linked to the LIN target package (LTP) library.
6. Analysis and emulation are performed with LIN Spector using the generated LDF.

## 54.14 LIN Network Architect

LIN Network Architect (LNA) is built for design and management of LIN networks. Starting with the entry of basic data such as signals, encoding types, and nodes, LNA takes the user through all stages of network definition.

**FIGURE 54.4** Volcano LIN tool chain.

#### 54.14.1 Requirement Capturing

There are two types of data administered by LNA:

1. Global objects (signals, encoding types, and nodes)
2. Project-related data (network topology, frames, and schedule tables)

Global objects shall be created first and can then be reused in any number of projects.

They can be defined manually or imported by using a standardized XML input file (based on Fibex rev. 1.0). Future versions of the tool will be able to import data directly from the standardized NCF. Comprehensive version and variant handling is supported (Figure 54.5).

The systems integrator combines subsets of these objects to define networks. Consistency check is being performed continuously during this process. This is followed by automatic packing of signals into frames (Figure 54.6).

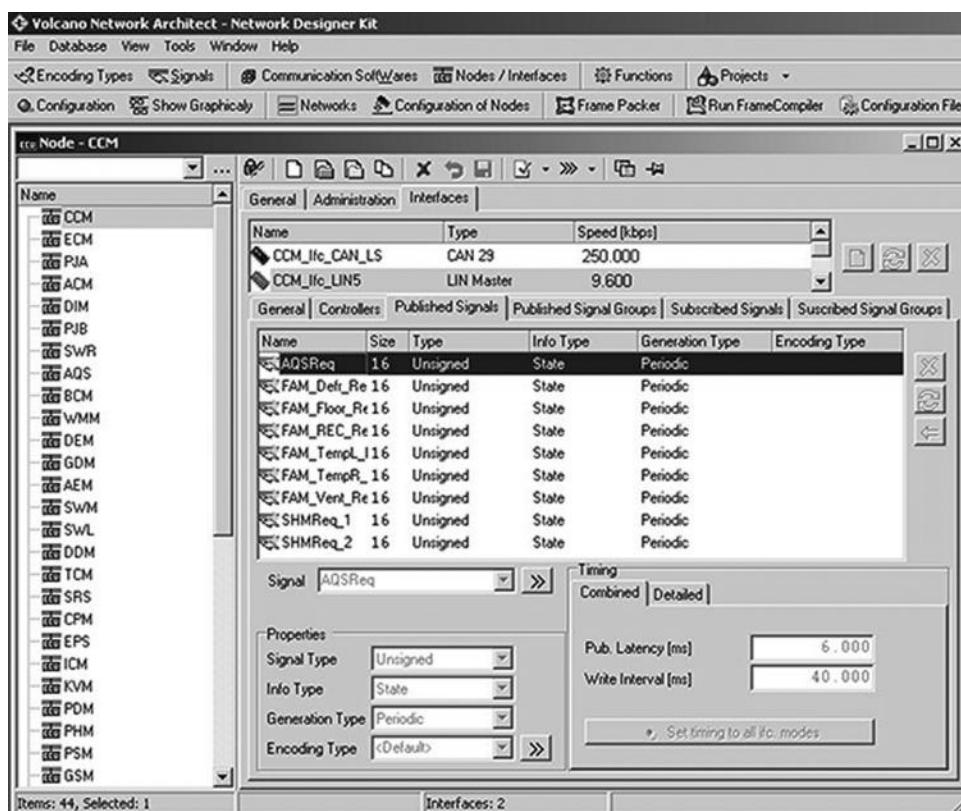

The last task to complete is that of generating the schedule table in accordance with the timing requirements captured earlier in the process. The optimization is considering several factors such as bandwidth and memory usage.

Based on the allocation of signals to networks via node interfaces, the tool will automatically identify gateway requirements between subnetworks, regardless whether LIN to LIN or LIN to CAN. The transfer of signals from one subnetwork to another will become completely transparent to the application of the automatically selected gateway node (Figure 54.7).

The tool uses a publish/subscribe model. A signal can only be published by one node but it can be received by any number of other nodes. Different nodes may have different end-to-end timing requirements (Figure 54.8).

The `max_age` is the most important timing parameter defined in the Volcano timing model. This parameter describes the maximum allowed time between the generation and consumption of a signal involved in a distributed function.

Changes can be introduced in a straightforward manner, with frame definitions and schedule tables automatically recalculated to reflect the changed requirements.

**FIGURE 54.5** Definition of global objects in LNA.

When the timing analysis has been performed and the feasibility of the individual subnetworks has been established, LDF will automatically be created for each network (Figure 54.9).

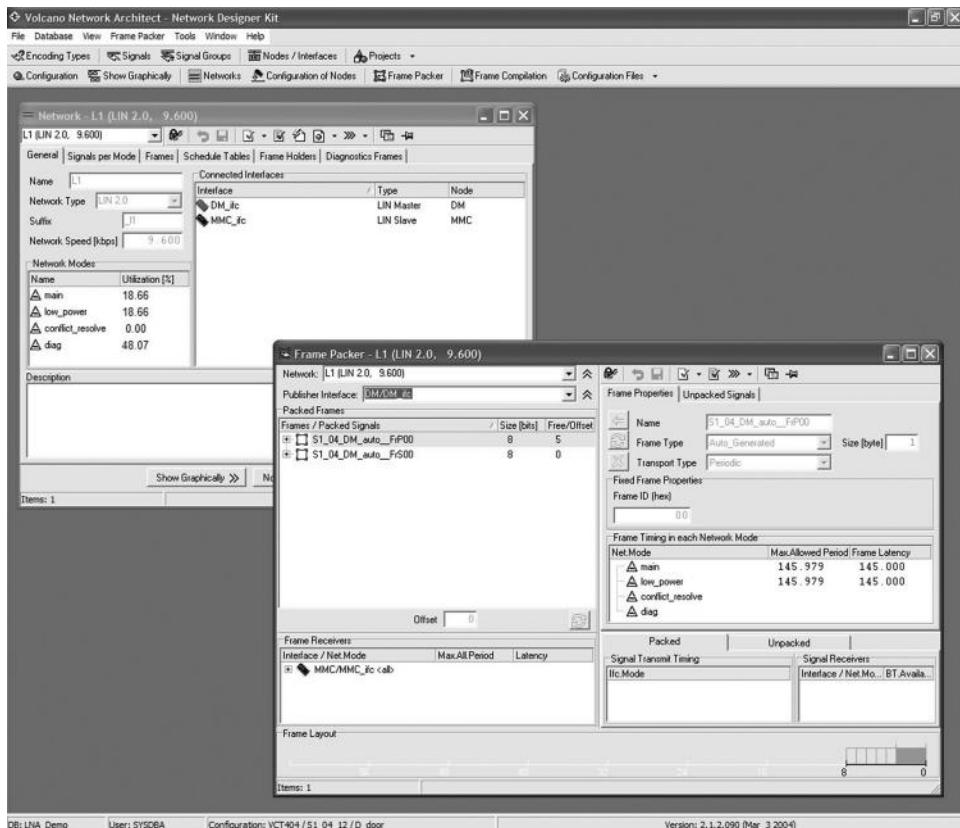

Textual reports can be generated as well to enhance the readability of information for all parties involved in the design, verification, and maintenance process.

## 54.15 LTP

The LTP represents the embedded software portion of the Volcano tool chain for LIN. The LTP is distributed as a precompiled and fully validated object library also including associated documentation and a command line configuration utility Lin Configuration generator tool (LCFG) with automatic code generation capability, generating the configuration-specific code and set of data structures.

Implementing the LTP with an application program is a simple process. The LDF created by the off-line tool contains the communication-related network information. In addition, a target file as an ASCII (American Standard Code for Information Interchange)-based script defines low-level microcontroller information such as memory model, clock, SCI, and other node specifics to the LTP. These two files are run as input through the command line utility LCFG. It converts both files into target-dependent code usable by the microcontroller. The output contains all relevant configuration information formatted into compiler-ready C source code (Figure 54.10).

The target-dependent source code is added to the module build system along with the precompiled object library. After compilation, the LTP gets linked to the application functionality to form the target image that is ready for download.

**FIGURE 54.6** Network definition and frame packing.

The application programmer can interface to the LTP and therefore to the LIN subnetwork through the standardized LIN API. API calls comprise signal-oriented read and write calls, signal-related flag control but also node-related initialization, interrupt handling, and timed-task management.

The low-level details of communication are hidden to the application programmer using the LTP. Specifics about signal allocation within frames, frame IDs, and others are carried within the LDF so that applications can be reused simply by linking to different configurations described by different LDFs. As long as signal formats do not get changed, a reconfiguration of the network only requires repeating the process described earlier resulting in a new target image without impact to the application. When the node allows for reflashing, the configuration can even be adapted without further supplier involvement allowing for end-of-line programming or after-sales adaptations in case of service.

LTPs are created and built for a specific microcontroller and compiler target platform. A number of ports to popular targets are available and new ports can be made at the customer's request.

## 54.16 LIN Spector: Test Tool

LIN Spector is a highly flexible analysis and emulation tool used for testing and validation of LIN networks. The tool is divided into two components: an external hardware and PC-based software. Using a 32-bit microcontroller, the hardware portion performs exact low-level real-time bus monitoring (down to 10 µs resolution) while interfacing to the PC via standard RS-232. Other connections are provided for external power and a 9-pin D-Sub for bus and triggering connections. The output trigger is provided for connection to an oscilloscope, allowing the user to externally monitor the bus signalization.

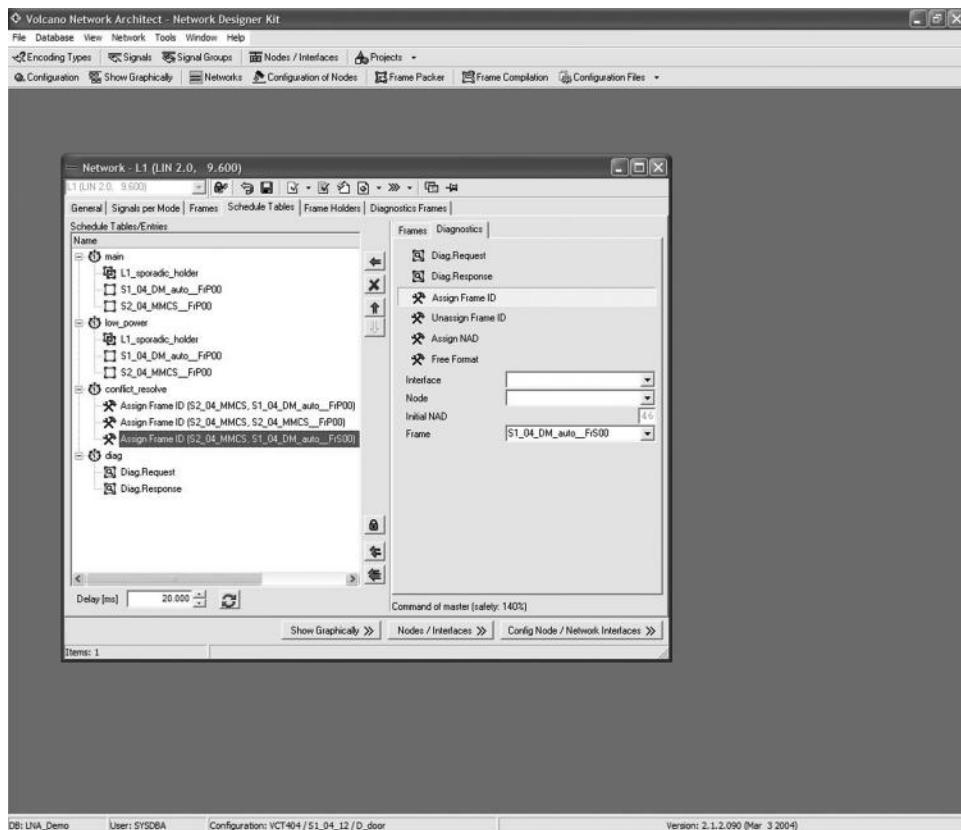

FIGURE 54.7 Manual and/or automatic schedule table generation.

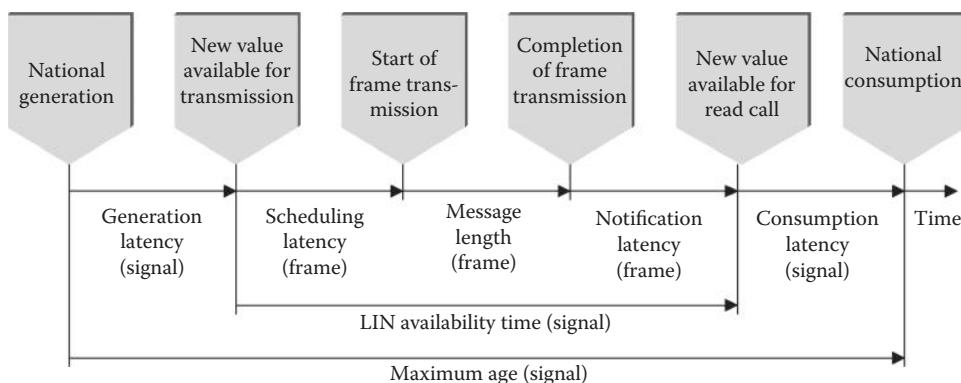

FIGURE 54.8 LIN timing model.

Starting with LDF import, the tool allows for monitoring and display of all network signal data. Advanced analysis is possible with logical name and scaled physical value views. Full emulation of one or many nodes—regardless whether master or slave—is possible using LDF information. Communication logging and replay is possible, including the ability to start a log via logic-based triggers (Figure 54.11).

An optional emulation module enables the user to simulate complete applications or run test cycles when changing emulated signal values and switching schedule tables—all in real time. The functions are specified by the user via LIN Emulation Control (LEC) files created in a C-like programming language.

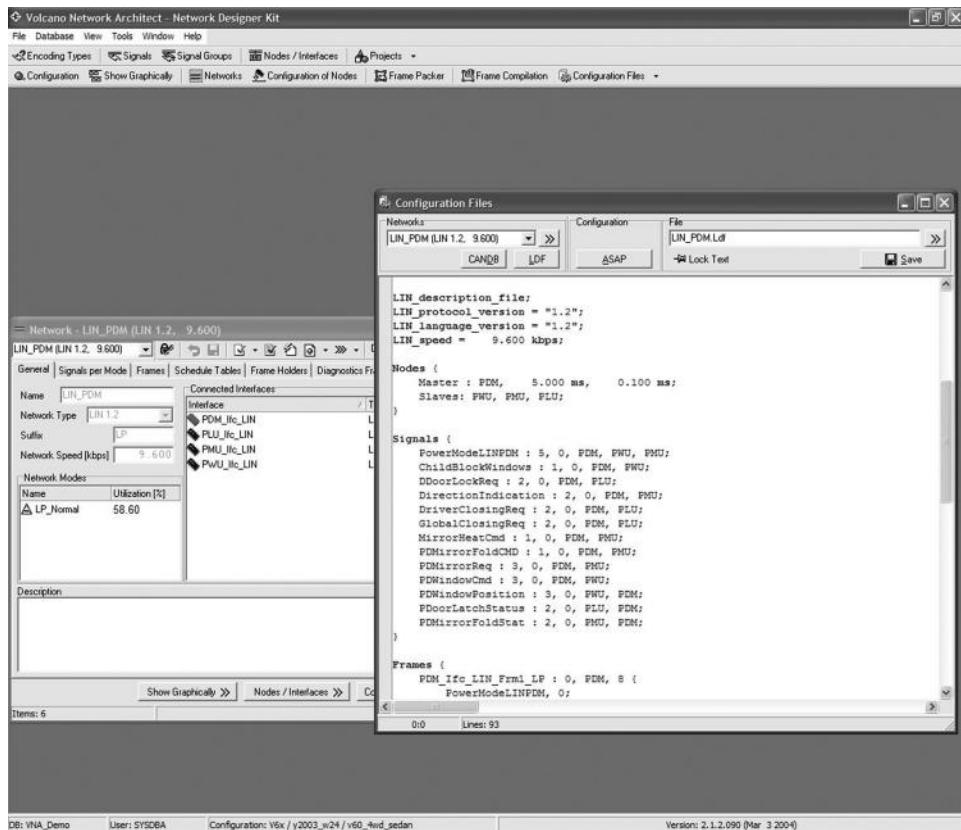

FIGURE 54.9 LDF generation.

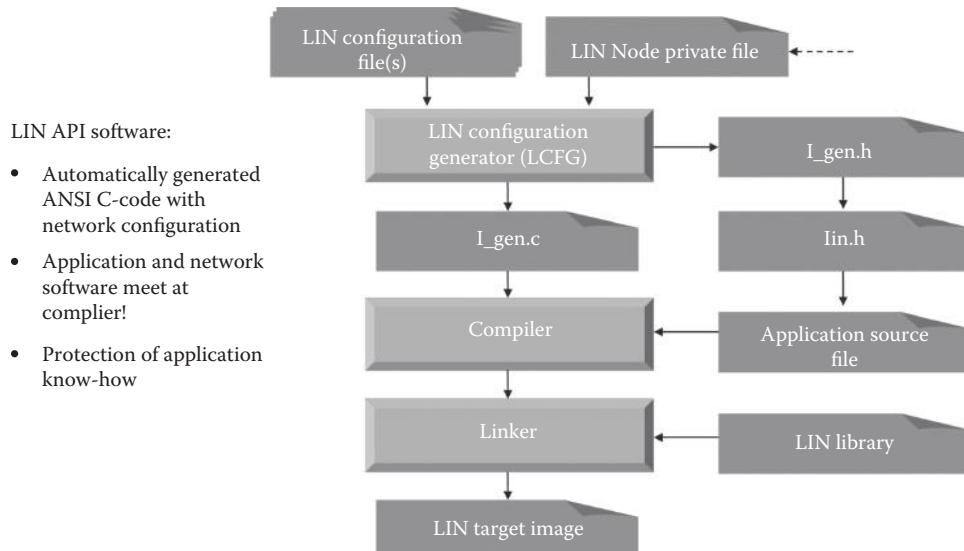

FIGURE 54.10 LTP.

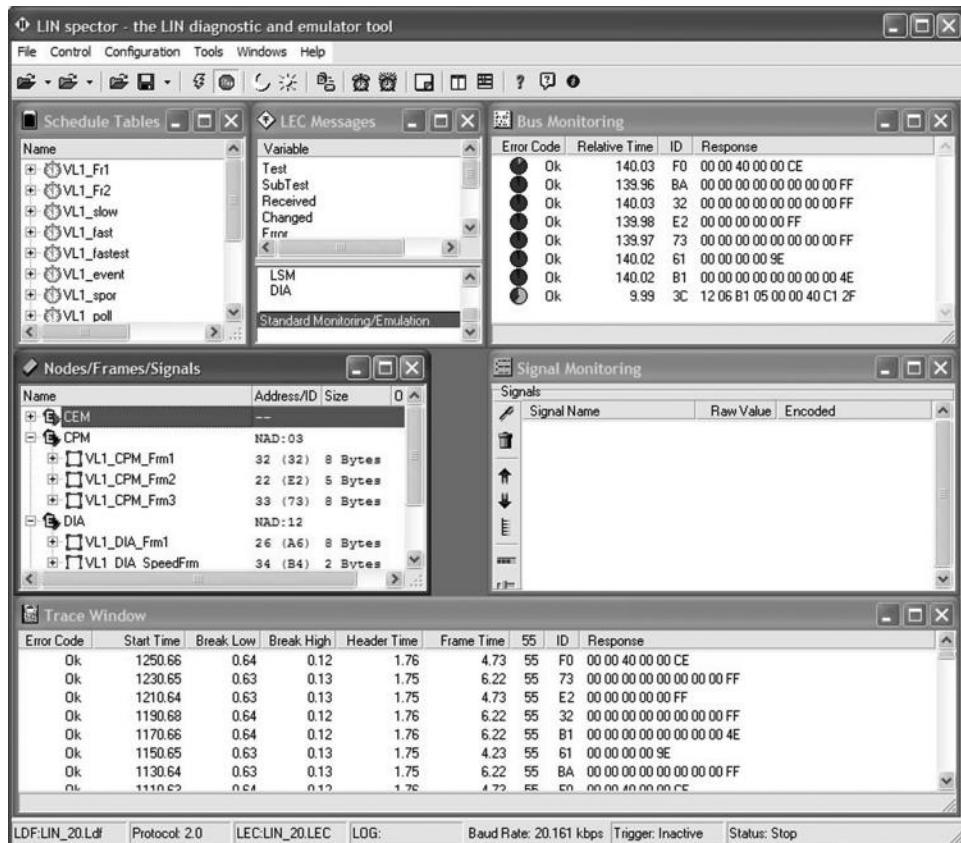

FIGURE 54.11 LIN Spector, diagnostics and emulation tool for LIN.

This can also be used to validate the complete LIN communication in a target module. Test cases are defined stressing bus communication by error injection on bit or protocol timing level.

Sophisticated graphical user interface panels can be created using the LIN Go feature within the test device (Figure 54.12).

These panels interface with the network data defined by the LDF for display and control.

## 54.17 Summary

LIN is an enabling factor for the implementation of a hierarchical vehicle network to achieve higher quality and reduction of cost for automotive makers. This is enabled by providing best practices of software development to the industry: abstraction and composability. LIN allows for reduction of the many existing low-end multiplex solutions and for cutting the cost of development, production, service, and logistics in vehicle electronics.

The growing number of car lines equipped with LIN and the ambitious plans for the next-generation cars are probably the best proof for the success of LIN. The simplicity and completeness of the LIN specification combined with a holistic networking concept allowing for a high degree of automation has made LIN the perfect complement to CAN as the backbone of in-vehicle communication. Some of the market Potential is related to the opportunity to downsize parts of the vehicle network from CAN to LIN, where limited communication requirements allow for that.

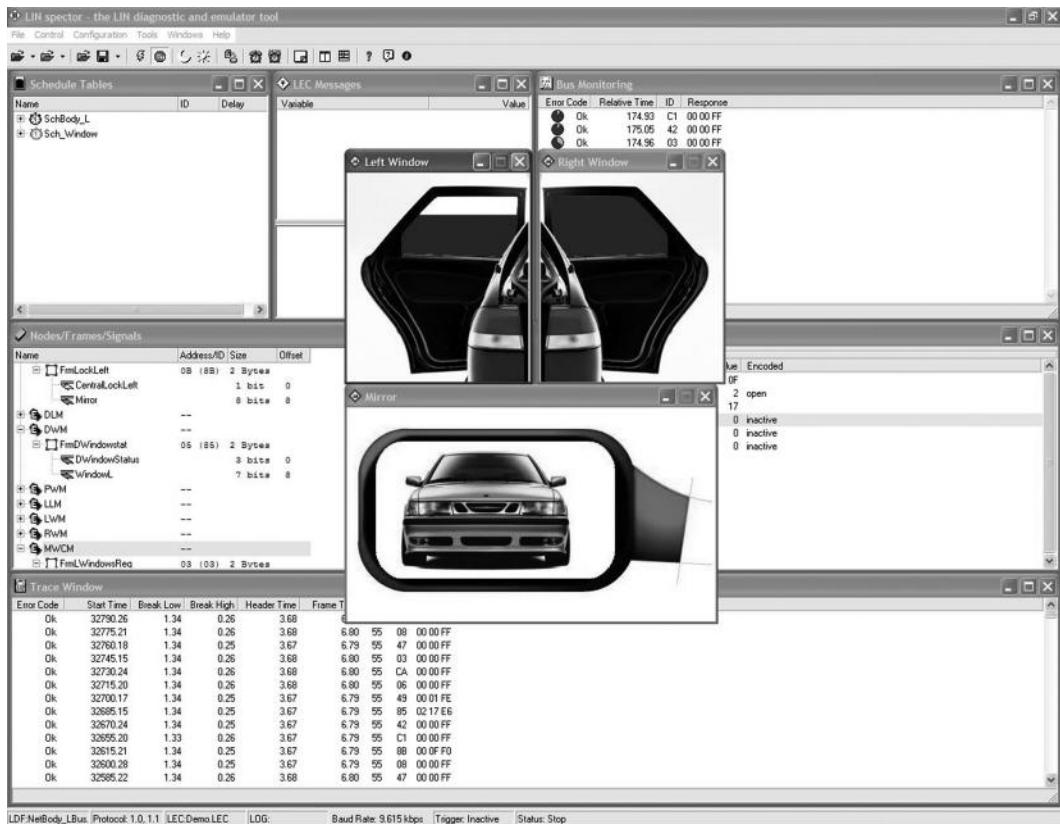

FIGURE 54.12 LIN GO—graphical objects.

The release of LIN 2.0 has further enhanced the reuse of components across car manufacturers and has added a higher degree of automated design capability by introduction of node capability description files and by defining mechanisms for reconfigurability of identical LIN devices in the same network.

VCT is offering the corresponding and highly automated tool chain to guarantee design to correctness. This shortens design cycles and—as a conceptual approach—allows for integration into higher-level tools. LIN solutions provide a means for the automotive industry to drive new technology and functionality in all classes of vehicles.

## Acknowledgments

I wish to thank Hans-Christian von der Wense of Freescale Semiconductor Munich and István Horváth and Thomas Engler of Volcano Automotive Group for their contributions to this chapter.

### 55.1 Introduction

*Building automation systems* (BASs) are historically grown systems. The core domains of BAS are heating, ventilation, and air conditioning (HVAC) as well as lighting and shading applications. Nowadays, BASs are a well-established way to provide automatic control of indoor conditions in functional buildings [4]. The overall aim is to improve comfort, save energy, and thereby reduce costs arising during the lifetime of a building [1,5]. Relatively new fields of operation where BAS gain importance are security applications like access control. Also, safety-critical applications like fire alarm systems are more and more integrated.

The evolution of communication systems also influences the automation domain which consequently leads to a change of paradigms in automation structures and models. While in the past a centralized control approach was followed, today's automation systems typically adhere to a distributed control approach. Section 55.2 presents an overview of hierarchical models in automation system and their evolution in recent times. For deploying automation systems, many different technologies and products are available. Unfortunately, there exists no technology that can be used for all automation domains at all levels of the control hierarchy. Some technologies are only used for a dedicated hierarchy level (e.g., fieldbus systems), whereas others are also domain specific (e.g., HVAC). Independent of the hierarchy level and the application domain, automation technologies are either based on open standards and specifications or exclusively provided by one manufacturer. Obviously, open standards are the basis for interoperability among different manufacturers. They further guarantee availability of products within the life cycle of a building. Based on these criteria, important representatives of automation systems of different application domains and control levels are presented in Section 55.3. Since no automation system exists that is able to address all domains and levels, interaction among different technologies is crucial for BAS. Besides pure

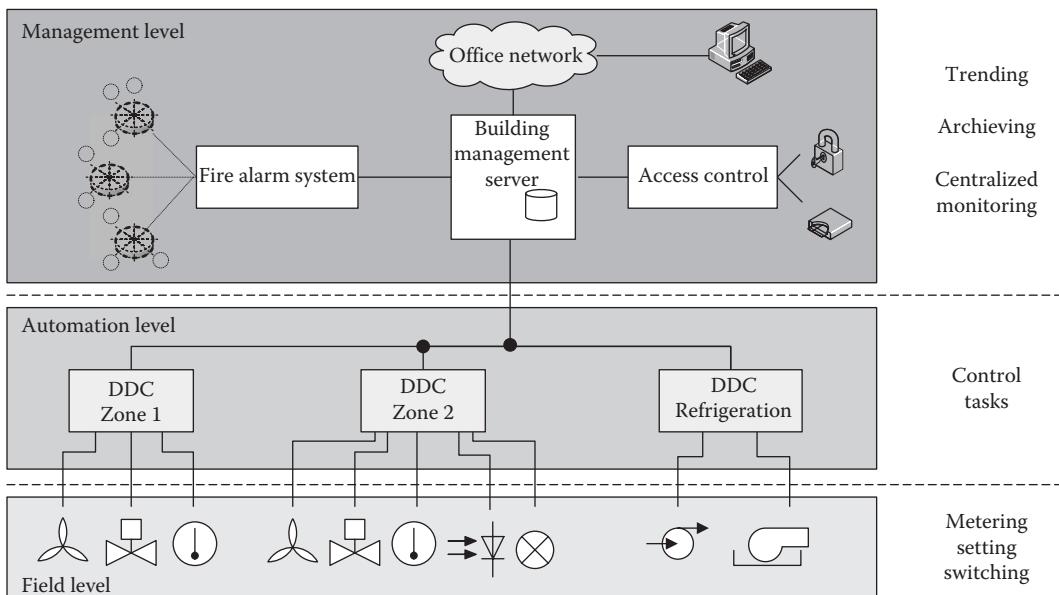

physical interoperability, data are only relevant if denotation and representation is uniquely defined, too. With the gaining importance of the Internet and according network technologies, the demand for integrating automation systems into web-based communication becomes more and more important. Thus, Section 55.4 discusses technologies and standards that allow a manufacturer-independent interaction, control, and visualization whereby also web-based access and interaction are addressed.

## 55.2 Functional Model and Reference Architectures

### 55.2.1 Automation Hierarchy

Large-scale BASs are hierarchically structured and typically follow a three-layer approach as depicted in Figure 55.1. At the lowest level, the so-called field-level, interaction with the process under control takes place (i.e., measuring, metering, switching, positioning). Sensors and actuators are connected to a field communication system, which is interfaced by direct digital control (DDC) stations. A DDC system collects and distributes data from sensors and actuators and controls local applications. For controlling complex applications that are distributed over more than one DDC, they cooperate at *automation level*. At the top level of this hierarchy, the *management level* acts as an interface to *building management* (BM) and enterprise applications. Centralized access to data points, configuration of the system, visualization, archiving and trending of process data are typical activities at this level. Another task of the management level is to provide interoperability between different systems and technologies used at the lower two tiers of the BAS. The overall application is defined as functions over data points. The relevant world standard [3] divides these functions into three categories: input/output, processing, and management.

All these three levels together form a commonly agreed model of BAS, the automation pyramid. The pyramid shape reflects the hierarchical and centralized control flow from the top level to the bottom level. Data reporting, on the other hand, takes place in the inverse direction. Equipment of an

**FIGURE 55.1** Three-layer automation pyramid model. (Adapted from Kastner, W. und Neugschwandtner, G., *Datenkommunikation in der verteilten Gebäudeautomation*, Bulletin SEV/VSE, 2006.)

underlying tier provides data to the superior one. Another aspect that is illustrated by the pyramid is the number of devices operating in each level. A high amount of relatively plain and cheap devices can be found at the field level. The number decreases when going upward, whereas the complexity and also costs for a single component rise.

### 55.2.2 Two-Tier Architecture

In recent times, the previously described three-layer model has been mutated to a two-tier architecture [37]. Due to the increasing processing capabilities and the decreasing costs of embedded systems, sensor and actuator devices are no more restricted to collecting and distributing data. In contrast, they are equipped with powerful hardware and adopt control tasks from formerly used DDCs. Thereby, the level of control changes from the automation level to the so-called control level, which combines the automation and field level. Consequently, the control approach changes from a strictly centralized nature as described in the previous section to a distributed one. At the control level, components act as input/output devices as well as local control instances of a distributed application. They cooperate in so-called control networks. For wide-spanning control applications across different control networks, these are interconnected by *backbone* networks. However, control is still performed at the lower level. The backbone network is further used to provide management communication such as visualization, trend logging, and high-level access.

### 55.2.3 Bridging the Networks

As mentioned previously, BASs are hierarchically structured and make use of a high diversity of technologies and standards. Besides the use of different technologies in each hierarchy level, different technologies are even used at the same level. In particular at the field level, a plethora of communication and automation protocols are facilitated within one system. To establish a connection between network segments using different technologies, so-called gateways are used. They can establish horizontal connection between two different technologies at the same hierarchy level or likewise connect different technologies used at different automation levels. Gateways can also provide a physical connection among different network media. For example, a gateway can establish a connection between a wireless network and a wired network. The more complex task of a gateway is the semantic cooperation. A gateway has to receive and interpret information from one network and translate and distribute it in another network. Depending on the differences regarding data representations, this causes a lot of processing and engineering effort. Thereby, detailed knowledge of the protocols in use is required. Also, changes or extensions of the protocol influence the behavior of the gateway.

If two network segments that base on the same technology shall be interconnected by an intermediate network, a *tunneling* connection is used. The intermediate network acts as a virtual medium such that so-called tunneling routers forward information in a transparent way. Due to the transparent connection, tunneling routers do not have to interpret or translate information. Thus, tunneling routers do not require as much processing capability as gateways. They are also aware against changes or extensions of the network protocol that has to be tunneled. Additionally, they only forward received data to the addressed tunneling router. In contrast to gateways, tunneling devices do not interpret or translate information, they transparently forward data. Due to the transparent nature of a tunneling connection, even engineering data can be transmitted by the tunneling connection. However, tunneling can cause several communication issues. If two network segments are connected transparently, it needs to be considered that the bus load in the joint network rises to the sum over the loads of each segment since no functional separation of the subnets takes place. To overcome this issue, filtering technologies can be used, which imply the necessity of interpreting data. It has to be further ensured that the intermediate connection is reliable. This essentially includes ordering of data packets and prevention of packet duplication. If more than two subnets are connected, additional filtering and routing concepts have to be considered.

## 55.3 Building Automation Technologies

---

After discussing different models of building automation, this section introduces a selection of the most important technologies and standards used in the context of building automation. At first, the big players in building automation are discussed according to the ISO/OSI reference model [9]. These technologies are widely accepted for years or even decades of years. The presented standards are open standards that are applicable in almost all automation domains. Further, well-known representatives of domain-specific technologies are presented. Finally, a number of technologies are listed and briefly described that are mostly used in home environments (*smart homes*). Some of the presented technologies are not based on open standards, but they are mentioned because of their relevance in a dedicated domain.

### 55.3.1 KNX

KNX is a well-accepted building automation technology, in particular in Europe and German-speaking countries (DACH). It is standardized under IEC 14543-3/EN 50090 [22,23] and maintained by the KNX Association [18]. KNX is typically used in the HVAC domain as well as for lighting and shading applications. However, it can also be used for other applications such as metering and access control. KNX is basically used for field-level communication and control but also specifies IP-based backbone communication mechanisms. It provides a framework for distributed control as well as a flexible communication system. KNX allows manufacturer-independent communication and control. For this purpose, KNX provides a common engineering tool software (ETS) that simplifies the engineering and integration process and allows the configuration and integration of components of different manufacturers. Nevertheless, it is also possible to configure small-scale installations without the use of the ETS by an autoconfiguration mode.

The KNX communication system is designed according to the ISO/OSI reference model [19]. At the physical layer (PL), KNX provides different media for communication, still the most important medium is based on a simple twisted-pair (TP) bus cable (KNX TP1). Due to its low bandwidth, the medium is robust against electromagnetic disturbances and can be installed in nearly any topological structure. A further medium called KNX PL110 facilitates the power line for communication. Thus, no additional communication infrastructure is necessary. However, if PL110 is used, additional filters are required to suppress high-frequency disturbances of the power grid. Repeaters are necessary in three-phase installations. If no wired medium is feasible, KNX supports also a wireless medium called KNX RF. This medium resides in the 868 MHz *industrial, scientific and medical* (ISM) frequency band and can be used without any license fees. Additionally, KNX is able to use the Internet Protocol (IP) as logical medium. Thereby, KNX devices can directly be connected to an IP capable medium.

While the lower part of the data link layer (DLL) depends on the communication medium and thus is responsible for specific medium access control and framing, the upper part of the DLL is independent of the medium and defines the KNX addressing scheme. This scheme foresees unicast, multicast, as well as broadcast addressing. Especially multicast communication allows designing functional and efficient applications. Unicast addresses, so-called individual addresses, allow point-to-point communication among KNX devices, whereas group addresses are used for multicast communication. Additionally, broadcast communication is possible by using a dedicated broadcast address. All KNX addresses have a length of 16 bits and are hierarchically structured. The network layer (NL) is responsible for data exchange among the levels of the communication hierarchy by so-called line couplers and backbone couplers. At the lowest level, a line contains up to 256 devices. Up to 16 lines are connected to a main line and up to 16 main lines are linked to a backbone line. At the transport layer (TL), connection-oriented (unicast) and connectionless communication channels are established. Additionally, the TL is responsible for reliable data transmission. While the session layer (SL) and the presentation layer are not implemented, the application layer (AL) provides an abstract communication interface for implicit communication by using objects and properties. The most important objects are group objects (GOs).

These GOs can be written and read by multiple devices that allow efficient communication. For realizing interoperable applications among devices of different manufacturers, datapoint types (DPTs) are specified. A DPT defines the format and encoding as well as the range and unit of a value. A functional block (FB) is a collection of different DPTs. Besides the input and output of data, an FB specifies a dedicated functional behavior. In an FB, DPTs can be used either as inputs or outputs. An application can be built by interconnecting FBs via their input and output objects of the same DPT, respectively. In most cases, GOs are used for instantiating DPTs, but it is also considerable that other object types like interface objects (IOs) are used.

An extension to KNX allows encapsulating KNX packets into IP frames. This extension, called KNXnet/IP [24], offers the possibility to interconnect KNX devices by a logical IP channel as mentioned earlier. Additionally, KNXnet/IP can be used as tunneling connection to connect two lines or to allow remote configuration and management of a KNX network. KNXnet/IP can also act as backbone line and connect multiple KNX segments by using KNXnet/IP routing. Since KNX uses open and commonly used media (e.g., RF and IP) and conquers security-relevant application domains, security gains importance. To address this, the KNX Association has recently published draft versions of security extensions to KNX [20,21].

### 55.3.2 LonWorks

Similarly to KNX, LON is an open standard that is used in building automation networks. Initially, LON was specified by the Echelon Cooperation. It was accepted as ANSI standard ANSI/CEA-709.1 [13,14] and became a European norm (EN 14908 [15]). The LON standard is maintained by the LonMark Association [17] and defines the communication as well as data representation and hardware [17]. The communication protocol is known as LonTalk. A special integrated circuit called *Neuron chip* implements the whole communication stack and supports the integration of small user applications. Thanks to the open specifications, second source protocol implementations exist besides the Neuron chip. Moreover, variants with integrated transceivers are available. LON also allows tool-based engineering and commissioning. For this purpose, the so-called LonMaker integration tool can be used. With this tool, networks can be graphically designed, devices can be configured, and applications can be deployed.

The LON standard is specified according to the ISO/OSI reference model, whereby all layers are implemented. At the PL, LON allows different types of media. The most popular medium is TP, which enables flexible wiring in arbitrary physical topologies. Additionally, power line communication can be used, which does not require any further cabling. However, additional hardware is required for phase bridging and filtering. Besides these most important media, communication is further specified via EIA 485, coax cable, and fiber optics. One physical segment is denoted as channel, whereby such channels can be coupled by bridges. The DLL is responsible for media access control as well as frame forming and encoding. LON uses carrier sense multiple access (CSMA) for media access and allows prioritized messages altogether labeled as *predictive p-persistent CSMA*. At the NL, LON specifies addressing and defines multiple network structures. These structures are independent of the physical topology. A LON device can be identified by a globally unique identifier (ID). A LON network is denoted as domain, whereby communication among domains is not foreseen. Within a domain, a device can uniquely be identified by a subnet and a node ID. A device can further be a member (member ID) of multiple groups (group ID), which enables multicast communication. To establish a connection among different subnets, routers are used. These routers are self-learning and also support multicast communication. The TL is responsible for reliable unicast and multicast transmission. It implements an acknowledgment mechanism and is able to detect duplicates and reordered packets. Additionally, it provides message authentication. The SL provides a request/response protocol between client and server nodes, which is the basic communication primitive for upper layers. The presentation and application layer provide implicit communication by so-called network variables (NVs). Besides, services for network management and maintenance are provided.

To guarantee interoperability among devices of different manufacturers, many NVs are specified as standard NV types (SNVTs). A functional profile (FP) contains a number of SNVTs, which either act as inputs or outputs. Besides mandatory SNVTs, an FP contains optional ones and additional configuration properties (some of them are also optional). In addition to the input, output, and configuration parameter, an FP implements a dedicated functional behavior. An FB is the implementation of an FP in a device, whereby a device may consist of different FBs. A distributed application can be realized by connecting the SNVTs of different FBs. This task is also known as *binding*.

LonTalk defines a weak security mechanism based on a 48-bit message authentication code, whereby the authentication algorithm is kept secret. Confidentiality and authorization are not supported. Thus, the security mechanisms are not sufficient for today's applications. For establishing a connection between two subnetworks or enabling remote management, an IP-tunneling standard [16] can be used.

### 55.3.3 BACnet

Building Automation and Control Network (BACnet) is an open communication standard for BASs. It enables the exchange of data between systems of multiple vendors to provide interworking. Among others, the standard defines services to access data points, to generate alarm and event notification on specific conditions and for network control purposes.

BACnet was developed by the *American Society of Heating, Refrigerating, and Air Conditioning Engineers (ASHRAE)* and was standardized in 1995. Initially designed for the use at the management and automation level of the three-tier automation hierarchy, BACnet has found its use in all kinds of building automation applications, nowadays. The current standard is BACnet 2010 [11]. ISO 16484-5:2012 [12] incorporates BACnet 2010.

BACnet implements the PL, the DLL, and the NL as well as the AL of the ISO/OSI model. The PL and the DL, which are affected by the selection of a so-called network option, are independent protocol standards and therefore not part of the BACnet specification. In the original BACnet standard, five network options describing the physical and the data-link layer are defined: Ethernet, ARCNET, master-slave/token passing (MS/TP), point-to-point (PTP), and LonTalk. Later on, two further network options have been defined, namely, BACnet/IP and ZigBee as a wireless network add-on. The choice of a network option does not influence the upper two protocol layers. It is even possible to use other PL/DLL combinations since BACnet is not limited to these network options. This allows the combination of multiple network technologies in one BACnet network and thus, interworking is provided at the upper protocol layers.

To allow remote devices to access process data, a *network-visible* representation of the stored data has been specified by BACnet. This representation follows an object-oriented approach. Up to now, 50 different *BACnet object types* are defined within the current standard. They differ in the composition of their so-called BACnet properties, which can be seen as data points. Each property has a unique ID referred to as *Property\_Identifier*, a designated property data type, and a conformance code attribute. The conformance code defines the access permissions of a property and specifies whether a property is mandatory in a distinct BACnet object or not. Valid values are readable (R), writable (W), and optionally present (O).

Vendors of BACnet devices are free to define their own proprietary object types (referred to as non-standard object types)—even the definition of proprietary property types is possible. However, there are three mandatory properties that must be defined for each BACnet object: *Object\_Identifier*, *Object\_Name*, and *Object\_Type*. The former two properties must be unique within a BACnet device. Since a BACnet object is always assigned to exactly one device (a BACnet object is never distributed across more than one device), the *Object\_Identifier* or *Object\_Name* property is used to uniquely identify a BACnet object within a device. The *Object\_Type* property is actually an enumerated value, which defines the kind of an object.

The most frequently used BACnet object types are generic ones, for example, the BACnet Binary Output Object Type or the BACnet Analog Value Object Type representing physical

and virtual data points, respectively. However, there exist also more advanced concepts in BACnet, like access to historical data (Trend Log Object Type), event scheduling (Schedule Object Type) or access control applications (Access Door Object Type). It is within the responsibility of the application program to map the control data of a dedicated application to certain BACnet objects. For primitive input or output objects, the Present\_Value properties represent the signal values of the physical I/O ports of a BACnet controller. Other ones like the Resolution or the Output\_Type properties provide additional meta-information about the physical quantity.

Services in BACnet are based on the client/server communication paradigm. BACnet controllers, which act as servers, hold objects representing physical values of the processes. User control units or management workstations—where values are set and process data are visualized and archived—act as BACnet clients. The complete set of service classes defined in BACnet consists of the following:

- *Object access services* allow manipulation, creation, and destruction of BACnet objects and are also used for getting (ReadProperty Service) or setting (WriteProperty Service) the value of a distinct property.
- *Alarm and event services* encompass mechanisms for event-based communication. The change of value (COV) subscription (Confirmed-/UnconfirmedCOVNotification Service), for example, is used to monitor data points on BACnet controllers by clients like supervisory devices. Other representatives of this class are the Intrinsic Reporting services, which allow the communication of fault conditions or the Algorithmic Change Reporting services for generating events on a set of conditions.
- *File access services* can access and manipulate files on BACnet devices.
- *Remote device management services* provide mechanisms, for example, network discovery (Who-Is and I-Am Services), clock synchronization, or device reinitialization.
- *Virtual terminal services* are rarely used routines defined for establishing terminal sessions between two BACnet devices.

#### 55.3.4 Modbus

Modbus is an open standardized communication protocol founded by Modicon in 1979. It was formerly designed for the communication among programmable logic controllers (PLCs) in industrial applications but gained importance in the building automation domain, especially for HVAC systems, DDCs, and room control. Modbus is a lightweight application layer protocol that facilitates different media. Modbus-TCP, a Modbus version based on TCP, is part of the fieldbus standard IEC 61158 [7].

According to ISO/OSI, Modbus focuses on application layer data exchange. However, different media are specified at physical and data-link layer, respectively. Modbus was originally designed for asynchronous serial data exchange via EIA-485 or EIA-232. While EIA-232 specifies only a point-to-point communication, EIA-485 is capable of bus communication. Thereby, the medium access is based on a master/slave approach, where a master requests a response from a dedicated slave identified by its slave address. Additionally, the master can send data to all slaves via broadcast. In this case, no response of the slaves is allowed. For serial communication, two different transmission modes are possible. On the one hand, the remote terminal unit (RTU) mode specifies a binary protocol for data encoding. On the other hand, in ASCII mode, every data byte is encoded by two ASCII signs.

Additionally, Modbus facilitates Ethernet and TCP/IP as additional medium, which is known as Modbus-TCP. Thereby, Modbus packets are encapsulated in TCP frames and IP addresses are used for identifying devices. A Modbus frame contains an additional Modbus application protocol (MBAP) header, which indicates the length of the packet, a transmission ID, and a protocol ID. Additionally, a unit ID is included in the header to address serial Modbus devices behind a gateway.

The application layer protocol is based on a request/response communication scheme between a client and a server. Thereby, a client sends a request to the server. The server may respond if data were requested.

In Modbus-TCP, a unicast connection between two devices is initiated by the client. In serial Modbus protocols, the master acts as client and requests data from the slaves, which act as servers. The medium-independent data frame consists of a function code and variable data field. The function code specifies the action that the server has to perform. For accessing and exchanging data, Modbus defines a simple object model based on network variables that are either readable or writable and accessible either bit-wise or word-wise. Thereby, Modbus distinguishes between four different input/output types. Independent from the access mode, these types can be overlapped in the memory such that read and write access can be granted. In contrast to other automation technologies, Modbus does not specify any data profiles.

Modbus provides no security mechanism at the common application layer. However, the TCP version specifies an access control mechanism that provides authorization. For this purpose, a list of allowed IP addresses is maintained by a server. Only if the remote client IP address is on the list, requests will be accepted. Unfortunately, since no authentication is used, this mechanism can be simply broken by faking the IP address. Since Modbus-TCP uses a dedicated well-known TCP port, firewalls can be used to increase security of the automation network. Extensions to Modbus have been published that propose concepts for securing the communication [38].

### 55.3.5 ZigBee

ZigBee is an open wireless standard for low-rate and lossy networks [27]. It is mainly used for home and building automation as well as for smart energy applications. The ZigBee standard is specified and maintained by the ZigBee Alliance [26]. ZigBee provides a reliable and flexible communication infrastructure and specifies a high-level information modeling scheme. It natively supports multihop communication and has self-healing capabilities. In contrast to other wireless technologies, ZigBee has less hardware requirements and demands less power. A ZigBee topology contains three different types of devices. A so-called personal area network (PAN) contains exactly one *ZigBee coordinator*. This device initializes the network, assigns addresses to all other participants, and acts as security manager, if required. Furthermore, a PAN contains *ZigBee routers* and *ZigBee end devices* (EDs). ZigBee routers are able to forward packets dynamically, a basic requirement for building mesh networks. ZigBee EDs have no routing capabilities and have to be directly connected to a ZigBee router or the ZigBee coordinator. ZigBee EDs require less memory than other ZigBee devices because they do not need to store routing information. Additionally, they can switch off their receiver for several time intervals, which reduces the energy demand of the device.

ZigBee is specified according to the ISO/OSI reference model whereby the PL and DLL are based on the IEEE 802.15.4 standard [25]. The ZigBee specification only defines the upper levels of the communication stack. At the PL, the IEEE 802.15.4 standard specifies different channels in different frequency bands. Besides the 2.4 GHz band that can be used nearly all over the world, region-dependent sub-GHz bands are specified, too. The DLL is mainly responsible for medium access and addressing. IEEE 802.15.4 provides two medium access mechanisms, whereby one is based on CSMA and the other one follows a slot-based, deterministic approach. However, ZigBee only uses CSMA for medium access. The addressing scheme consists of a unique 64-bit extended address (EUI-64) and a 16-bit short address in combination with a so-called PAN-ID that identifies the network.

At the NL, ZigBee specifies mechanisms for unicast and broadcast communication. For building mesh networks, ZigBee uses a dynamic and efficient routing approach. This increases the reliability and allows overcoming long distances. For point-to-point messages, ZigBee provides end-to-end acknowledgments and uses the ad hoc on-demand distance vector (AODV) routing protocol. To increase the efficiency in pure sensor networks, ZigBee additionally supports a so-called many-to-one routing mechanism. For broadcast transmission, an efficient passive acknowledgment mechanism is used. Multicast communication is realized by defining so-called multicast groups and filtering broadcast messages accordingly.

The AL provides an abstract communication interface and a powerful information modeling framework. ZigBee devices consist of so-called application objects (AOs) that specify the functionality of the device.

Every device contains a specific AO, the so-called ZigBee device object (ZDO). This object defines basic properties of the device such as device type and implements the basic functionality. The communication among AOs is realized by *clusters* and *attributes*. An AO contains a set of clusters whereas clusters consist of a set of attributes and commands. For example, the *OnOff* cluster has one attribute that represents the state of an arbitrary device (i.e., on/off) and several commands for turning the device on or off or changing the state somehow. For interoperability reasons, the definition of clusters is specified in the so-called ZigBee cluster library (ZCL) according to their functional domain. Nevertheless, clusters can also be defined application specific. For proving interworking at device or application level, application profiles are defined. These profiles act according to particular application domains such as *home automation*. An AP contains the definition of devices and specifies the interaction between devices. A device consists of dedicated AOs with instantiated clusters. In addition to clusters out of the ZCL, an AP can further specify application specific clusters. For example, an AP defines devices like on/off switches and lighting actuators. In this case, both devices contain an instantiated *OnOff* cluster representing the state of a light.

Since ZigBee uses an open medium for communication, security is a crucial topic. Although IEEE 802.15.4 provides optional security services, ZigBee defines its own, independent ones. In ZigBee, security services are located at two different layers. However, security is optional at both layers. At the NL, basic security mechanisms are located that provide network-wide security. At the AL, the recent version of ZigBee provides an advanced security mechanism including end-to-end security, key establishment, as well as key distribution and management by a so-called security manager. While all these mechanisms are based on the symmetric advanced encryption standard (AES) [39], the *smart energy* AP defines additional asymmetric encryption mechanisms for key distribution.

## 55.3.6 Trade-Specific Technologies in Building Automation

### 55.3.6.1 DALI

A major part of building automation concerns about lighting. Besides simple switching, demand-specific and energy-efficient lighting is an important topic in modern buildings. Digital Addressable Lighting Interface (DALI) as ratified in IEC 60929 [6] is an open interface specification that exactly addresses this domain. This interface allows a manufacturer-independent integration of lighting systems. DALI is based on a twisted-pair medium, the so-called DALI loop, which allows flexible network topologies and link-powering sensor devices. The medium access is performed by a master/slave mechanism, whereby at most 64 slaves are possible. Additionally, a multi-master mode is provided. Since DALI covers the whole lighting domain, different types of devices are required. These components are categorized according to their functionality. Sensors can be used for motion detection or brightness measurement. Panels such as light switches or remote controls allow direct control by the user. The category *DALI gear* consists of devices that directly control lights such as dimmers. Devices that establish a connection to analog-controlled actuators or gateways to other BASs (e.g., KNX) are part of the category *interfaces*.

### 55.3.6.2 SMI

For installing and controlling drives in combination with various shutters and blinds (exterior as well as interior sun protection), a special interface called standard motor interface (SMI) exists [29]. The interface specification includes wiring and switching schemes. Besides the electrical and mechanical properties, a digital communication interface is specified that is based on a master/slave communication scheme. For this purpose, two wires of a five-wire cable are used allowing a bidirectional data transmission with a transmission rate of 2400 bit/s. The remaining wires are used as power supply for the drives. Due to the digital control interface, it is possible to control up to 16 drives by connecting them in parallel. The protocol supports individual addressing, group addressing, and broadcast communication. Besides sending incremental and absolute movement commands and querying of current positions, drive parameters and diagnostic telegrams can be transmitted.

### 55.3.6.3 EnOcean

EnOcean is a lightweight and ultralow-power wireless technology for building automation applications. It is mainly used for lighting applications but also provides sensors and actuators for the HVAC domain. EnOcean was developed in 2001 by the EnOcean GmbH, a spin-off company of Siemens AG. EnOcean is an emerging technology that still gains importance in the building automation domain. This is mainly caused by the special properties regarding energy demand and simplicity. Due to the ultralow-power consumption, EnOcean is used for devices that draw their energy from the environment, which is also known as *energy harvesting*. For instance, wireless buttons can be powered by the piezoelectric or electromagnetic energy gained from pressing the corresponding button. Other devices use solar cells or thermoelectric effects.

EnOcean was laid down as international standard IEC 14543-3-10 in 2012 [8]. It uses short telegrams of 14 bytes and supports unidirectional as well as bidirectional communication. Thus, instead of an acknowledgment mechanism, data packets are retransmitted at random intervals. Since EnOcean does not support mesh networking due to the limited communication resources, a backbone network such as KNX or ZigBee is required. For this purpose, gateways are used that establish the connection. To guarantee interworking among different manufacturers, EnOcean defines so-called EnOcean equipment profiles. These profiles specify the representation of data and telegram types. Until now, these profiles are not part of the IEC standard.

### 55.3.6.4 M-Bus

Technologies for metering applications in homes and buildings are important for building smart grids. For this purpose, a specific standard called *Metering Bus* (M-Bus) was ratified as EN 13757 [10] that supports network-based reading of various utility metering systems. Next to the classical wired bus system, a wireless pendant called *wireless M-Bus* (wM-Bus) exists. While the communication in wired standard is based on a master/slave medium access scheme, wM-Bus uses different transmission modes in the 868 MHz ISM band according to IEC 60870-5-2 [41]. Additionally, wM-Bus includes a security mechanism to protect transmitted data over the open medium. Communication is established between two types of devices in a client/server manner. In a wired system, usually the master represents the client and requests data from a slave that can be seen as server. Thereby, the metering device represents the server and the client acts as data collector. The latter displays or possibly forwards metering data (e.g., to a smart grid interface). Nevertheless, it is possible that metering devices actively initiate a communication.

## 55.3.7 Home Automation Systems

Adopting automation technology is equally attractive in the residential domain. Besides efficiency considerations, increased comfort and peace of mind are key motives here. Also, elderly people can live in their own homes longer (ambient assisted living, smart home care). The importance of this aspect continuously increases as life expectancy does.

Despite having a considerable number of things in common, there is a difference between home automation (residential settings) and building automation (functional buildings). Since mechanical ventilation is seldom present in residential settings (although continuing attention to low energy consumption can be expected to change this situation in the long run), lighting and shading control have a more visible position in home automation than HVAC. Considerable emphasis is placed on the integration of consumer electronics (entertainment systems) and household appliances.

Building automation focuses on the goals of energy efficiency, optimized management, and detailed accounting. While energy efficiency is a growing concern in the residential domain as well, the additional comfort and peace of mind a home automation system promises are still influential decision factors. One obvious difference is the scale of the system: The number of devices involved in a home automation project is by orders of magnitude lower than for large building automation projects.

Nonetheless, the complexity of home automation projects must not be underestimated, not at least since a large number of application domains must be integrated. All mentioned field, automation, and management functions are relevant. Equipment, commissioning and maintenance costs have to be kept very low. Easy configuration is of particular importance, since the disproportionately high setup cost will otherwise reduce the attractiveness of automation. This favors robust *plug-and-play* systems with the capability of communicating via the mains or wireless. Acknowledging these specific challenges, one explicitly speaks of *home automation* or *domotics*. The term *building automation* will remain reserved for functional buildings.

A large number of proprietary, mostly centralized solutions is available. Many of them are application domain specific; a certain focus on multimedia aspects can be noted. Published networking and middleware standards of particular relevance are X10 for simple control via power line (in North America), KNX RF for household appliances (in Europe), ECHONET (in Japan), and UPnP (mainly for multimedia applications). Device profile for web services (DPWS) is intended as a web services (WS) conformant successor to UPnP. Regarding unpublished consortium standards, the OpenTherm protocol has reached importance in Europe for point-to-point communication in home heating systems, while Z-Wave has gained momentum in North America for wireless automation purposes. Dynamic application frameworks—OSGi [36] being the prime, open example—allow providing residential gateways with the flexibility required to have multiple service providers connect from remote to a variety of devices within the home environment. Remote access can be expected to increase in importance as building services equipment, alarm systems, and entertainment systems in homes increase in features and complexity.

In the rest of this section, a collection of selected technologies in the context of *smart homes* is presented. The applications are not restricted to lighting and shading or HVAC applications. Also, in-house network communication and multimedia systems are considered. In contrast to the previously mentioned building automation technologies, the discussed technologies are not necessarily based on open standards. There is also often no need of integration into BM systems.

One technology that is used for network communication by facilitating power line communication is *HomePlug* [32]. This system allows Ethernet communication without having any special network infrastructure. If a network connection is required somewhere, a HomePlug device is simply plugged in a power socket. In contrast to Wi-Fi systems, this technology is still working among different rooms or floors. HomePlug AV further allows the transmission of high definition video and audio signals. Security mechanisms are another feature of HomePlug.

A further technology that facilitates power line communication is called X10. It was developed by General Electric and is mainly used for lighting applications. Due to the limited address space and its unreliable behavior, it is infeasible for large-scale networks or critical domains. CEBus is an open standard that was developed to overcome the limitations of X10 [33]. Similarly to X10, it facilitates the power line medium. It supports different control and monitoring commands that allow simple interaction and even autoconfiguration.

A quite recent home automation system is *digitalSTROM* [31]. It is an open standard that supports different application domains such as lighting and shading, HVAC, audio/video, and security applications. Additionally, it can be used for smart metering applications. In order to support web-based applications, a web server is available that provides RESTful WS, where applications can be based on. A connection to other automation domains or even to the smart grid can be established using this interface as well.

Z-Wave is a wireless home automation technology [30]. It is a proprietary protocol that resides in a sub-GHz frequency band. Z-Wave supports up to 232 network devices and allows mesh networking. Similarly to ZigBee, Z-Wave specifies different device classes. A network contains one *controller* that is aware of the entire topology. Additionally, a network consists of *routing slaves*, which are able to relay data packets along predefined routes and *slaves* that only receive and confirm packets. Besides pure home automation, Z-Wave can also be used for entertainment systems. Since Z-Wave provides secure communication by link encryption, security applications are another field of use.

## 55.4 Integration

---

*System integration* is an everyday reality (and necessity) even for BASs that solely target the HVAC domain. System parts must be combined to form the HVAC control system, and devices must be configured to interact properly. Often, cabling, sensors/actuators (field devices), cabinets, controllers (for those pieces of equipment that do not have their own), and management infrastructure are tendered separately and provided by different specialist contractors (as is, of course, the HVAC equipment itself).

This division is even more pronounced between building disciplines, since they have evolved separately. Consequently, their respective automation systems are as well still entirely separate in most buildings today. However, information exchange between systems of different domains undeniably provides benefits. Actually, such cross-domain integration is indispensable for intelligent buildings [2].

A key area of cross-domain integration is room automation. For example, window blinds have considerable impact on HVAC control strategy, as incident solar radiation causes an increase in air temperature as well as in immediate human thermal sensation. Automatically shutting the blinds on the sunlit side of a building can significantly decrease the energy consumption for cooling purposes. An important guideline defining room control functions independently of the technology (i.e., hardware, software, communications technology) is VDI 3813-2 [42].

A (computer-aided) facility management system that has direct access to data from the BAS becomes an even more efficient tool for, among others, accounting and controlling purposes. For example, take into account cost allocation for climate control and lighting using live metering data.

As another example of BAS integration with IT systems, consider conference rooms to be air-conditioned only (and automatically) when booked. Also, hotel management systems can automatically adjust HVAC operation depending on whether a room is currently rented or vacant.

Yet, in all cases, the benefits reached by tighter integration come with a drawback. In an integrated system, examining subsets of system functionality in an isolated manner becomes more difficult. This introduces additional challenges in fault analysis and debugging as well as functionality assessment. Additionally, if multiple contractors are working on a single integrated system, problems in determining liability may arise.

This assessment problem is of special concern where life safety is involved. For this reason, fire alarm systems traditionally have been kept completely separate from other building control systems. Although a considerable degree of integration has been achieved in some projects, building codes still often disallow BAS to assume the function of life safety systems. This of course does not extend to less critical property safety alarms, such as water leakage detection. Similar considerations apply to security systems.

These issues need to be addressed by carefully selecting the points of interaction between the different systems, with the general goal of making the flow of control traceable. Interfaces have to be defined clearly to ensure that no unwanted influence is possible. Typically, systems stay stand-alone for their core purpose. Only a highly limited number of interaction points are established at the highest system level. However, such *high-level integration* can already yield considerable benefits.

A modern building is not realizable relying on one building automation technology. Such a BAS integrates a variety of different systems taking use of the specific benefits of each single technology. Vendors of automation equipment implement various protocol standards, like BACnet, LonWorks, and KNXnet/IP, as mentioned in the previous sections. Especially at the interface between automation level and management level of BAS, these different technologies join together. Since there is an inherent necessity of interfacing these heterogeneous systems by management level applications, a way must be found to learn them understand the same *language*. In other words, the goal is to achieve *interoperability*.

The classical, but not very convenient, way to reach this goal is to integrate technology-specific interfaces (i.e., drivers communicating with the underlying networks) in the management level applications. The disadvantages of this approach are a lock-in to distinct technologies and vendors. Furthermore, little flexibility for future extensions including new network standards exists.

A more promising way is to define and agree on a *general application model* covering the functionality of these underlying systems. Hereby, a unified interface to these networks is introduced. Since IP-based networks are not only commonly used at the top level of today's BAS but also at lower levels, the most suitable concept of communication is one that is aligned with IT standards. HTTP and HTML certainly are popular in BAS as well but are limited to user interfaces since HTML is ill-suited for machine-to-machine communication. Therefore, by tradition, OPC [28] has fulfilled this role. However, it is in its classic design incarnation restricted to Windows platforms due to its use of object linking and embedding/distributed component object model (OLE/DCOM).

Today, solutions emerge that follow the current mainstream trend of using WS for machine-to-machine interaction over a network. WS are entirely platform independent. They can be implemented using any programming language and run on any hardware platform or operating system. This maximizes interoperability and greatly improves the reusability of the services they provide. Central to WS are the use of XML for data representation and a standardized resource access protocol (typically SOAP, sometimes also plain HTTP). WS follow a modular concept. This allows the use of off-the-shelf standards for transmission, eventing, discovery, security, and many more. However, a drawback is the additional overhead introduced by the XML encoding (especially if small amounts of data are transmitted frequently) and the fact that servers cannot push information to clients (unless the latter implement a server themselves). Given the hardware resources available at the management level, this is typically not an issue, though.

The commitment to use WS technology determines low-level aspects of data representation and transmission. Still, the application domain remains to be modeled. BACnet WS (BACnet/WS) [11] and oBIX [35] have been developed with special regard to building automation and are freely available to the general public. Both provide historical data access and event and alarm management besides a data point abstraction. After a short overview on OPC, a brief introduction to the development of BACnet/WS and oBIX, their information modeling mechanisms as well as the communication concepts are described. Finally, devices profile for WS (DPWS) [40] is outlined, which gained some importance in the field of home automation.

## 55.4.1 OPC

In the 1990s of the last century, a task force of different vendors of human–machine interface (HMI) and SCADA software (later called *OPC Foundation*) defined a standard that provides services for reading, writing, and monitoring of control data in automation systems. Since it used Microsoft's technology Windows OLE as a unified way to access the network, the name *OLE for process control* (OPC) was chosen. In addition to this first standard release, many other OPC specifications have been defined. Therefore, the initial OPC standard was later renamed to OPC Data Access (OPC DA). Other important standards in this context are OPC Alarms&Events (OPC A&E), OPC Historical Data Access (OPC HDA), OPC Batch, OPC Security, OPC Data Exchange (OPC DX), OPC Compliance Tests, and OPC and XML. Due to the focus-oriented design of OPC, the specification family was very successful. Thanks to the existence of well-defined interfaces, developers of OPC client software do not have to consider communication details of the underlying network technologies.

### 55.4.1.1 OPC Data Access

OPC DA is the first and the most frequently used kind of the OPC family that allows exchange of real-time data among distributed high-level components. For this purpose, Microsoft's DCOM is used. The communication is based on a client/server relation where an OPC DA server provides data entities to clients in the form of a three-tuple containing the actual value, quality, and timestamp. Typically, OPC DA is used for communication among systems of different manufacturers. It is also used by automation systems to provide data to HMI or monitoring entities.

Due to the unified access method, information can be exchanged independent of the underlying system. However, due to the use of DCOM, systems based on this proprietary interface strongly depend

on Microsoft operating systems. Further, dynamic port assignment is applied, which complicates secure data exchange via the Internet.

#### 55.4.1.2 OPC Alarms and Events

In contrast to OPC DA where process data are exchanged periodically, OPC A&E allows event-based communication. Thereby an OPC server offers information of a system behind in form of event notifications. An OPC client can subsequently subscribe on dedicated alarms or events. If an event occurs, the server notifies all subscribed clients. However, events are not triggered by the OPC server but by the system behind the server. OPC A&E defines three different types of events. The `OPCSimpleEvent` specifies the basic properties of an event, whereof the `OPCConditionEvent` and the `OPCTrackingEvent` are adopted. The tracking event extends the simple event in a way that it is able to keep track about the activator of the actual event. A condition event notifies the subscriber about the incidence of a specified condition on a state value. It is further possible that the event requires an acknowledgment by the client. For each subscription, a client can define a filter. Such a filter can be based on different properties of an event such as severity or process area.

#### 55.4.1.3 OPC Historical Data Access

The OPC HDA framework is used by a client to request historical data from a server. While OPC DA is designed to exchange periodic real-time data, OPC HDA is used to make process data accessible from a client, which has been collected by a database for a specified period in time. Thereby, data is only exchanged on request by a client.

### 55.4.2 BACnet/WS

Due to the evolution of the Internet and IP-based networks, WS are gaining importance within the building automation domain, too. Therefore, in 2006, ASHRAE decided to specify a WS interface for BACnet. This standard extension, also known as BACnet/WS, uses WS as an interface to a generic data model that can be used for integrating control data to existing management applications. Initially defined as BACnet Addendum 135-2004c [34], BACnet/WS is now part of the BACnet standard.

Although the intention of BACnet/WS was to enrich the BACnet protocol with a WS interface, BACnet/WS is not limited to the BACnet protocol. Due to its generic design, BACnet/WS can in principle be used for any kind of technology. Therefore, BACnet/WS can also act as a standardized, WS-oriented way to access data originating from other technologies like KNX.

#### 55.4.2.1 Information Modeling in BACnet/WS

The fundamental elements of the data model in the BACnet/WS are *nodes*. Except the root node, which represents the entry point of the underlying data model, each node has exactly one parent node and may have an arbitrary number of children. Using this way of arranging nodes, a *hierarchy* can be defined, which maps the structure of the underlying data model.

A node represents a data primitive within the data model. The network-visible data of a node are represented as a set of *attributes*. Attributes are used to describe nodes and may themselves have attributes. While it is possible to specify proprietary attributes, BACnet/WS defines a fixed set of standard attributes. Some of these standard attributes are mandatory, while others are optional. However, it can be assumed that the set of available attributes will remain unchanged in normal operation and changes only occur after reconfiguration of the server. There are three types of attributes. Primitive attributes are attributes of data types defined by the XML schema standard (e.g., Boolean, string, or double). Enumerated attributes are enumerations of the XML schema data-type string. The set of allowed values is defined by BACnet/WS. Array attributes are attributes that consist of an array of primitive attributes. In general, neither the definition of proprietary data types for attributes nor an extension of existing data types is possible in BACnet/WS. In the following, the most important attributes are described in more detail.

The `NodeType` attribute is required for all nodes and allows the general classification of nodes. This attribute is an enumeration where the following values are allowed: `Unknown`, `System`, `Network`, `Device`, `Functional`, `Organizational`, `Area`, `Equipment`, `Point`, `Collection`, `Property`, and `Other`. Note that this set of node types cannot be extended. The only way for user-defined node types is to use the `NodeSubtype` attribute that can be set to any arbitrary string.

The `DisplayName` and `Description` attributes are used to provide a human-readable name and a description of the node for user interfaces. The `Value` attribute represents the effective datum of a node (e.g., the actual value of a data point like a temperature value or the actual state of a light). Its type is defined by the `ValueType` attribute, which is mandatory for all nodes. Note that the `value` attribute is optional. If a node does not represent a real process (but, e.g., a node of type `Area` that models a room), the `ValueType` attribute can be set to `None`. Other important attributes are the `Units` attribute (used to model engineering units), the `Attributes` attribute (lists the available attributes of the node), the `Children` attribute (lists the child nodes), and the `Reference` attribute (used to reference other nodes).

The information model concept of BACnet/WS is very restricted—it is not possible to specify user-defined node types (except using the `NodeSubtype` attribute) or user-defined data types of attributes. It is only possible to define proprietary attributes as well as to use the `NodeSubtype` attribute to define proprietary subtypes of already existing node types. However, defining a type hierarchy and modeling node types in the same way as normal data is not possible in BACnet/WS. Additional semantic can be added to the data model by the hierarchy of the nodes. By linking child nodes to their parent, it is possible to define a structure beneath the data model.

In addition to defining parent-child relationships, it is also possible to specify so-called reference nodes. A reference node is a node that refers to another node (called referent node) within the hierarchy. Except for the attributes `Children`, `Aliases`, `Attributes`, and `Reference`, reading an attribute of the reference node has the same result as reading the attribute of the referent node. Therefore, a client may not be able to distinguish between the reference and its referent node (except for the attributes mentioned before). It is also possible to define multiple reference nodes that point to the same referent node. However, reference loops and self-references are not allowed. Reference nodes are used to model different views and to define multiple hierarchies.

Nodes and attributes are addressed by their path. Paths are character strings that are composed of two parts: the node part followed by the attribute part. The node part reflects the node hierarchy and consists of node IDs separated by forward slash “/” characters. An empty node part refers to the root node of the hierarchy. The attribute part is made up of attribute IDs separated by colon “:” characters. If the attribute part is empty, the `Value` attribute is assumed by default. The complete path form is

`[/nodeid[/nodeid]...][:attributeid[:attributeid]...]`

IDs are case sensitive and have to consist of printable ANSI X3.4 characters except of the following characters: /;— < > \* ?” [] {}|. Additionally, node IDs beginning with a period “.” character and attribute IDs not beginning with a period “.” character are reserved by the BACnet/WS standard. Hence, proprietary node IDs defined by a BACnet/WS server must not begin with a period “.” character, whereas proprietary attribute IDs have to.

#### 55.4.2.2 Services and Communication in BACnet/WS

The communication concept of BACnet/WS is based on the client/server model. A BACnet/WS server aims at providing a uniform access to the control data of the underlying BAS. To achieve this, it collects the control data, processes it, and represents the data as BACnet/WS nodes within the server’s node hierarchy. Modified values are written back to the originating devices. BACnet/WS clients can access the node hierarchy by reading or writing the individual nodes of the hierarchy.

In BACnet/WS, a set of WS is defined to provide read and write access to the node hierarchy. Currently, 11 different WS are defined, which are mainly used to read and write the attributes of nodes or to retrieve information about the attributes (e.g., the array size). Typical examples are the `getValue()` and `getValues()` services to read the value of one or more attributes as well as the `setValue()` and `setValues()` services that are used to change the value of one or more attribute, respectively. Other services like services to change the data model (e.g., add or delete nodes) or to query the node hierarchy are not supported (browsing the node hierarchy has to be done by reading the `Children` attribute).

The implementation of these services shall conform to the Web Services Interoperability Organization (WS-I) Basic Profile 1.0, which specifies the use of SOAP 1.1 over HTTP 1.1. The data encoding shall be based on XML 1.0 (second edition). In addition, an extension of BACnet/WS that provides the opportunity to use RESTful services has been specified.

### 55.4.3 oBIX

The open Building Information eXchange (oBIX) specification [38] is maintained by the Organization for the Advancement of Structured Information Standards (OASIS).<sup>\*</sup> The first specification oBIX 1.0 has been published in December 2006 [35]. The main goal of oBIX is to provide an open WS interface for accessing any kind of BASs. As a platform-independent technology, oBIX can be used on top of any existing technology. To exchange data, oBIX defines a small set of WS that can be used over SOAP or HTTP binding. The object model is concise but very flexible due to its support for object-oriented concepts.

The work on oBIX 1.1 started in 2009 and mainly consists of bug fixes as well as some additional features like a binary encoding scheme for the used object model. By 2010, a draft has been released that became a de facto working standard for oBIX 1.1.<sup>†</sup> Recently, in 2013, the standardization effort on oBIX gained momentum and additional protocol bindings and message encodings were added, which are discussed within Chapter 59, which has a focus on future trends in smart homes and building automation technologies.

#### 55.4.3.1 Information Modeling in oBIX

The basic elements within oBIX are *objects*. Each object is of a certain object type. Currently, 17 standard object types have been specified where each type directly maps to an XML element name. Typical examples are objects that model single data items like `bool`, `int`, `real`, and `str` as well as object types for time and date representations (e.g., `date` and `time`). However, object types that represent references to other oBIX objects (`ref`) and types that can be used for lists (`list`) are also available. Each object has different *attributes* that further describe the object and thus add semantics to it. Some of these predefined sets of attributes are called *facets*, which represent metadata of an object. Typical examples are `displayname`, `min`, `max`, and `units`.

In addition to model normal data (e.g., data points of type `real` or `bool`), oBIX provides the concept of operations (`op`). Operations are methods that can be invoked by a client. They take exactly one oBIX object as parameter (specified by the `in` attribute) and one oBIX object as result (specified by the `out` attribute). If multiple parameters or results are required, nested objects must be used.

The main feature of the object model in oBIX is that objects can have subobjects. Using this nested concept, complex data structures can be defined. Another important feature is that objects and their attributes are represented by XML. Each object (or subobject) is directly mapped to an XML element—attributes and facets are mapped to XML attributes of the corresponding XML element.

An important concept of oBIX is the use of so-called contracts. Contracts can be compared to templates—they are used to define new object types but also provide a possibility to specify default values. Contracts are represented as normal oBIX objects by using the same XML syntax. Thus, there is no difference between a contract and a normal object, and oBIX clients can access type definitions the same

---

<sup>\*</sup> <http://www.oasis-open.org>.

<sup>†</sup> The remainder of this discussion will be based on that draft version of 2010 and focus on the core specification.

way as they can access normal data. To specify that an object implements a contract, the `is` attribute is used. If an object references to a contract using the `is` attribute, the object can be seen as an instance of the contract since it inherits the structure of the contracts as well as the default values. However, to add additional semantics, the object instance can override dedicated subobjects or attributes (e.g., the object name) or extend the structure by adding new subobjects. The `is` attribute can also be a list of contracts and so, multiple inheritance is possible, too. A contract can itself be an implementation of another contract. This means that it is possible to define type hierarchies like it is common in other object-oriented concepts.

Objects are identified by either a name, a hyperreference, or both. Names are used to define the role of an object and used as programmatic IDs. The name of an object is represented by the `name` attribute and should not be used for display purposes—instead, the `displayname` facet shall be used. Names are often used to define semantics of subobjects. The hyperreference of an object is specified by the `href` attribute. In general, uniform resource identifiers (URIs) are chosen to define a hyperreference. For the root object, an absolute URI has to be selected. For all other objects, it is possible to take absolute (e.g., `http://knx/building1/room1/light1`), relative URIs (used to address an object relative to its location within the data structure, e.g., `light1`), or fragmented URIs (used to name objects within the same oBIX document, e.g., `#light1`).

In addition to these basic information modeling concepts, the oBIX specification provides a *core contract library*. Within this library, basic objects like `Units` and `Weekdays` are already defined. Furthermore, oBIX defines the following concepts:

- **Points:** Points provide an abstraction of the datapoint concept within the automation system.
- **Watches:** Watches are used by the client to register to dedicated objects for monitoring object changes.
- **Alarming:** Concepts for querying, watching, and acknowledging of alarms are also provided by oBIX.
- **History:** oBIX also supports mechanisms to retrieve the history of object values.

#### 55.4.3.2 Services and Communication in oBIX

oBIX is also based on a service-oriented client/server architecture where oBIX clients can access the data of an oBIX server using WS. However, compared to other technologies, oBIX only defines three services. The `Read` service is used to read the complete state of an object. The object to be read is specified by the object's URI—the current state of the object is returned as XML document. The `Write` service is used to update the state of an object. As parameters, the object's URI as well as the new object state are passed to the service. If successful, the server responds with the updated state of the object. Finally, the `Invoke` service is used to execute operations. The request contains the input parameter object and the server responds with the output object after having executed the desired operation.

For implementing these three request/response services, two different protocol bindings are specified by the oBIX standard. The HTTP binding simply maps oBIX requests to HTTP 1.1 methods. The second protocol binding maps the services to corresponding SOAP services.

The network messages that are exchanged during service execution have to be encoded. While within oBIX 1.0 only an XML encoding scheme is defined, the new version oBIX 1.1 also defines a binary encoding scheme. The main advantage of this new binary encoding scheme is its efficiency, which makes it suitable for narrow bandwidth networks as well as for small embedded devices.

#### 55.4.4 DPWS

The DPWS was initially created by Microsoft and is meanwhile available as OASIS standard.\* It defines a subset of WS-\* standards in order to provide interoperability between resource-constrained WS

---

\* <http://docs.oasis-open.org/ws-dd/dpws/1.1/os/wsdd-dpws-1.1-spec-os.html>.

implementations. The main areas of this specification address messaging, discovery, description, and eventing. The profile intends to constrain the WS protocols and formats to allow implementation on consumer electronics hardware or embedded devices but still be compatible with WS implementations on resource richer devices. The specification addresses the message exchange between clients and services hosted on a device. The specification identifies a device service that contains several hosted service, which are hosted by the device service.

#### 55.4.4.1 Information Modeling in DPWS

DPWS does not offer a metamodel that can be used for information modeling. As the name implies, it is a profile that defines a subset of WS-\* standards for the usage on resource constraint devices. For information modeling, DPWS does not come with a custom metamodeling language. For representing devices, process control variables, process data points, or the topology of a BAS XML schema can be used. XML schema is a metamodel that allows to define the structure of XML documents. It uses basic types, which are common in many other information modeling languages like *xs:string*, *xs:decimal*, *xs:integer*, *xs:float*, *xs:float*, *xs:date*, and *xs:time*, and further some XML-schema-specific basic types, which are *QName*, *anyURI*, *language*, *ID*, and *IDREF*. Basic types are neither allowed to contain subelements nor attributes. Furthermore, there are complex types, which may contain nested elements and attributes. It is possible to define value restrictions on XML types and also some requirements regarding the structure.

#### 55.4.4.2 Services and Communication in DPWS

DPWS uses a client/server model for communication and is based on the WS-\* standards described earlier. In contrast to other building automation standards using WS, there are no generic or uniform services defined, except the transfer of metadata about the offered services, the services required by the WS-Discovery standard, and several attributes describing the host service and its hosted services. For messaging, the use of SOAP 1.2, SOAP-over-UDP, HTTP 1.1, WS-Addressing, UUIDs (RFC 4122), and Message Transmission Optimization Mechanism (MTOM) are required. WS-Discovery is obligated to be used for discovery. It allows to find WS adhering to a certain port type by using UDP broadcast messages within an IP network. The description of the capabilities of a device and its hosted services is based on WSDL to describe the interfaces and the exchanged messages. The exchange of this metadata about the WS is done using WS-MetaDataExchange, which itself uses WS-Transfer and WS-Addressing. This allows to offer and exchange the metadata in a standardized way. To express the capabilities of a device, DPWS provides several extensible XML complex types, which are *dpws:ThisModel* and *dpws:ThisDevice*. Furthermore, *dpws:Host* and *dpws:Hosted* provide standardized attributes and subelements that describe the services running on a device. This includes, for example, the port types used by WS-Discovery. A client can subscribe to events and receive notifications according to WS-Eventing. DPWS defines a filter dialect that allows to subscribe to one or more notifications exposed by a hosted service. The event types and the type of a notification are not covered by the standard.

## 55.5 Conclusion

---

Building automation technologies were primarily used for simple control tasks, but they developed to highly complex systems. Today's BASs are crucial for large buildings. They help to save energy and human resources. Additionally, the comfort of facility users is increased and maintaining safety in buildings is a key asset.

This chapter aimed to give an introduction into state-of-the-art technologies used in building automation. First, structural models of building automation were presented to show the big picture of the topic. Due to the enormous number of different technologies, products, and standards in this domain, a selection of the most important technologies was presented. Many of these technologies were developed

years or even decades ago. Nevertheless, they are still widely used today. It is hardly imaginable that these technologies are replaced by any other technology in the near future.

For modern buildings, it is crucial that building automation technologies are able to cooperate with each other. It is common practice that different technologies are used within one system. There are technologies that are used for dedicated applications. Other subsystems are historically grown and therefore use different technologies. For this purpose, high-level approaches were presented that provide a basis for interoperability among this high diversity in technologies. They are further capable for providing an abstract and unified interface for high-level control and visualization.

The recent development toward an Internet of Things (IoT) also influences building automation and technologies. Future automation systems have to be integrated in this new world. This consequently offers new possibilities but also new challenges. Due to the interaction with almost everything and everyone within a building, synergy effects arise that can be exploited by upcoming technologies. Thus, Chapter 59 addresses recent developments and trends in the context of building automation and the IoT.

### 56.1 Distributed LonWorks® Networks

---

The LonTalk® Communication Protocol defines rules for the communication in LonWorks networks. All nodes connected to a local operating network need to support the LonTalk protocol to such an extent that all communication services are supported. Otherwise, the performance and the openness of the system may not be guaranteed. The LonMark Interoperability Association, founded by significant producers of LonWorks-based devices in 1993, issues guidelines for the development and integration of interoperable LonWorks networks. The LonMark Interoperability Guidelines describe a unique platform for interoperable (manufacturer-independent) LonWorks networks. One task of the LonMark Interoperability Association is conformance testing and certification of LonWorks-based products according to their interoperability guidelines. The protocol has also been advanced to the ISO standard level in ISO/IEC 14908 [1] (Figure 56.1).

Significant application areas for LonWorks-based systems are building and process automation, electrical appliances in homes, restaurants, transportation, and other applications with distributed data acquisition and control. The data exchange between two applications requires reaction times of several milliseconds. This is the time interval in which a message is sent from the application on node A transmitted over the network and received by the application program in node B (end-to-end response time). The LonTalk protocol is only partly suitable for the transmission of audio and video data streams. This characteristic is common to all known control network protocols. It is due to the requirements for short end-to-end response times in real-time control applications, but the overall data throughput is low. Control networks are often used over communication media with heavy disturbances from electromagnetic coupling, signal interference, and mechanical disturbances. Therefore, reliable transmission

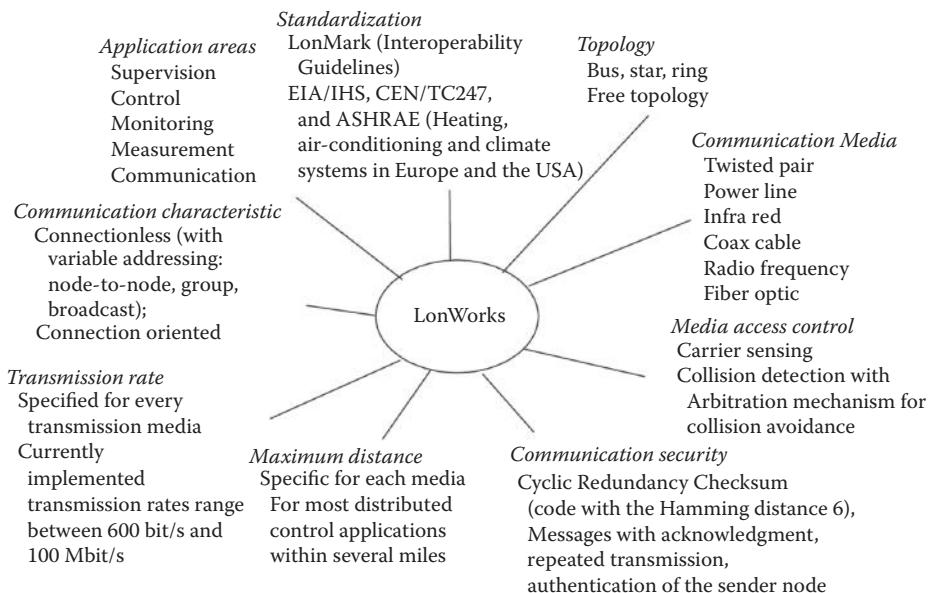

FIGURE 56.1 Features of a LonWorks network.

of control data is often an important criterion for the selection of a control network. The LonTalk protocol defines a 16-bit cycle redundancy check polynomial, which provides the failure recognition with Hamming Distance 6 for each data packet. Furthermore, services for acknowledged end-to-end communication, automatically repeated transmission, and transmitter authentication provide means for secure transmission.

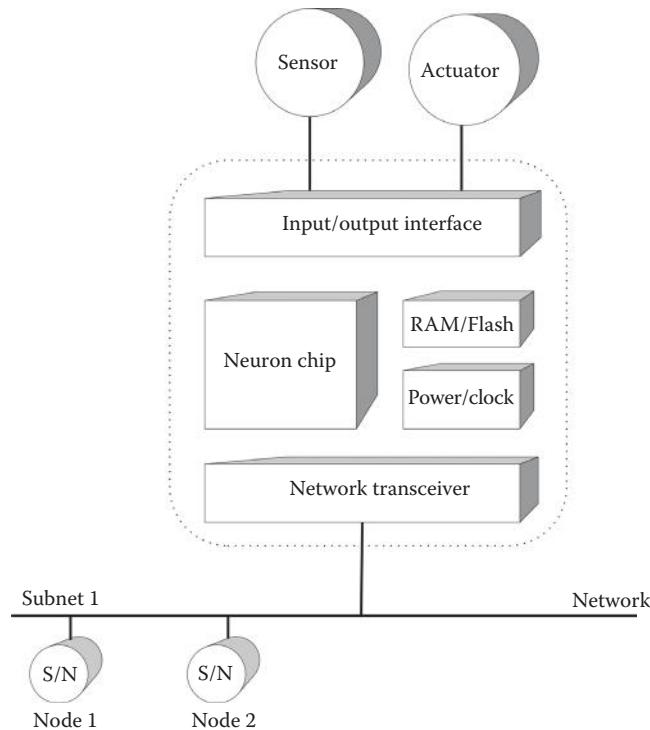

## 56.2 Node Architecture

For the last 10 years, the Neuron® chip manufactured by Motorola, Toshiba, and Cypress was the only microcontroller that supported the LonTalk protocol. Only in the last few years, with the adoption of the LonTalk protocol as a European and ANSI standard, some platform-independent implementations are available on the market [2]. The traditional LonWorks node is shown in Figure 56.2.

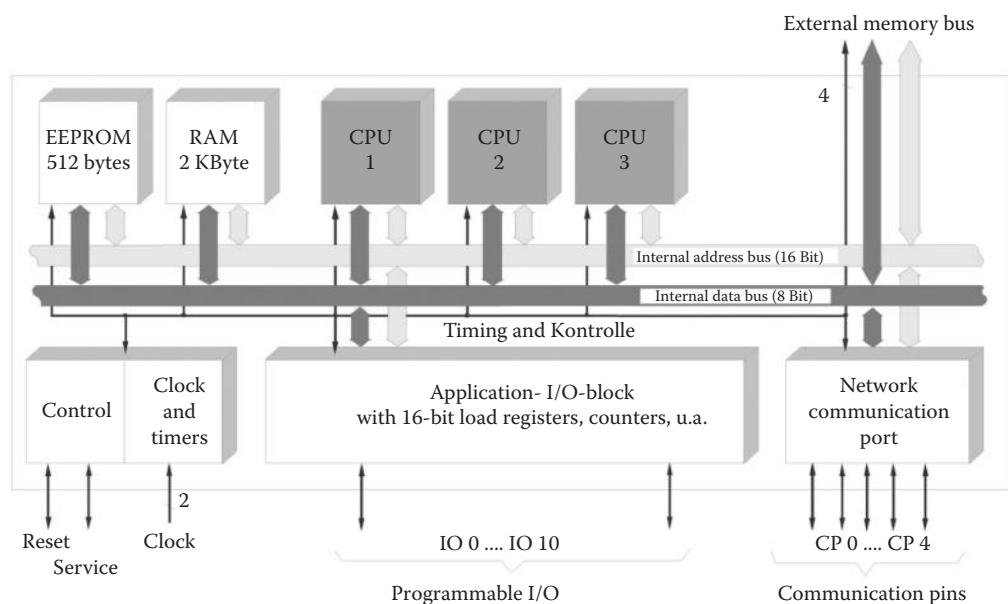

The Neuron chip executes the LonTalk protocol and the application program that interfaces to sensors and actuators through the input/output (I/O) interface. The block diagram of the Neuron chip is shown Figure 56.3.

Two versions of the Neuron chip are available. The 3150 provides an external memory bus interface to expand the internal EEPROM and SRAM with external Flash and SRAM. The 3120 is optimized for low node cost applications and has a built-in 10 kByte ROM, 2/4 kByte EEPROM, and 2/4 kByte SRAM but has no external memory interface [3]. The memory layouts for three versions of the Neuron chip are shown in Figure 56.4.

As shown in Figure 56.3, the Neuron chip has 11 I/O pins available to connect to sensors and actuators. A more detailed view of the I/O interface of the Neuron is shown in Figure 56.5. Each Neuron chip contains two independent timer/counter circuits with a width of 16 bits each. These two timer/counter blocks are used to count pulses from sensors and to generate frequencies or pulse-width-modulated signals to stimulate actuators. These timer/counters as well as the remaining I/O pins can be programmed through software libraries supplied with the development tools for the Neuron chips.

**FIGURE 56.2** Typical LonWorks network node architecture.

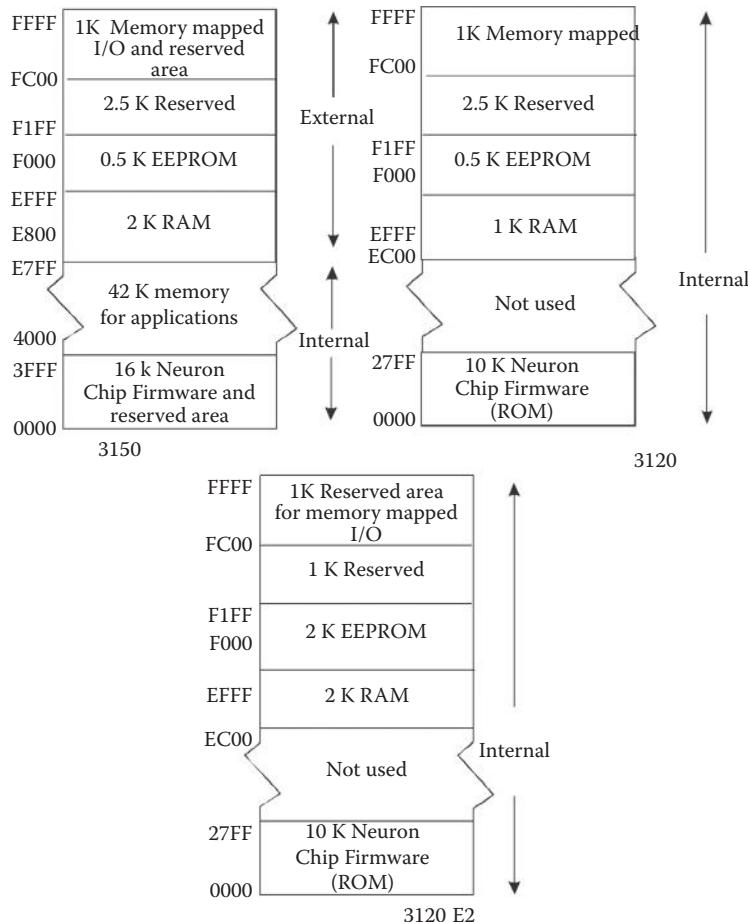

FIGURE 56.4 Memory layout for the 3150, 3120, and 3120E2 Neuron chips.

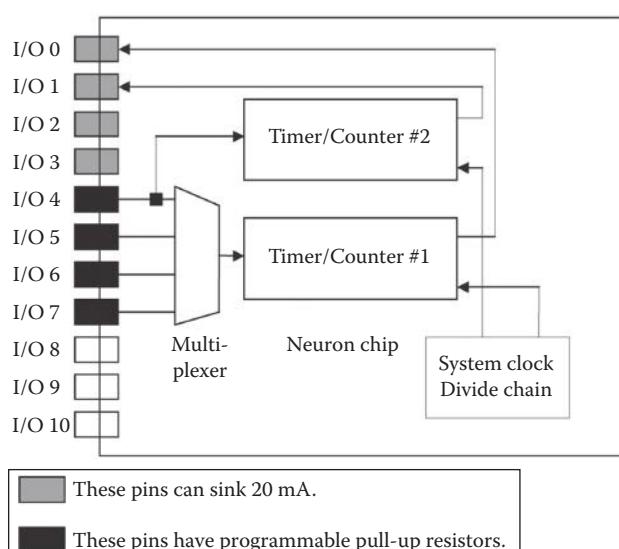

FIGURE 56.5 I/O system of the Neuron chip.

### 56.3 Programming Model

An ANSI C derivative language called Neuron C is used to program the Neuron chip. Neuron C uses language extensions to schedule application events and to react to incoming data packets (network variables [NVs]) from the network interface. The user does not have to deal with internal details, for instance, how the C compiler produces machine code and how the hardware of the Neuron chip processes this code at run-time. If desired, the compiler generates a comprehensive compilation protocol, which also contains the assembly listing. A number of frequently required functions are available in the firmware library of the Neuron chip, so that there is no need for the user to implement these functions. The C compiler outputs very compact machine code, which efficiently utilizes the memory resources. However, in comparison with other processors, users with assembly language experience will miss possibilities that a direct access to the internal registers on assembly level typically would offer. The lack of software or hardware interrupt capabilities especially in the application programs is sometimes a bit cumbersome. Hence, the development of applications that require fast response times to external events is not trivial. Decentralizing the desired functionality onto multiple Neuron chip-based nodes is, besides using a more powerful platform as explained at the end of this chapter, sometimes the only solution to achieve reasonable response times. The Neuron chip task scheduler that controls the flow of the application program allows event-oriented programming in C. It recognizes external and internal events and executes the associated task (Neuron C *when-clause* statement) of the application program. Due to its nonpreemptive mode of operation, it cannot interrupt the active task. Hence, the reaction time to an occurring event greatly depends on the programming style of the software developer.

The operation of the Neuron chip task scheduler is shown in Figure 56.6. The scheduler is initialized after power-on or after a restart of the application program. The scheduler starts with the reset task if

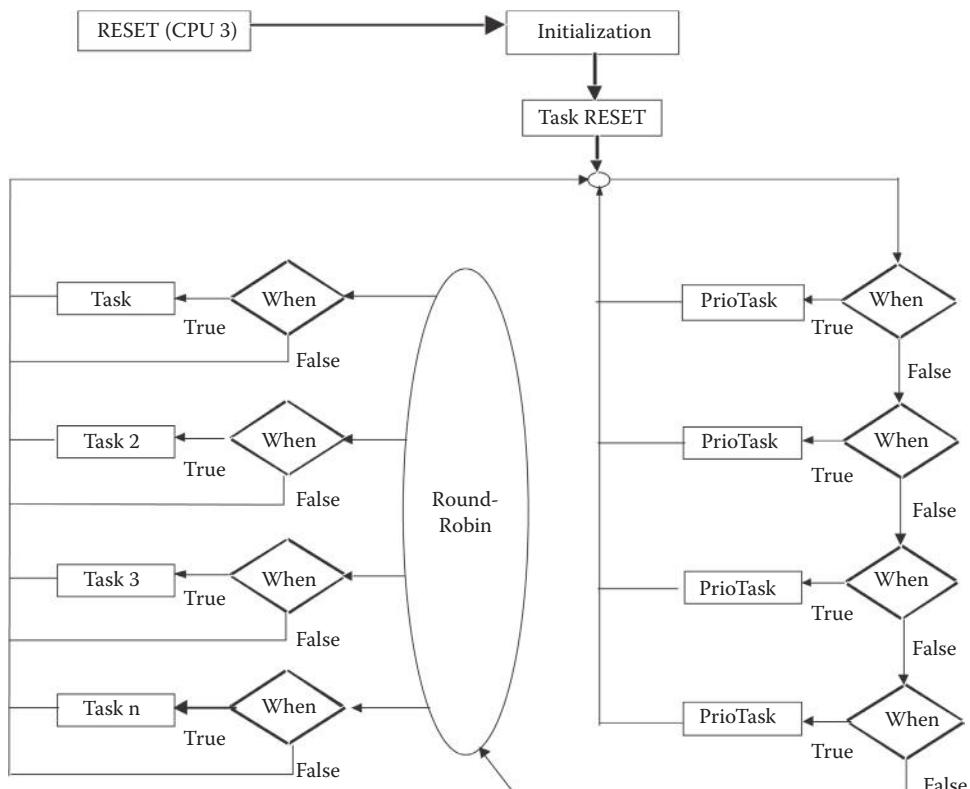

FIGURE 56.6 Neuron C scheduler.

it is present. Inside the reset task, all application-specific initialization can be performed. After that, all the system-specific tasks and priority tasks will be checked. If one of the tasks evaluates true, the task will be executed, and the scheduler returns to the beginning of the scheduler loop. If none of the priority tasks evaluates true, the nonpriority tasks will be checked. These tasks will be selected in a round-robin fashion. Between nonpriority tasks, all system-specific tasks and priority tasks will be checked regardless of whether the task was executed or skipped. The nonpriority tasks will be executed in the order of their definition in the application program. If the last nonpriority task is checked and maybe executed, the scheduler starts again with the first priority task.

## 56.4 Communication Elements

---

Communication between network nodes can be done in two ways. The preferred method are so-called NVs. NVs are variables (like variables in a C program) that can be propagated over the network and are defined in the application program. NVs have a type, for example, SNVT\_temp to represent a temperature in degree Celsius or SNVT\_amp to represent an electric current in Amps or mA. SNVT is the acronym for Standard Network Variable Type. Each SNVT has a valid range defined by the upper and lower boundary, a resolution, and an SI unit. Network nodes communicate with each other by exchanging NVs. Examples for different NV declarations are given as follows:

```
network output SNVT_temp_p Room_Temperature;
network input SNVT_temp_p Outdoor_Temperature;
```

NVs can be input or output NVs. If the application program assigns a new value to an output NV, this value will be automatically transmitted to other nodes on the network. The data packet generation and transmission is transparent for the application program without calling special functions to assemble and to transmit the packet. A simple Neuron C code example for transmitting the value (new\_value) for the NV Room\_Temperature is shown in the following statement:

```
Room_Temperature = new_value;
```

Another way to communicate between nodes are explicit messages. These messages do not use pre-defined variable types but can use any combination of bits and bytes assembled in the data packet.

The logical binding between input and output NVs or explicit messages on different nodes can be done differently depending on the system architecture.

- It can be done at the factory if the node is part of a closed system (e.g., copy machine).
- For homogeneous systems, it is possible to implement self-binding strategies.
- Depending on the number of available input pins or application parameters, the node can create the binding itself.
- For complex systems (e.g., large buildings), the binding will be accomplished with an installation tool. This is called system integration.

## 56.5 Communication Topologies and Media

---

LonWorks supports a variety of different topologies and communication media. In most cases, the topology of fieldbus systems is a line structure as shown in Figure 56.7. To avoid reflections, nodes are connected to this line by short stub cables.

In home or building automation, pure line topologies are barely applicable. To minimize the wiring cost, stub lengths up to several meters are required. If stubs are getting longer and start to branch out, we go from a pure line topology to a so-called free topology as shown in Figure 56.8. In any case, the network cable must be properly terminated according to the impedance of the network cable, which is typically in the  $100 \Omega$  range.

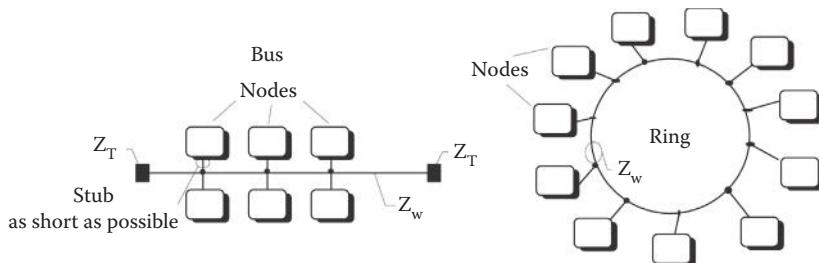

FIGURE 56.7 Line topologies shown as bus and as ring topology.

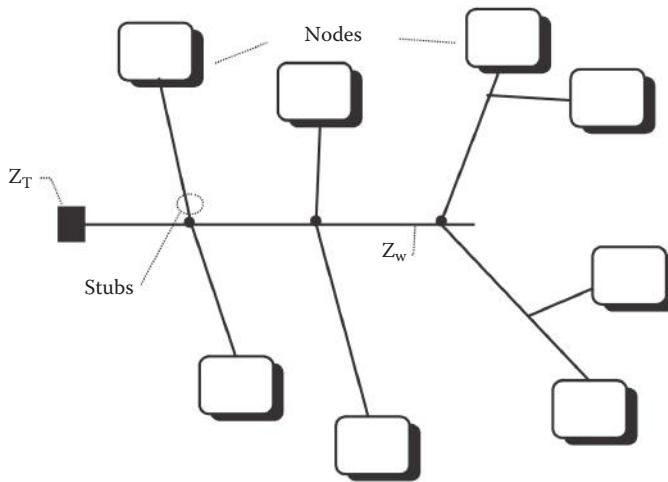

FIGURE 56.8 From long stubs to free topology.

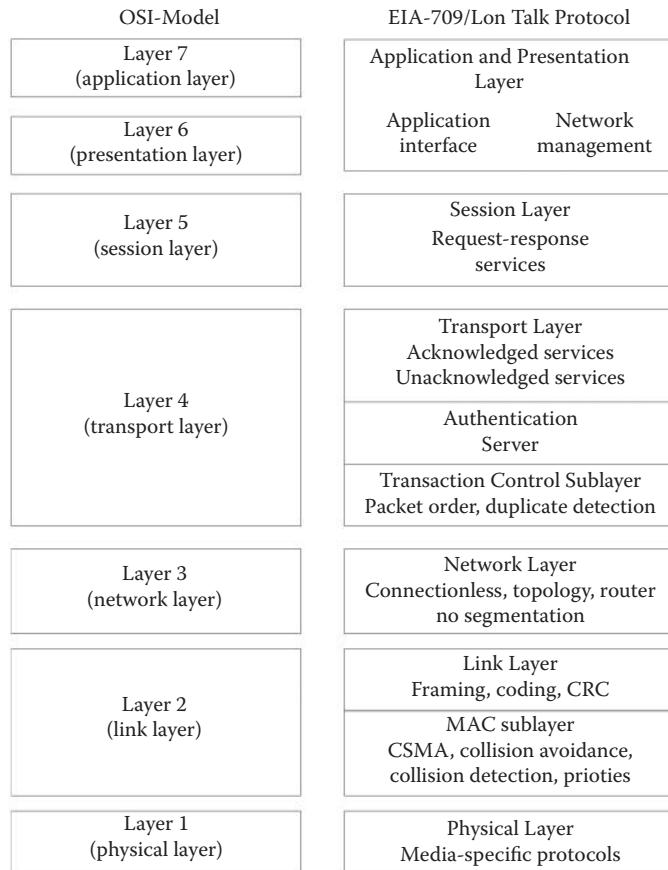

The most popular communication media today are 78 kbps (CEA-709.3) or 1.25 Mbps twisted-pair communication, 4 kbps power line communication (CEA-709.2), a 1.25 Mbps fiber-optics interface, and RS-485 interfaces at various bit rates between a few hundred bps and 1.25 Mbps. A brand-new channel type is the EIA-852 Internet Protocol (IP) channel in order to tunnel CEA-709 data packets through Ethernet IP (Intranet, Internet) networks.

## 56.6 ANSI/CEA-709 Protocol Standard (LonTalk)

One of the characteristics of LonWorks is its unique seven-layer protocol implementation called LonTalk or LonWorks protocol. Unlike other fieldbus protocols, all seven layers of the ISO/OSI reference model are actually defined and implemented in every single network node. One characteristic is its media-independent OSI Layer 2 that supports various communication media like twisted-pair cables, power line communication, radio frequency channel, infrared connections, fiber-optic channels, as well as IP connections based on the EIA-852 protocol standard. The OSI reference model and the corresponding functionalities of the CEA-709 protocol are shown in Figure 56.9.

The medium access control sublayer provides an arbitration mechanism called predictive p-persistent carrier sense multiple access (CSMA), which avoids collisions on the network. The link layer provides a connectionless service whereby the functionality is restricted to the generation of the frame and the error detection. Detected errors will be indicated to the upper layers to correct them.

The network layer transmits data packets as a connectionless unacknowledged service that neither allows segmentation of messages nor assembling of partial messages to a complete message. Self-learning

**FIGURE 56.9** OSI reference model for the ANSI/CEA-709 protocol.

routers will be supported, but a tree structure of the network will be assumed. In contrast to self-learning routers, configured routers that are using routing tables can be used also in networks with physical loops as long as the logical connections are built in a tree structure.

The main functions of the LonTalk protocol are processed by the transport layer and the session layer. Layer 4 can be split up into (1) transaction control sublayer, (2) authentication server, and (3) transport layer. The duplicate detection in the transaction control sublayer detects duplicated packets to guarantee the correct order of the packets. The purpose of the authentication server is to provide an authenticated data exchange. The (3) transport layer provides a peer-to-peer connection between the source node and one or more destination nodes.

The session layer provides a simple request-response mechanism for the access from clients to distant servers. Based on this functionality, application-specific remote procedure calls can be defined. The network management protocol, for instance, makes use of the request-response mechanism contained in the session layer.

Presentation layer and application layer provide the basic functionality for interoperability. The application layer provides all services required for transmitting and receiving messages. Furthermore, the concept of the NVs is embedded in the application layer. The presentation of data in the presentation layer is independent of the application. This allows simple data exchange between nodes of different manufacturers.

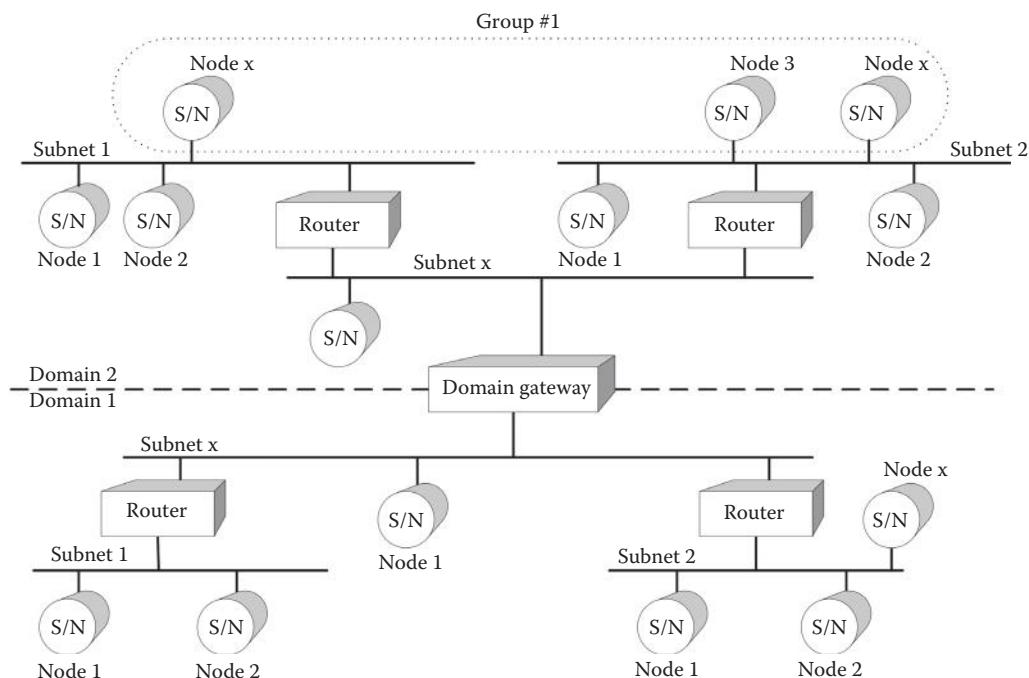

The basic frame layout for a twisted-pair media is sketched in Figure 56.10. The preamble allows for bit synchronization at the receiver, and the start bit indicates the beginning of the byte boundary.

The header field carries information about the importance of the data packet expressed in a priority bit and an estimation of the number of expected data packets on the bus in the near future. This estimation is used to adjust the bus arbitration algorithm. The source address holds the subnet/node address of the transmitting node, and the destination address holds the address of the receiving node(s) followed by the user data that can be between 1 and 228 bytes long. Finally, a 16 bit CRC (CCITT-Polynomial) protects the frame from bit errors (Hamming Distance 4), and the code violation indicates the end of the frame. After the CV, a new round of bus arbitration can take place if nodes have data to be sent over the network [4]. On twisted-pair cables, a p-persistent CSMA bus arbitration scheme is used. For other communication channels, for example, IP over Ethernet, the arbitration scheme defined for this media is used by the CEA-709 protocol stack.

Another characteristic is its elaborated OSI Layer 3 that supports a variety of different addressing schemes and advanced routing capabilities as shown in Figure 56.11. Every node in the network can be identified with a unique 64 bit physical address (Neuron ID) and with a logical address composed of three address elements: the domain identifier, the subnet number, and the node number. Node numbers can be in the range of 1–127, subnet numbers within 1 and 255; hence, a maximum of  $127 \times 255 = 32,385$  nodes can be addressed within a single domain, and up to  $2^{48}$  domains can be addressed. Domain gateways can be built between logical domains in order to allow communication across domain boundaries. Groups can be formed in order to send a single data packet to a group of nodes using a multicast addressed message.

**FIGURE 56.10** LonTalk frame layout on a twisted-pair cable.

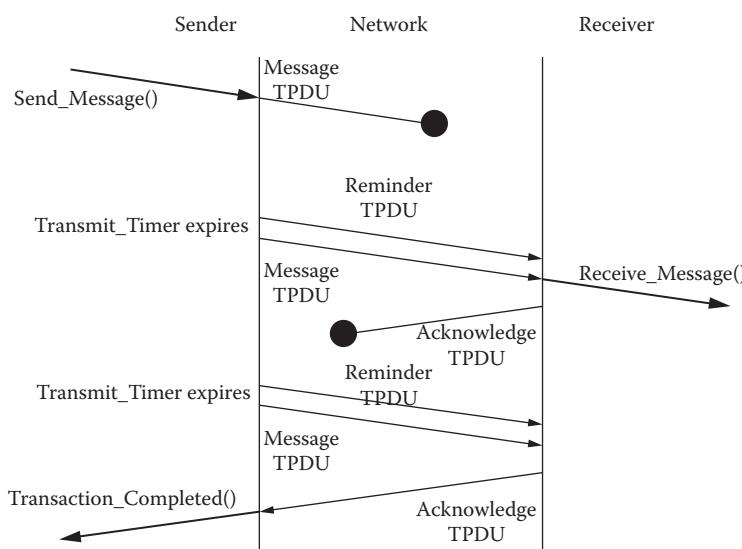

**FIGURE 56.11** Addressing elements in CEA-709 networks. Up to 32,385 nodes can be addressed within one domain, and up to  $2^{48}$  domains are possible.

**TABLE 56.1** Addressing Schemes

Type	Address Format	Logical Address Components	Destination
#0	Broadcast	Domain, sourceSub-Node, destSubnet = 0	All nodes of a domain
#0	Broadcast	Domain, sourceSub-Node, destSubnet	All nodes of a subnet
#1	Multicast	Domain, sourceSub-Node, destGroup	All nodes of a group
#2a	Unicast	Domain, sourceSub-Node, destSub-Node	One node within the subnet
#2b	Multicast	Domain, sourceSub-Node, destSub-Node, Group, Group Member	One node within the subnet
#3	Unicast	Domain, sourceSub-Node, destSub, Neuron ID	One node with name = Neuron ID

Optionally, routers can be used to keep local traffic within the subnet and only forward packets that are addressed to another subnet as shown in Figure 56.11. A CEA-709 node can send a unicast addressed message to exactly one node using either the physical Neuron ID, or the logical subnet/node (S/N) address, or a multicast addressed message to either a group of nodes (group address) or to all nodes in the subnet or all nodes in the entire domain (broadcast address). All possible addressing schemes are summarized in Table 56.1.

OSI Layer 4 supports four service types. The unacknowledged service simply transmits the data packet from the sender to the receiver and hopes that the message does not get lost or destroyed. The unacknowledged repeated service transmits the same data packet a number of times and assumes that at least one data packet will get through to the receiver. The number of retries is programmable. The acknowledged service transmits the data packet and expects an acknowledgment coming back from the receiver. If the acknowledgment is not received, the transmitter retransmits the same data packet. The number of retries is again programmable. This service is shown in Figure 56.12. Here the original message (transport protocol data unit [TPDU]) is lost on the way to the receiver; hence, the transmitting node is repeating this message after the transmit timer expires. This message is received at the receiving node, but the acknowledgment packet is lost on the way back to the original sender. Hence, the sender again sends out this message after the transmit timer expires. Now the TPDU is received at the receiver, and the acknowledgment is received at the sender, and therefore the transaction is completed and a new transaction can begin.

**FIGURE 56.12** Acknowledged service with retries.

The request response service sends a request message to the receiver, and the receiver must respond with a response message. This service type can be used to retrieve, for example, statistics information from a network node. Authentication can be used to authenticate the sender at the receiver side.

## 56.7 Network Infrastructure

---

Great care must be taken when designing the network infrastructure for a CEA-709 network. There are a number of requirements that must be met in order to guarantee reliable communication between all the nodes in the network. The maximum cable length must be met, the network cables must be properly terminated, the number of nodes on each physical channel must not exceed the specification, the expected network traffic must be estimated, and a network topology chosen to keep local traffic local—only data packets that need to travel across network segments should leave the local segment. The bandwidth utilization must be kept below a certain limit, and the number of CRC errors, due to collisions and noise on the network media, must be measured on each channel and kept within well-defined boundaries. Only a reliable network infrastructure with built-in diagnostics and troubleshooting functionality can guarantee reliable operation of the building or factory.

Depending on the network media and the network transceiver, a variety of network topologies are possible with LonWorks nodes. Traditional bus, ring, star, as well as free topology are supported. Complex networks require networking elements like repeaters, routers, and gateways available in CEA-709 to segment the local traffic from traffic crossing segment boundaries. Such networking elements include Layer 1 repeaters to extend the physical length of a network cable, Layer 2 bridges, and Layer 3 routers to decouple individual segments from a networking backbone and gateways to bridge between the levels of hierarchy in the automation pyramid (see Figure 56.11).

Modern network infrastructure products [2] have built-in network diagnostics capabilities and can monitor the health state of the network 24 h a day 7 days a week. They immediately report network malfunctions or deviations from the normal operation to the system operator. All monitoring and reporting can be done either from local on-site or from remote through an intranet or Internet connection.

## 56.8 Interoperability and Profiles

---

Open standards allow individual companies to build single pieces of a bigger puzzle and enable system integrators (SIs) to design complete systems consisting of those building blocks. Node developers must follow certain rules in order to make the *bigger picture* work. These rules are defined in interoperability guidelines and in profiles. Compatible does not necessarily mean interoperable, and not at all plug and play. More elaborated guidelines need to be established for plug-and-play, interchangeable, and interworkable products. Different committees have set guidelines to define those terms and to establish the rules. The LonMark organization, for example, has published interoperability guidelines for nodes that use the LonTalk protocol [5]. It is important to note that interoperability must be guaranteed on all seven OSI layers. Interoperability on all seven OSI layers is still not a guarantee to have interworkable products. A typical node only uses a subset of all the possible protocol features. Profiles define these subsets based on the intended use of the node. Task groups within LonMark define functional profiles for analog input, analog output, temperature sensor, humidity sensor, CO<sub>2</sub> sensor, VAV controller, fan coil unit, chiller, thermostat, damper actuator, etc. As of today, LonMark hosts different task groups for fire, home/utility, petrol station, HVAC, lighting, sun blinds, security, etc., type of applications.

## 56.9 Development and Integration Tools

---

In order to program the Neuron chip, the user has two tool options. For node manufacturers, it might be sufficient to buy the NodeBuilder from Echelon; the more advanced and also more expensive tool is the LonBuilder from Echelon. Both tools allow writing Neuron C programs, to compile and link them

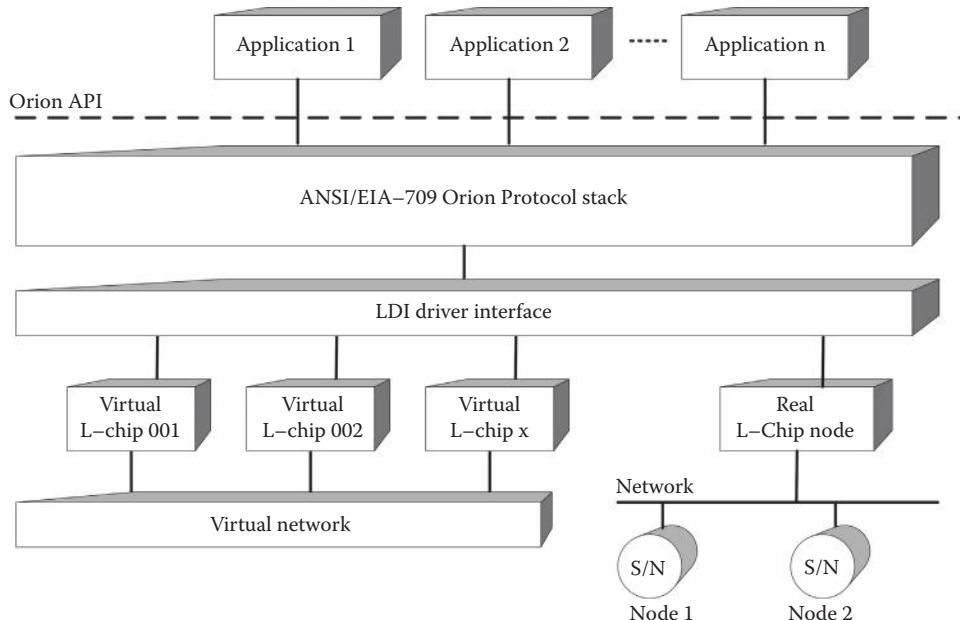

and download the final application into the target node hardware. The LonBuilder supports simultaneous debugging of multiple nodes whereas the Nodebuilder only supports debugging of one node at the time. The LonBuilder has a built-in protocol analyzer and a network binder to create communication relationships between network nodes.

SI need tools to design the network and define the communication relationships before the nodes are actually installed in the field. Similar to creating a schematic of resistors, capacitors, ICs, diodes, etc., the SI creates a floor plan of all the nodes in the network. After physically installing the nodes in the network, a network management tool is required to configure (also called commission) the nodes. During commissioning, nodes get a logical address (subnet/node/domain) assigned, and the binding is created. Binding is the name of the process to establish the communication relationships between sensors, actuators, and controller nodes. Protocol analyzers are used to debug communication problems and to gather traffic and error statistics. During the maintenance phase of the network, the network management tool also supports replacing faulty nodes and extending the network with additional nodes and changes in the communication relationships.

## 56.10 New Developments for ANSI/CEA-709 Networks

As mentioned earlier, until 1999, the Neuron chip was the only vehicle to execute the LonTalk protocol. Due to the limited resources available on the Neuron chip (CPU performance, memory space, I/O capabilities, etc.), many applications could not be realized with the existing technology. Recent hardware platform-independent implementations of the ANSI/EIA709 protocol allow for good scalability of the CPU performance and memory requirements tailored to the specific application. Furthermore, simulation of the network behavior before actual hardware exists is now possible as shown in Figure 56.13.

Different application programs run on top of the ANSI/EIA709 protocol stack that talks to an interface layer (LDI), which communicates with the virtual network devices. As shown on the right-hand

**FIGURE 56.13** Platform-independent ANSI/EIA709 implementation. Simulation environment with virtual nodes linked to a physical network.

side in Figure 56.13, the LDI can also talk to a real physical network; hence, existing nodes in a network can be part of the system simulation. The application programs do not see a difference if the node already exists as a physical device or is a virtual device simulated on a PC or workstation [6,7]. This architecture is fully portable between different hardware platforms and different operating systems, and allows cross development, for example, on a Windows platform for an ARM9-based target hardware. Since the application programming interface on top of the CEA-709 protocol stack is the same on all hardware platforms, and under all operating systems, the final application programs can easily be ported between different target systems. This approach allows full hardware-software codesign since the application programs can be developed, while the hardware development of the network node is still going on.

With the new ANSI/CEA-852 standard that defines how CEA-709 packets are tunneled through IP networks, standard hardware platforms with an Ethernet interface like PCs or embedded controllers can be used to develop LonWorks-based network nodes.

Another development that has achieved wide acceptance are multiprotocol processors that can support multiple different protocols. These processors are also very well suited for gateway applications to bridge the gap between various protocol standards. One such development is shown in Figure 56.14. The LC3K chip supports the ANSI/CEA-709 protocol, BACnet, and various IP-based protocols all within a single device and all at the same time [8]. This is especially important in today's converging application domains that formerly have been isolated installations. Modern systems implement cross-domain functions that require gateways or true multiprotocol devices that expose control data into other technologies or provide multitechnology interfaces.

Safety and redundancy are emerging topics in CEA-709 networks. Redundant network topologies offer protection against single failures of cable (e.g., cable break of an FT-10 two-wire installation) and failure of routers (twin-router concept). Products such as the L-IP Redundant enable building network infrastructure that is robust against those single failures and provide an alarming mechanism to notify facility management about failures. This marks one step into the direction of functional safety. Another development is the EU research project SafetyLon. SafetyLon nodes can coexist on the network with regular nodes and embed their control network data into regular CEA-709 frames. That has the advantage of using existing network infrastructure components. The embedded SafetyLon protocol has a much lower residual error probability. In addition, the SafetyLon hardware consists of two tightly coupled CPUs in one device, which monitor each other, so that SIL-3-compliant applications can be built with CEA-709.

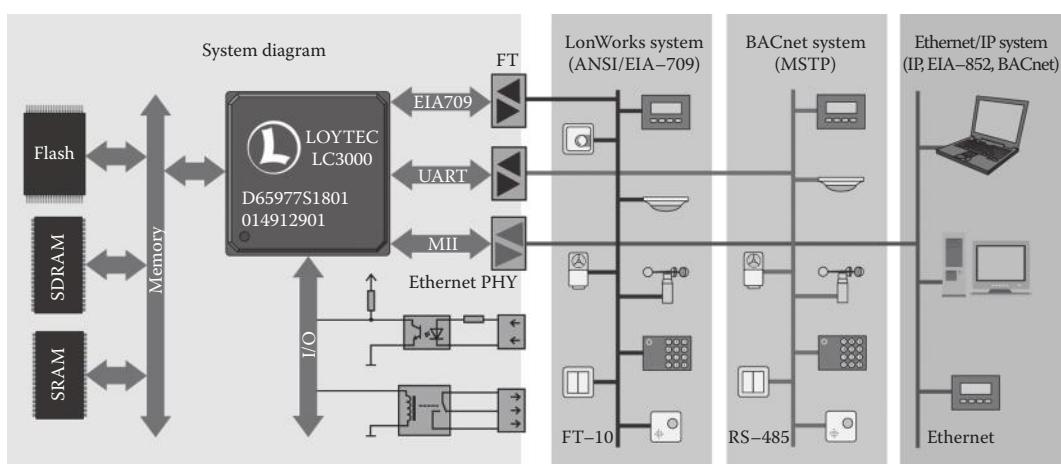

FIGURE 56.14 Multiprotocol processors can support different fieldbus protocols.

## 57.1 BACnet as a Standard

---

BACnet (Building automation and control networks), as the name implies, is a communication protocol specifically designed for the purpose of building automation. Since the committee SSPC 135 within the ASHRAE (American Society of Heating, Refrigerating and Air-Conditioning Engineers) started the specification activities in 1987, BACnet was continuously maintained and extended. Right after the first publication in 1995, BACnet became ANSI (American National Standards Institute) standard and has meanwhile become part of the ISO-Norm 16484 (part 5, BACnet Standard, and part 6, Conformance Testing Standard).

## 57.2 BACnet: The Idea of an Open Standard

---

The basic idea of BACnet is interoperability between systems of different vendors. In the 1980s, mainly proprietary systems have been sold, and connecting devices from different vendors always required a programmer to develop an interface between two proprietary systems and communication protocols. If a third, or fourth, vendor entered the project, those installations became a nightmare for the facility manager.

Mike H. Newman, responsible for the facility management at Cornell University, started the initiative to specify a communication protocol designed for building automation, later called BACnet.

Meanwhile, many companies changed the communication of their building automation components from proprietary communication to BACnet. Using BACnet in projects does not mean that always multivendor systems must be installed. Today, it may easily happen that BACnet is used by a single company in a project to communicate between devices of the same product family. BACnet, like other open communication protocols, is about to replace proprietary systems and proprietary communication more and more.

## 57.3 Basic Idea of BACnet: Interoperability!

---

The basic idea of BACnet is that vendors following the BACnet standard will be able to exchange data on an interoperable basis. As we will see later in this book, BACnet does not stop at the data-exchange level. BACnet specifies highly sophisticated functionality like file access, alarming, scheduling, trend logging, and remote device management.

## 57.4 BACnet Organizations

---

The main organization driving BACnet is ASHRAE with their working group SSPC135 maintaining the standard. ASHRAE as the head organization publishes the standard and addenda. SSPC135 over the years has become an international committee with working group members from all over the world.

The ISO organization maintains BACnet as an ISO standard in the international norms ISO 16484-5 and 6.

Several interest groups worldwide promote the BACnet technology; the largest is the BACnet Interest Group Europe ([www.big-eu.org](http://www.big-eu.org)).

Last but not least, BACnet International ([www.bacnetinternational.org](http://www.bacnetinternational.org)) represents North American vendors (formerly the BACnet Manufacturers Association) and end users (formerly the BACnet Interest Group North America).

## 57.5 Three Major Parts of BACnet

Like other communication protocols, BACnet specifies three major parts:

1. The network media (so-called data-link layer)
2. Objects to transport the building automation data
3. Services to transport the data between BACnet devices

### 57.5.1 Network Media (BACnet Data-Link Layer)

BACnet uses a 4-layer collapsed architecture. According to the ISO/OSI (International Organization for Standardization/Open Systems Interconnection) model, layers 1, 2, 3, and 7 are specified by BACnet (layers 4–6 are not required and so omitted) (Figure 57.1).

The network layer 3 provides routing between the different physical media. The most commonly used data-link layers are *BACnet*/Internet Protocol (*IP*) (IPv4 for now, but IPv6 is already specified as well) and master–slave/token passing (*MS/TP*, a layer 2 protocol based upon EIA-485 serial networks specifically designed for BACnet). While BACnet/IP is mainly used for automation stations (programmable direct digital control (DDC) controllers or programmable logic controllers (PLCs)) and operator management stations, devices based on EIA-485 are likely intelligent field devices like variable frequency drives, valves, pumps, VAV boxes, and room controllers.

Point-to-point connections using the BACnet PTP (point-to-point) protocol may connect different BACnet subnetworks using public phone lines. In the times of the Internet, modem connections likely disappear though.

### 57.5.2 BACnet Object Model

BACnet uses a decentralized approach to store all information related to the physical or virtual data points. Compared to classical systems where only the present value was requested and all information was added in the management station, BACnet objects provide all information related to the data point in the device processing the data.

As of today, BACnet specifies a total of more than 50 different object types. Object types include analog, binary and multistate input, output, and values. Additionally, primitive value objects represent simple data. In addition to the basic types, objects to represent more specific functionality like load control, structured views, groups, commands, accumulators and pulse converters, trend-log data, schedule programs, calendars, notification classes, lighting output and channels, and counter values are

specified in the standard as well. Devices like fire alarm systems may be represented through the life-safety objects. To represent access-control devices, BACnet specifies a total of seven objects. In a future revision of the standard, BACnet will support representation of elevators and escalators.

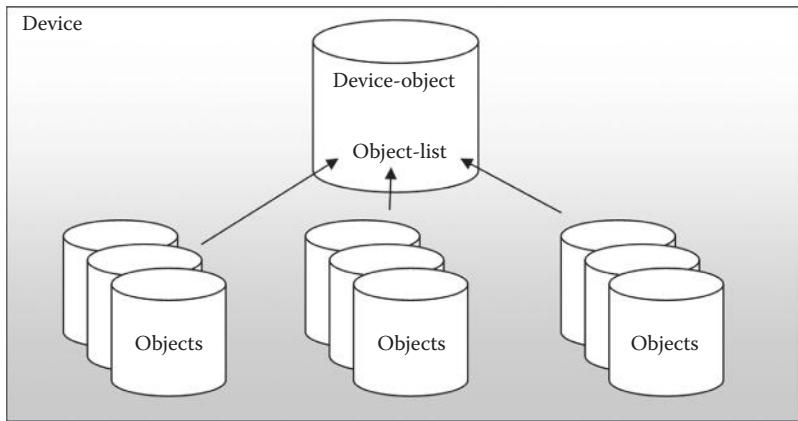

All objects consist of properties that represent the physical or virtual information. A property may be the present value, which is likely the most important information. The engineering unit, alarm limits, and even state text information are provided by the properties as well.

A minimum set of properties is specified as being required (conformance code = "R"), others may be implemented as an option ("O"), and few others are required to be writable ("W") (Table 57.1).

**FIGURE 57.2** BACnet objects addressed through the device object.

**FIGURE 57.3** Object ID.

BACnet objects are represented in the network through the device objects. Every device (and the device object) in the network shall be unique, and every object within the device shall be unique as well.

The object list in the device object presents a list of all objects contained in the device (Figure 57.2).

To uniquely address objects, BACnet uses a 32-bit identifier (ID), which consists of a 10-bit type and a 22-bit instance number. In addition, every object uses a unique object name to allow name resolution.

Object ID 4.194.303 is reserved as a wildcard and shall not be used to address a device (Figure 57.3).

### 57.5.3 BACnet Services

A total of 35 application services provide access to the devices, objects, and properties.

Another set of 20 services on layer 3 is used to exchange router information and provide security services for authentication.

The BACnet application layer specifies services for data access, alarming, scheduling, trend logging, and device and network management.

Basic services are read or write services that are likely the most commonly used services. More sophisticated services allow file transfer, device discovery in the network, read range from logging objects, and alarm or change-of-value notifications.

Device communication control or reinitialize device services as well as time synchronization, text-message transport, or even proprietary services (confirmed/unconfirmed private transfer) complement the basic services.

## 57.6 BACnet Network Numbers

Every BACnet subnetwork connected through routers is uniquely identified by a 16-bit BACnet network number known by the router devices. Routers connecting different BACnet data-link layers exchange their routing information on layer 3 using network layer messages like *Who-Is-Router-To-Network* and *I-Am-Router-To-Network* to discover the active routes in a BACnet internetwork.

## 57.7 Device Address Binding

Beyond the logical addressing using the device-object ID, BACnet physically addresses devices using the so-called BACnet MAC address. The BACnet MAC address consists of the BACnet network number in the range from 1 to 65.535 plus the MAC address assigned to the device (Table 57.2).

Virtual MAC addressing was introduced to allow larger addresses used in Zigbee or IPv6 but to keep the existing network layer header compatible (Table 57.3).

TABLE 57.2 MAC-Address Length

Data-Link Layer	MAC-Address Length
Ethernet	6 octets address of the network card
IPv4	4 octets IP address + 2 octets UDP port
MS/TP (EIA-485)	1 octet 0–127 master nodes, 0–254 slave nodes
Arcnet	1 octet
LonTalk	2–7 octets
Zigbee	3 octets virtual MAC address
IPv6	3 octets virtual MAC address
Virtual networks	Up to 6 octets

TABLE 57.3 Examples of BACnet MAC Addresses

135, 0xC0 A8 01 02 BA C0	Network # 135, address 192.168.1.2, port 47808, BACnet/IP
23, 0x7F	Network # 23, address 127, e.g., MS/TP

```

FIGURE 57.4 Device address binding (physical and logical address).

As an alternative to the optional manual configuration, the services *Who-Is* and *I-Am* provide a method for dynamic device binding. In response to a *Who-Is* request or spontaneously sent (e.g., at the time of the device start), the *I-Am* service provides the logical address (device ID) sent from the physical address. In case the telegram is forwarded by a router, the actual physical address is encoded in the network protocol data unit (NPDU) (network layer) (Figure 57.4).

Dynamic object binding is provided by the *Who-Has* and *I-Have* services. A device may ask for an object name on the network, and other devices containing such an object respond with the respective object ID.

The dynamic device and object binding services are typically used as broadcast messages in the network but may be transported using unicast addressing as well.

## 57.8 BACnet Transaction Handling

BACnet communication uses a client/server model to exchange requests and responses to or from BACnet devices. Telegrams may be unconfirmed, confirmed, and optionally segmented. Using confirmed services, the requestor may get the expected response (e.g., the current value of the requested property). In case of errors, the responder uses an appropriate error class/error code to inform about the error reason (e.g., *Property/Value\_out\_of\_range* or *Services/File\_Access\_denied*). Additionally, reject-messages and abort-messages demonstrate an invalid communication between two devices on the network.

## 57.9 Encoding BACnet Telegrams

BACnet messages are encoded into a sequence of tags and values according to the relevant ASN.1 definitions specified in the BACnet standard.

Figures 57.5 through 57.7 demonstrate the encoding of a typical request/response interaction between two devices. The capture was taken using the free open-source protocol analyzer *Wireshark* ([www.wireshark.org](http://www.wireshark.org)), which provides an excellent BACnet decoder. For demonstration purposes, the pictures show the telegrams starting on top of the UDP communication and do not show the IP part of the telegram.

Using the ASN.1 syntax, BACnet telegrams are relatively small and compact. The majority of requests in a BACnet network typically have a length between 64 and 256 octets.

## 57.10 BACnet Procedures

BACnet is specifically designed to fit the requirements of building automation installations. For this, BACnet specifies procedures for backing up or restoring a device configuration by interoperable services and introduces a schema to realize command prioritization.

### 57.10.1 Backup/Restore

A client station invokes a backup or restore by calling a special form of the device communication control service, and the device being backed up or restored provides information about the file objects to be written to or read from the device. The content of the files may still be proprietary (some use XML, others binary data—this is up to the vendor), but the general procedure is interoperable between vendors.

### 57.10.2 Command Prioritization

In building automation systems, multiple entities may control and manipulate an object. There may be a need to arbitrate between a schedule program, manual operation by the facility manager, and access from the service technician. For so-called commandable properties (like the present value of output-object types), BACnet uses a 16-level prioritization schema where 1 is the highest priority (Manual Life Safety) and 16 is the lowest. A default value is taken from the property “Relinquish\_Default” in case all slots in the priority array are uninitialized (the data-type “NULL” is used to identify an uninitialized entry = *no value* for either of the 16 slots).

### 57.10.3 Elapsed Active Time Counting/Status Change Counting

Binary objects may be implemented to support elapsed active time counting and/or change-of-state counting. This functionality is often used in building automation systems to detect necessary maintenance, for example, a filter change.

#### 57.10.4 Minimum On or Off Times

Binary objects may optionally support the tracking of minimum on or off times. For example, chiller devices or gas lamps require a certain on time before they may be shut down. Serious damage will likely appear if those devices are switched off earlier than specified.

The minimum time functionality provided on priority level 6 assures that only services with a higher priority (service technicians, manual life-safety operation, or critical-equipment control) will be allowed to invoke a shutdown.

### 57.11 Proprietary Extensions

---

Even though BACnet is designed to be an open and vendor-independent communication protocol, it allows vendors to extend an implementation by using proprietary communication.

Data-link layer may be implemented as long as it is routable (implementing the network layer 3) or may use tunneling. In the past, there have been implementations supporting, for instance, the token ring (by International Business Machines Corporation [IBM]) networks even though this network standard is not specified by BACnet.

Proprietary objects may be designed as long as they support the addressing schema and present at least the three properties: Object\_Identifier, Object\_Name, and Object\_Type. Standard objects may be enhanced by adding proprietary properties.

Services may be defined by using the confirmed private transfer/unconfirmed private transfer services.

### 57.12 BACnet Conformance

---

Devices may be specified from implementing a small sensor or actuator device up to freely programmable controller or workstation. This means the level of BACnet functionality implemented varies from device to device.

How to assure interoperability of different devices?

Every vendor may provide a BACnet protocol implementation conformance statement (PICS). This *BACnet data sheet* explains the level of BACnet functionality implemented in the device described in the PICS. The major parts of the PICS are again the supported network layers, the BACnet objects, and the BACnet services.

By comparing the PICS documents, interested parties like project designers may check if the supported functionality matches their requirements in a project and if the level of implementation matches those of other devices intended to interact with the device.

So-called BACnet Interoperability Building Blocks (BIBBs) represent functional blocks of services supported by the device. BIBB type "A" specifies the initiator of BACnet services, while "B" specifies the executor of that services.

---

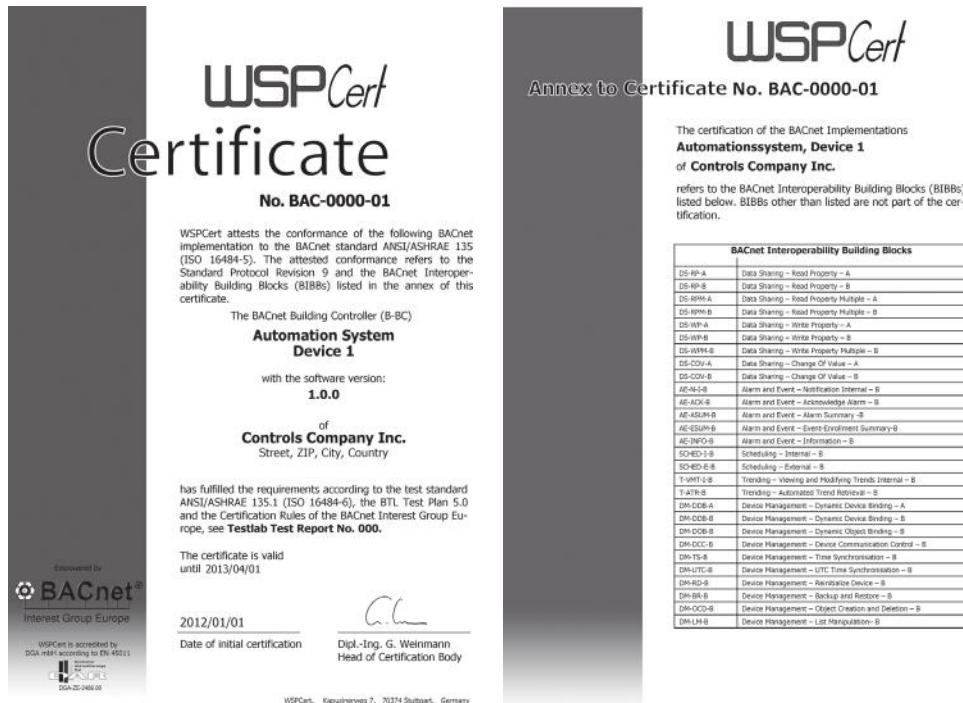

#### Example

A server device provides the capability to allow others to read data from the device:

- Data-Sharing-Read-Property-B (DS-RP-B) demonstrates support for the ReadProperty service executing requests from other devices.
- Data-Sharing-Read-Property-A (DS-RP-A) specifies the capability to initiate a Read Property request to retrieve data from a device providing Read Property B.

If for a specific interoperability area both A and B are present, the functional service specified by these BIBBs may be used to interact between the two.

---

(a) Cover page of certificate, general information about the device

(b) Details page of the certificate, details about the supported BACnet Interoperability Building Blocks (BIBBs)

FIGURE 57.8 Example of a (neutral) BACnet certificate.

## 57.13 BACnet Testing, Listing, and Certification

The organizations BACnet International and BACnet Interest Group Europe started a global testing, listing, and certification program for BACnet devices. A BACnet Testing Laboratories (BTL)-recognized laboratory is required to be accredited according to ISO 17025 and shall be recognized by the two organizations to perform BACnet testing services. A test report issued by the laboratory may be used to request a listing for the tested product at BACnet International. This includes allowance to use the BTL mark on the device as long as the implementation is kept conform to the standard.

Many project designers and end customers in Europe request a certificate, which is required to fulfill European requirements for energy performance. A test report from one of the recognized laboratories may be used to request a certificate for the device (Figure 57.8).

Round-robin tests performed by all recognized BTL worldwide assure that the laboratories come to comparable results.

The test specifications (BTL test package) are maintained by the international working group BTL-WG of the BACnet International. A major part of the testing specifications is documented in ISO 16484-6 (the testing standard).

## 57.14 Interoperability Workshops

Vendors wanting to test their implementations against implementations of other vendors may attend interoperability workshops (aka *BACnet Plugfests*). BACnet International and the BACnet Interest Group Europe organize these events (twice a year, in spring at different places in Europe and in fall in the United States) (Figure 57.9).

FIGURE 57.9 Picture taken at the European Plugfest 2013 in Berlin, Germany.

## 57.15 Character Sets

When BACnet started in 1995, the main focus was the North American target market. Character sets supporting special characters have only been rarely used at that time. Mainly the 7-bit character set ANSI X3.4 was used. Over the time, BACnet became an international standard, and BACnet was used in many countries where special characters are required.

To smoothly move from ANSI X3.4 to international character set support in BACnet, 135-2010 UTF-8 (encoded according to ISO 10646) replaced ANSI X3.4—considering this is still upward compatible because the first 7 bits are identical.

The long-term approach is to use international characters only.

## 57.16 Network Security

Designed as an open communication protocol, BACnet is mainly used openly in projects. Building automation components, as we know today, rarely uses network security yet, even though BACnet provides up-to-date network security features.

There is still space left for improving the network security of such components, especially when connecting them to the Internet. At the moment, the security (like in other communication protocols) in most building automation projects is to be provided by the network infrastructure due to missing security features.

In fire-, security-, or access-control systems, BACnet network security features are most likely implemented while this is often missing in building automation components.

## 57.17 BACnet/IP Specific Functionality

In IT networks, IP routers connect small subnetworks and most likely block broadcast messages. As we have seen earlier, BACnet uses broadcast messages, for instance, for dynamic device and object binding. In such networks where routers block broadcast messages, every subnetwork may be equipped with a

BBMD (BACnet Broadcast Management Device). A BBMD transports broadcast messages as forwarded unicast messages to other BBMDs, where the broadcast is then locally distributed.

A BACnet-FD (Foreign Device) is a single device connected to a BBMD without the capability to distribute the broadcast to the local subnet.

BBMD and FD support is often implemented in building automation controllers and workstations and may be activated where necessary.

Reserved BACnet/IP port: BACnet reserved the port Transmission Control Protocol (TCP) and UDP dec. 47808. This is easy to remember; in hexadecimal, the reserved port is 0xBAC0. BACnet may be transported through all other ports as well.

At the moment, BACnet only uses UDP (the User Datagram Protocol) and does not communicate through TCP (except for other services like a Hypertext Transfer Protocol [HTTP] browser interface). In the context of using the transport layer security, the use of TCP for BACnet is already under discussion in the BACnet community.

## 57.18 MS/TP Specific Functionality

MS/TP is a serial network where master nodes share the communication on the bus. Slave devices only respond to requests by master nodes. This means only master nodes may be used for dynamic device and object binding (a slave node is not allowed to initiate a telegram on the network).

To allow this feature for slave nodes as well, a master node may support the slave proxy functionality. On behalf of the recognized slaves, the master responds to *Who-Is* and *Who-Has* telegrams as a proxy.

## 57.19 Vendor IDs

Vendors of BACnet devices may request a unique vendor ID from ASHRAE. The growth of the number of vendor IDs assigned clearly shows the BACnet success over the past years (Figure 57.10).

As of February 19, 2014, a total of 726 vendors worldwide have requested and were assigned a vendor ID.

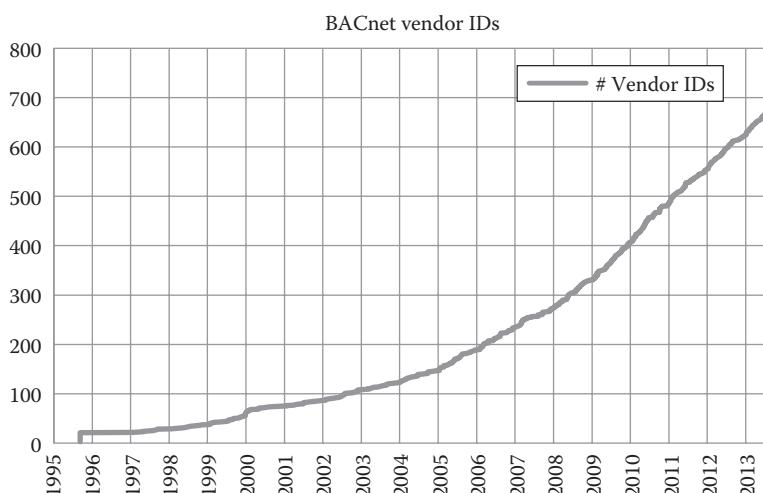

FIGURE 57.10 BACnet vendor ID growth.

## 57.20 BACnet Mappings

---

### 57.20.1 Web Services

To map information contained in objects, BACnet optionally provides web services including a RESTful version. The RESTful version of BACnet/WS extends the logical data model with more complete data modeling, subscriptions, semantic tagging for searching and filtering, and security based on Transport Layer Security (TLS) and OAuth2.0. Users will enjoy greater flexibility of data management as well as increased throughput.

### 57.20.2 KNX Mapping

The BACnet standard contains a chapter describing the mapping schema from KNX systems into BACnet.

Though gateway mappings in the future will likely not become part of the standard anymore, they are intended to complement the standard by providing separate specifications in addition to the BACnet standard.

### 57.20.3 OPC UA Mapping

An example of such a mapping profile was presented by the working group OLE for Process Control (OPC) UA (Unified Architecture) and BACnet. The OPC Foundation and BACnet Interest Group founded a working group specifying a mapping of BACnet data (objects and services) to OPC UA as a specification expected to be released by the end of 2013. A second specification will describe how to access OPC UA servers and present the data to BACnet.

## 57.21 Conclusion

---

Starting in the late-1980s, BACnet is still up-to-date and is being permanently maintained and extended to encompass new applications. The evolution of BACnet is quite similar to the evolution and success of the IPs. In the 1970s, it was hard to believe in establishing a worldwide video conference just by a simple mouse click (the computer mouse was not even invented at this time). Meanwhile, the IP has become the basis for nearly all computer communication worldwide.

BACnet is on the way to become the same success story as the worldwide standard to connect building automation, life safety, and access-control systems, including specific functions such as lighting control, elevator/escalator representation, or even load management.

International organizations such as BACnet International and the BACnet Interest Group Europe actively support marketing of BACnet, and last but not least, the number of customers requesting BACnet installation (and BACnet providing vendors) is on the rise.

To learn more about BACnet, explore [www.bacnet.org](http://www.bacnet.org).

### 58.1 Introduction

---

The home and building automation (HBA) is a technological effort aiming to make houses and buildings more controllable, autonomous, and comfortable. Recently, the demand for occupant comfort, flexibility in the management of a building equipment, and the need for efficient energy use have become pressing issues. Safety and comfort requirements, along with energy management, can be achieved only if an intelligent control and monitoring of devices and appliances is performed. A wide array of building automation and control systems (BACS) have been developed and implemented in commercial products, focused on improving energy consumption and minimizing waste and maintenance (reflecting guidelines of the European Standard EN 15232 [1]).

An HBA system requires a large deployment of sensors and actuators in order to detect contextual information and then transfer control data to all building components. A point-to-point interconnecting building device is impractical as it largely increases the amount of wires and consequently the installation complexity and the related costs. A solution is in a deployment of a system using a common, and shared, communication medium by exploiting a well-known and dependable protocol.

BACS are based on bus infrastructures identified as the most effective technological solution for interconnection and communication. Over time, a plethora of protocols have been progressively developed and deployed. Nowadays, the ISO/IEC 14543-3 EIB/KNX [2] (KNX in short) can be recognized as a de facto standard for HBA. It joins and enhances three legacy bus standards, namely, EIB, EHS, and BatiBUS. A KNX medium (twisted pair [TP], radio frequency [RF], power line [PL], or IP/Ethernet) can interconnect heterogeneous bus devices making them able to share and exchange information in a uniform way. Each KNX component can be seen as a sensor detecting an environmental situation (weather stations, lighting sensors, monitoring systems, presence sensors) or an actuator controlling building equipment such as blinds or shutters, safety appliances, energy managers, heating, ventilation and air-conditioning systems, and multimedia devices. Every appliance can be monitored, supervised, and signaled via a shared protocol without the need for single extra control centers.

## 58.2 KNX: Short History

---

In 1997, three main European associations were involved in the HBA centered around on-a-bus communication among devices and appliances. Batibus Club International (BCI) was a French no-profit association promoting the BatiBUS medium originally developed by Schneider Electric. European Home Systems Association (EWSA) was a Dutch association promoting the EHS technology, resulting from a European project aiming at the automatic configuration of bus-compatible white (washing machine, cooker) and brown goods (video, hi-fi). European Installation Bus Association (EIBA) was a Belgian cooperative society developing the EIB technology implemented by a consortium of manufacturers headed by Siemens. EIBA consisted of shareholders (*members*) and users of the technology (*licensees*). EIBA developed and marketed a configuration tool called EIB Tool Software.

The fusion of the mentioned associations resulted in a new association called *KNX Association*, and its final aim was the definition of a common standard for a new bus system named KNX [2]. It had the following basic features:

- A backward compatibility with EIB
- A simple and effective configuration method essentially based on a PC procedure exploiting ETS but also using central controllers, code wheels, and so on
- The possibility to include heating, ventilation, and air-conditioning (HVAC) systems among supported appliances
- The support for RF and IP media

The KNX standard was approved by the European Committee for Electrotechnical Standardization (CENELEC). In April 1999, the KNX Association was officially founded in Brussels by nine members. Currently, it groups over 340 members in 37 countries (March 2014), including companies that were previously not a member in any of the promoting associations.

In May 2002, the first version of the KNX specification was released among the KNX members starting the KNX Certification Scheme for Products. The intellectual property rights (IPR) clearance was effective from June 2003. As a result, all KNX members may use the KNX technology free of any patent claims of fellow members in KNX-certified products. In 2003, the national committees of CENELEC Technical Committee TC205 (*Home and Building Electronic Systems*) approved a subset of the KNX specification referred to as KNX media and KNX stack, making it a European Standard (as part of the EN 50090 bus family standard). In 2006, the same documentation was approved again by the European CEN for application in BACS. It is registered as EN 13321-1, series EN 50090. The KNX idea to tunnel and route KNX telegrams across IP networks (see later on for details), that is, the KNXnet/IP protocol, was also approved in 2006 by CEN as EN 13321-2, and finally, in the same year, the EN 50090 series achieved the international recognition as ISO/IEC 14543-3. In 2007, the Chinese translation of KNX specification reached the status of national standard as GB/T 20965.

Today, the KNX Association is responsible for all the activities related to the KNX system, and in particular, it oversees the following:

- The specification work conducted by the expert groups
- The technical hotline support to members
- The international standardization of novel features and characteristics but also the KNX certification by incoming organizations
- The logo protection
- The management of the training documentation
- The advertising and communication strategy (e.g., publication of the official association journal twice a year, diffusion of brochures, organization of biannual award for best KNX projects, presence at fairs)
- The management of national groups, that is, groups of member companies in a given country responsible for the local promotion of the KNX system
- The scientific partnership, that is, the involvement of universities, research centers, and technical institutes in scientific and educational initiatives as the annual organization of the KNX Scientific Conference
- The management of the partnership for trained and certified contractors

## 58.3 KNX System Specification

---

The KNX specification covers all technical elements of the standard, ranging from the low-level device details and certification rules to testing and application descriptions. In what follows, the fundamentals of the protocol will be outlined according to the KNX specification, version 2.0 [2]. Supported transmission media will be briefly surveyed and both meaning and function of protocol layers defined in the standard will be clarified. Then a description of the reference network architecture and the addressing features will be reported, followed by a section related to the integration of the KNX protocol with IP networks. Finally, details about application-level objects will be given.

### 58.3.1 Transmission Media

The KNX system offers the possibility for the manufacturers to choose between several transmission media, according to market requirements and specific habits. Moreover, it is also possible to combine them to build multimedia and multivendor network configurations.

The basic TP and PL communication media are accompanied by the RF support in order to make KNX networks flexible and adaptable to multiple application domains and installation situations. Some of the main features of supported media are presented in the following:

- TP TP1 is the basic medium inherited from the EIB protocol. It provides a solution for wired cabling, using a safety extralow-voltage (SELV) network and a supply system. KNX supports both TP1-64 and TP1-256 media, which differ in the number of connectable devices per physical segment (64 or 256). TP1-256 is backward compatible toward TP1-64. The TP1 transmission rate is 9600 bit/s with a character-oriented asynchronous data transfer mode and a half-duplex bidirectional communication. It also complies with the carrier sense multiple access with collision avoidance (CSMA/CA) protocol. All network topologies (e.g., line or star) may be used and mixed.
- PL PL110 is also inherited from the EIB protocol and enables communication over the main power supply network of a building. It is based on an asynchronous transmission of data packets and a half-duplex bidirectional communication. PL110 uses the central frequency of 110 kHz with a 1200 bit/s data rate; it complies with CSMA and the EN 50065-1 standard [3].
- RF enables a communication via radio in the 868.3 MHz band for short-range devices. It supports the frequency-shift keying, a maximum duty cycle of 1%, and a Manchester data encoding.

KNX allows integrated solutions for IP-enabled media like Ethernet IEEE 802.2 [4], Wireless LAN IEEE 802.11 [5], and FireWire IEEE 1394 [6] exploiting the KNXnet/IP protocol as explained in Section 58.3.5.

The KNX v1.1 specification also supported TP0 and PL132 media to ensure a fully backward compatibility with EHS and BatiBUS protocols. Those media are no longer available in the new KNX v2.0 protocol. The related documentation was phased out in the last specification and both TP0 and PL132 cannot be used in applications for the KNX certification.

### 58.3.2 Protocol Layers

The KNX protocol defines a seven-layer stack compliant with the ISO/OSI model [7]. On top of the physical layer, a common kernel model is shared by all devices of the KNX network. The reference structure is shown in Figure 58.1.

The *physical layer* is on top of the communication channel. It mainly consists of a logical unit, a medium attachment unit (MAU), and a medium interface (i.e., the connector). Each medium needs a dedicated MAU and a suitable logical unit. The MAU is used for encoding the logic signals to physical ones and vice versa. In the transmission mode, the logical unit serializes each data octet in a bit sequence; then, it frames the obtained data and transforms them in an asynchronous timed logical signal. In the receiving mode, the logical unit reverts the obtained signal in a data bit stream to be checked, rebuilt, and aggregated into several data octets. Finally, the medium-independent sublayer of the logical unit transfers the received octets to the upper layer.

A general *data link layer*, built above each data link layer specific for each medium, provides a high-level medium access and logical link control. It also takes responsibility for the transmission of single KNX frames between two or more devices on the same subnetwork.

During transmission, the data link layer (i) builds a complete frame starting from data coming from the network layer, (ii) gains access to the medium according to the particular access policy in use, and (iii) transmits the frame to the data link layer of each peer entity, using the services of the physical layer.

When receiving, the data link layer (i) detects possible corruptions in the frame, (ii) transfers the frame to the upper layers, and (iii) issues positive or negative acknowledgments back to the transmitting data link layer entity.

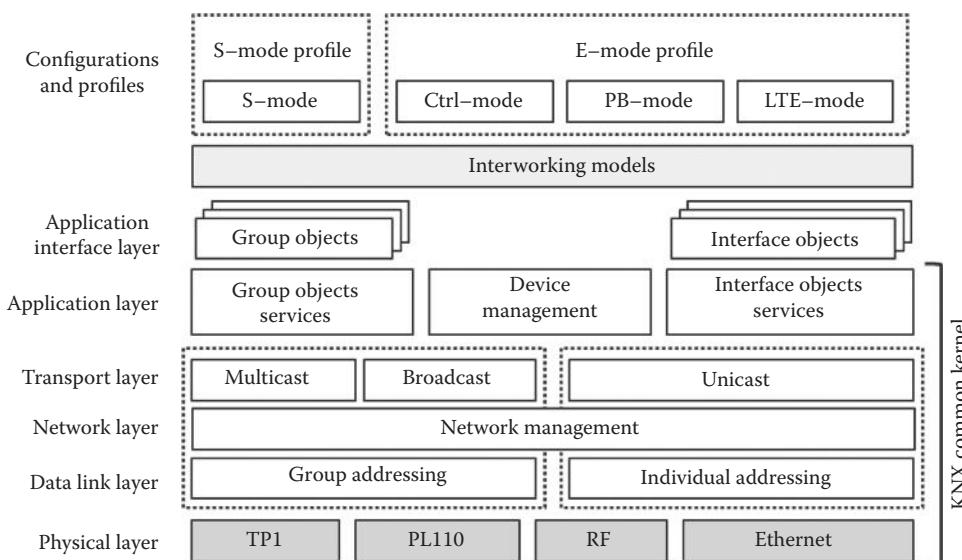

FIGURE 58.1 KNX protocol stack and reference architecture.

The data link layer also manages unicast, multicast, and broadcast communication options and device addressing, as described in Section 58.3.3.

The *network layer* takes care of managing communications across KNX subnetworks. Hence, its role is relevant mainly to the nodes with routing functionalities. As an example, this layer provides a segment-wise acknowledged telegram and controls the hop count of a frame.

The *transport layer* enables the data transmission over different communication modes. Five kinds of communication are defined in the standard:

1. Point-to-multipoint, connectionless (multicast)
2. Point-to-domain, connectionless (broadcast)
3. Point-to-all-points, connectionless (system broadcast)
4. Point-to-point, connectionless (unicast)
5. Point-to-point, connection oriented (unicast)

Finally, *session* and *presentation layers* are unused, while the *application layer* offers several services to application processes. Each different service depends on the communication used at the transport layer. Usually services related to point-to-point communication and broadcast mainly refer to network applications, whereas services related to multicast are used for runtime operations.

Each layer interacts with the layers above and below. In the first case, it acts as a *service provider* making available a set of resources for the above *service user* layer. The interface between both layers defines how the available services can be accessed, how the service parameters must be handled, and how the response should be interpreted. The communication between the interfaces of layers N and N – 1 occurs via *service data units* (SDUs). The KNX specification also defines a rule set for the peer layer communication between devices. In this case, *protocol data units* (PDUs) are used, which mainly consist of user data and layer-specific *protocol control information* (PCI). In addition, four different communication primitives are defined: *request* (req), *indication* (ind), *confirmation* (con), and *response* (res). Services do not always need to use all the primitives and can be classified as in what follows:

- *Locally confirmed services*: require a request, an indication, and a confirmation. In this case, a request and the corresponding PDU are generated at layer N and passed to the lower layers until transmission on the physical medium. On the receiver side, the peer layer N is activated with an indication, the received PDU is progressively decoded, and the data are passed to the layers above. The sender layer N receives a confirmation from the local layer N – 1 indicating if the request has been processed correctly.
- *Confirmed services*: consist of a request, an indication, and a confirmation, but for these services, the peer remote layer generates an acknowledgment after receiving the indication. At the sender side, the received acknowledgment is passed to the local layer N as a confirmation.
- *Answered services*: always need a request, an indication, a response, and a confirmation. As shown in Figure 58.2, the response is generated by the remote service provider as a novel request issued toward the sender that will be received at the local layer N as a confirmation.

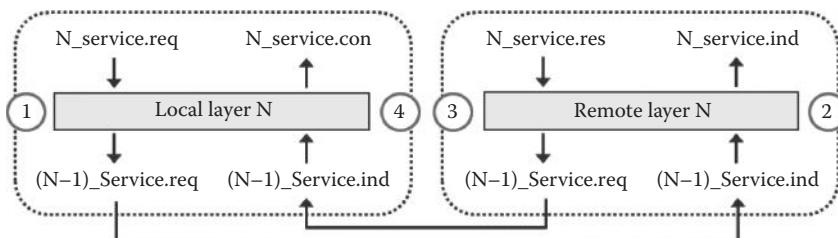

FIGURE 58.2 Answered service communication.

### 58.3.3 Network Architecture and Addressing Scheme

The KNX specification enables to build a fully distributed network, which accommodates up to 65,536 devices by exploiting a 16-bit individual address (IA) space. The logical topology or *subnetwork* structure allows 256 devices for each *line*. As shown in Figure 58.3, lines may be grouped together with a *main line* into an *area*. An overall domain is formed by 15 areas coupled with a *backbone line*. Not considering the addresses reserved for area and line couplers, up to 61,455 end devices may be joined by a KNX network.\*

All components, that is, couplers or end devices, are unambiguously identified and subsequently accessed via their IA, reflecting the *area.line.device* topology. As shown in Figure 58.4, the IA consists of a two-octet value: the first byte defines the subnetwork address (SNA), while the last octet specifies the device address (DA) unique within a subnetwork. Routers always have a DA 0; other devices may have a DA with values ranging from 1 to 255. Devices needing no IA for operations may use a default IA ( $FF_h$ ). This default IA shall consist of the DA for unregistered devices and the medium-dependent default SNA.

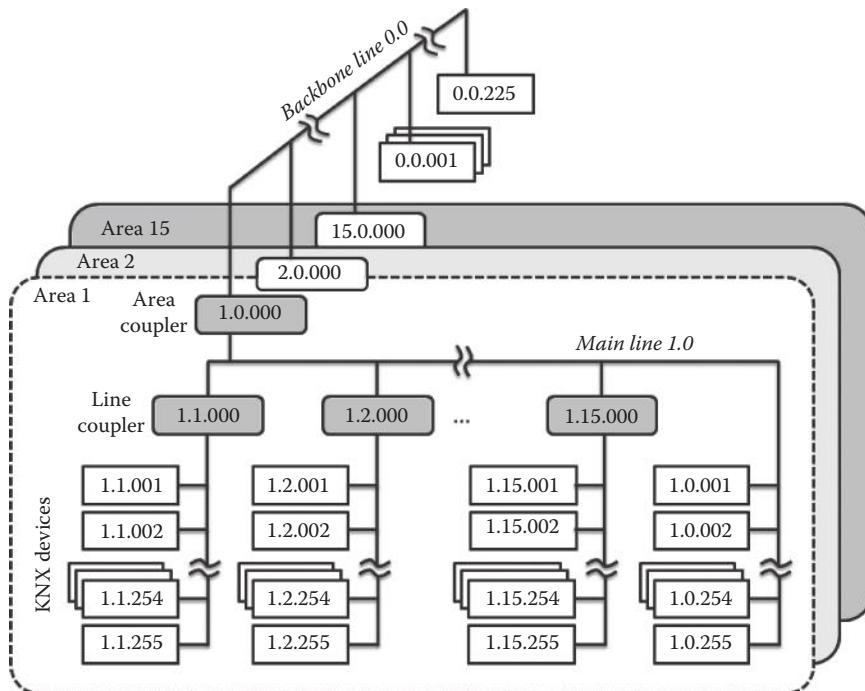

FIGURE 58.3 KNX network architecture.

Individual address								Group address															
Octet 0				Octet 1				Octet 0				Octet 1

Area address		Line address		Device address												Main group		Middle group		Little Group			
Subnetwork address																							

FIGURE 58.4 KNX IA and GA.

\* Installation and product guidelines should be taken into account. Possible restrictions may depend on implementation (e.g., medium, transceiver types, power supply capacity) and environmental factors (e.g., electromagnetic noise).

KNX also supports a full multicast addressing mainly used for the runtime communication, considerably reducing bandwidth requirements. The protocol provides a 16-bit group address (GA) space usually used in the format *main.middle.little* device groups as shown in Figure 58.4. Sometimes GA space can also be adopted with a two-level (main group/subgroup) or with a freely defined structure. The GA does not need to be unique. In fact, a device can also have more than one GA. Furthermore, each device is associated by default to the group zero (0/0/0) as request frames addressed to GA 0 will be sent in broadcast. In this way, a device is associated to the sender addresses with the aim of sharing its datapoints (i.e., group communication objects), thus creating a kind of network-wide variables. This communication model will be better described in Section 58.3.6. Since the protocol makes a 16-bit address space available to such GAs, it is possible to define about  $2^{16}$  shared variables each with any number of local device instances.

In addition to IAs and GAs, if the network is built on an open medium (e.g., PL\*) shared by devices of different subnetworks, a domain address (DoA) is required as an identifier to logically separate each subnetwork.

### 58.3.4 Frame Structure

Figure 58.5 shows the structure of a generic KNX frame built above the data link layer.

The control field is used to detect possible *repeated* frames (the flag R identifies a first transmission or already-sent frames), to indicate the frame *priority* (the flag PP can assume a *system*, *high*, *normal*, or *low* value), and to establish the frame *type* (standard or extended<sup>†</sup>). Then, there is an individual *source address*, in terms of area.line.device, and an individual or group *destination address* (respectively, in case of unicast or multicast communication). The destination address type is determined by a special field (*address type* [AT]) defined at the beginning of the network protocol data unit (NPDU). In addition to AT, the NPDU includes the *network layer protocol control information* (NPCI) field, a hop counter decreased by routers to avoid looping messages. NPCI ensures a frame can appear in seven physical network segments at most in order to avoid packets circulating endlessly due to errors in the network setup; when it becomes zero, the frame is silently discarded. The *length* field specifies the size of the NPDU, while the *transport layer protocol control information* (TPCI) field controls the communication at transport layer level, for example, specifying service codes and sequence numbers used to build up and maintain a point-to-point connection. Analogously, the *application layer protocol control information* (APCI) field contains the application layer service codes. The APCI has a length of 4 or 10 bits, depending on the specific service code. According to both addressing scheme and APCI, the standard frame can carry up to 14 *data* octets. Finally, the frame is closed by the *checksum*, which contains an odd horizontal parity value calculated over all preceding octets. This ensures data consistency and reliable transmissions.

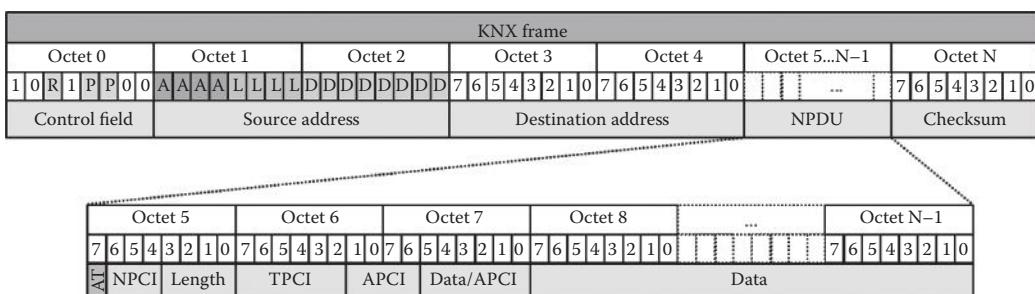

FIGURE 58.5 KNX frame structure.

\* On a PL, nearby domains are logically separated with a 16-bit DoA.

<sup>†</sup> Despite the standard frame ensuring a direct backward compatibility toward the EIB protocol, an extended frame (identified by a “00” code in the two most significant bits) can be used to store up to 248 bytes of data.

### 58.3.5 Integration with IP Networks

The KNX specification describes a compact and flexible Internet protocol (IP) tunneling protocol, named *KNXnet/IP*, used to carry a KNX frame over an IP stretch enabling the communication of KNX implementations (e.g., KNXnet/IP devices) on the top of IP networks. In this way, several KNX subnetworks can be connected via an IP line acting as a fast (if compared to classic KNX transmission speeds) backbone. A widespread deployment of IP-based networks and applications is an opportunity to expand building control and communication beyond a local KNX network. Further benefits include (i) fast interface between local area network (LAN)-based and KNX-based systems and (ii) remote configuration and usage of home and building devices.

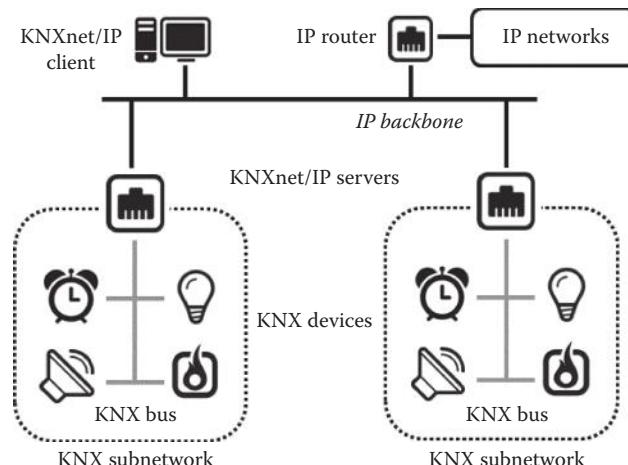

A KNXnet/IP system contains at least the following elements:

- A KNX subnetwork (e.g., KNX-TP1, KNX-RF, KNX-PL110) with up to 255 end devices.
- A KNX-to-IP network connection device (named *KNXnet/IP server*). It is a special device having a physical access to a KNX network also implementing the KNXnet/IP protocol to communicate with *clients* or other servers on an IP network channel. A server is by design also a KNX node with a unique IA.
- Additional software for remote operations hosted by client workstations (e.g., configuration tools, building management systems or browsers).

Figure 58.6 shows a basic network configuration where a KNXnet/IP client is connected to multiple KNX subnetworks via IP. The KNXnet/IP client may access one or more KNXnet/IP servers at a time.

When a KNXnet/IP server communicates with another server via IP, it acts also as a KNXnet/IP *router* exploiting a multicast one-to-many communication, where KNX data are simultaneously transferred from a sender device to one or more receivers over IP. A router can also replace a line or an area coupler and directly connect main lines and backbones, allowing the usage of existing cabling (e.g., Ethernet) and ensuring faster transmission times between KNX subnets.

A KNXnet/IP frame is a PDU moving along a non-KNX network. It contains a header, similar to the header of an IP data packet, and a body, if present. As shown in Figure 58.7, the header maintains information about the protocol version, the header length,\* the total length of the packet, and the

**FIGURE 58.6** KNXnet/IP network example.

\* Although the length of the header is always fixed, it is possible that it changes with newer versions of the protocol. The header length can be used as an index into the KNXnet/IP frame data to find the beginning of the KNXnet/IP body.

KNXnet/IP header												KNXnet/IP body												
7	6	5	4	3	2	1	0	7	6	5	4	3	2	1	0	7	6	5	4	3	2	1	0	
Header length								Protocol version																
Services type identifier												Structure length												Communication channel ID
Total length												Sequence counter												Service type specific
Connection type specific header (variable length, optional)												cEMI frame (variable length)												

**FIGURE 58.7** KNXnet/IP frame structure.

KNXnet/IP service-type identifier. KNXnet/IP services include, but are not limited to, information regarding device discovery, connection management, and KNX data transfer.

The header may be followed by a KNXnet/IP body of variable length, depending on a specific service. An example of a body is shown in Figure 58.7. It embeds the data into a basic KNX frame and starts with data fields that specify additional general information about the connection. Those fields compose the *connection header* whose appearance is fixed, varying only the content according to the connection options. Finally, the IP body includes the so-called cEMI frame consisting of the TP1 telegram structure, excluding the checksum field that is not used in IP communications as the error detection is done by IP.

### 58.3.6 Application Models

The *application interface layer*, as shown in Figure 58.1, is an additional abstraction level between the application layer and the user applications. It eases the communication tasks by offering a common interface that abstracts from many application layer details. It allows to expose shared objects and use them as local variables. In addition, it takes care of handling network management calls. The application interface layer contains the following objects:

- *Group objects* (GOs): they are accessible via application layer services in the multicast communication mode and provide a communication schema named *shared variable model*. GOs may also refer to one or more interface objects (IOs).
- IOs: they are accessible via application layer services in unicast and broadcast communication modes and are used for a *client/server* interaction. IOs are also classified as *system* IOs (e.g., device objects), relevant to network and device management, and *application* IOs, defined by the user applications.

The GO structure is shown in Figure 58.8. It consists of three parts: *description*, *value*, and *communication flags*. The GO description must at least include the GO *type* and the *transmission priority* (urgent, normal, or low). Optionally, the *config flags* include static information about the GO (e.g., read, write,

Interface Object		Group Object	
Object		Group Object description	
Property i-th		Value length/type	
Property description		Priority	
Property_id (1 octet, unsigned8)		Config Flag	
Property Datatype (1 octet, unsigned8)		Group Object value	
max_nr_of_elem (4 bit exponent + unsigned 12)		Group Object communication flags	
Access (1 octet, unsigned8)			
Property value			
Array(0)=current nr. of elem (unsigned 16/32)			
Array (1 ... max_nr_of_elem) = value			
....			

**FIGURE 58.8** Interface and GO structure.

or update permissions). According to the GO type, the size of the value field can vary from 1 bit to 14 bytes. Finally, the communication flags show the *state* of a GO. The following states are enabled: *update*, *read\_request*, *write\_request*, *transmitting*, *ok*, and *error*.

The IOs are instances of the general structure shown in Figure 58.8. Starting from this common schema, two object types are derived: *full* IOs and *reduced* IOs.

Full IOs exactly comply with the data structure reported in Figure 58.8. They consist of a number of *object properties* composed by a *description* and a *value* field. In turn, a property description consists of the following fields:

- Property index: it is unique for each IO. The first property has index 0, and further ones are numbered with subsequent values without gaps.
- Property IDentifier (PID): this value is encoded in the *property\_id* field and is usually used to identify the specific IO.
- Property data type (PDT): it describes the most appropriate data type for the IO property.
- Maximum number of elements: the value of a property is always an array, so this field specifies the array size: suitable indexes range from 1 to *max\_nr\_of\_elem*, while the element at position 0 contains the current number of valid array elements. This value is automatically updated if an element is written beyond the current last element but always within the maximum allowed number of entries.
- Read/write access levels: this attribute indicates the access level needed to read or write the property value.

Moreover, each property description has also a *write-enable flag* that specifies whether the property value can be written or not. In particular, the property with *property\_id* equals to 1, and *index* 0 is named *IO type* (PID\_OBJECT\_TYPE) and contains the description of the IO itself. This property is mandatory for every IO.

As opposed to full IOs, reduced IOs only support a subset of the common IO structure. A property description is only composed of the *property\_id*, while the property value can be a single value or an array.

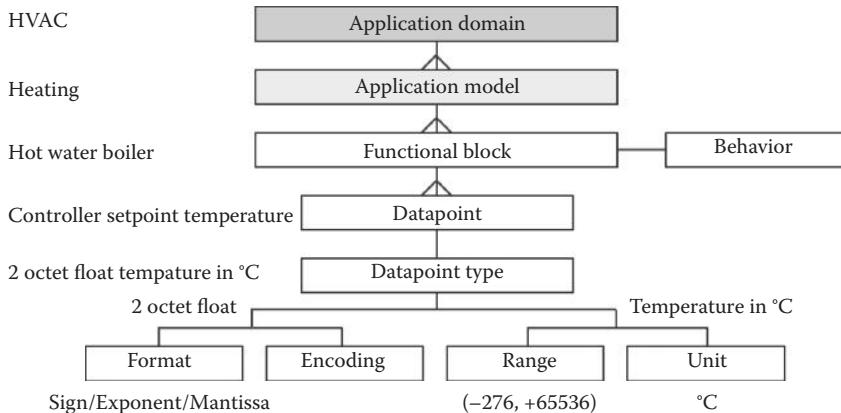

## 58.4 Development and Configuration

---

On the top of KNX networks, several distributed applications can be built, enabling a tight interaction among different devices. This section summarizes some distinctive characteristics of the KNX standard at the application level. Modeling guidelines and interworking models are resumed to give a sketch of a comprehensive and multidomain building communication system. Hence, device configuration modes and development tools are detailed and a basic configuration example of a KNX system is provided.

### 58.4.1 Interworking Specification

The interworking between devices enables different and multivendor products to send and receive datagrams and properly understand and react on them without additional equipments (e.g., gateways). In this, devices from different manufacturers can interwork in a given application domain as well as across different applications. Interworking is a relevant feature of the KNX standard: products not complying with this specification cannot obtain the KNX certification. In order to establish this communication model, a set of requirements was defined, grouped into the *application interworking specification* (AIS). AIS is defined for various application domains and can be further extended by submitting proposals to the KNX Association. In fact, the application *modeling* (the process of analyzing and defining the model for each application) is the responsibility of various application *specification groups* of the KNX Association.

**FIGURE 58.9** Example of an application modeling.

As presented in Figure 58.9, each application domain encompasses one or more applications, each of them defined in terms of *functional blocks* (FBs) that communicate with each other. In this way, a *distributed* application is composed of a number of shared FBs implemented in various devices in the network. In addition, a manufacturer may group one or more FBs, of the same, or of different applications, to build a device. An FB is described by the product developer as an object with well-defined behaviors; it uses one or more *datapoints* for interchanging information, which represent inputs, outputs, parameters, or diagnostic data. A datapoint can be seen as a generic interface used to set, receive, or transmit data during the runtime operations.

The information exchanged through datapoints is associated to a *DataPoint Type* (DPT) featuring the data in terms of the following:

- *Format*: describes both sequence and length of the fields composing the DPT.
- *Encoding*: indicates how the data are encoded according to the given format.
- *Range*: describes the limitation of the values that may be encoded in the DPT. This may be a minimum/maximum indication or an explicit list of values.
- *Unit*: specifies the measurement unit of the carried information.

The DPTs are identified by a 16-bit *main number* separated by a dot from a 16-bit *subnumber* (e.g., 7.002). The main number identifies DPTs with the same format and encoding, whereas the subnumber indicates a specific dimension (different range and/or unit).

### 58.4.2 Network Configuration

The KNX standard allows each manufacturer to select the most proper configuration mode according to different markets, local habits, level of training needed, or application environment. In particular, four different *configuration modes* are available:

1. *System (S) mode* (S-mode): the most versatile and multiusage configuration process. The overall application setup is done by a configuration master. Usually, it is done by means of a set of PC-based tools from the engineering tool software (ETS) family, developed by the KNX Association. With the aid of the ETS tools, described in Section 58.4.3, it is possible to configure the S-mode compliant devices and set them into operation.
2. *Controller (Ctrl) mode*: an external controller device is required to set the IAs and the needed parameters in the devices. The controller is not needed after configuration but may also have additional runtime functionalities.

3. *Push-button* (PB) mode: no tools or external devices (e.g., PC, controller, ETS) are needed for the configuration and linking management. Devices themselves are able to set up the links and assign the IAs and GAs. However, to enable the development and manufacturing of low-cost products, the software overhead for the mandatory configuration and link procedures must be as small as possible.
4. *Logical tag extended* (LTE) mode: mainly designed to cover the specific needs of an easy configuration for HVAC, which needs a longer set of structured data. These data are exchanged via IOs using the extended frame of the KNX protocol. Also in this case, a simple device configuration is possible without using PC tools, manufacturer specification, or the knowledge of device object structures and GAs.

In order to facilitate the network design and configuration and to simplify the device certification, previous configuration modes have been grouped in so-called configuration profiles. The KNX profiles have been designed to cover all needs and habits of the KNX Association community. In particular, a profile specifies how a device should be configured and the minimal device requirements for this process. The KNX specification defines the following profiles:

- *S-mode* profiles: suitable for end devices and system components (i.e., couplers) supporting the S-mode configuration. This type of setting procedure is adopted by well-trained KNX installers in order to realize advanced building control functions enabled via ETS tool using specific product databases provided by device manufacturers. Each database includes all supported functionalities and ETS is also used to set the device parameters as required by the installation. S-mode offers the highest degree of flexibility for building KNX networks.
- *Easy mode (E-mode)* profiles: adopted for devices supporting the controller, PB, and LTE configuration modes. The installation of such components can be also made by users with a basic KNX experience. E-mode compatible products offer limited features compared to S-mode. In this case, components are usually preprogrammed and loaded with a default set of parameters. With a simple configuration software, the device parameter settings and communication links can be partially reconfigured.

### 58.4.3 Development Tools

In order to plan, design, and commission a KNX installation, a software tool is required to assist designers and electrical installers. For that reason, a manufacturer-independent configuration tool named ETS was developed by the KNX Association. ETS4 [8] is the current release of the tool, replacing since 2010 ETS3. During its development, the user interface has been basically kept very similar to the one of previous releases. On the other hand, both functions and operating philosophy of the ETS4 user interface has been completely reengineered, making them simplified compared to ETS3. ETS is available in three different versions:

1. *Professional*: which enables the development of KNX installations of any size without limits in terms of maximum number of addresses, devices, or project.
2. *Light*: maintaining the same functions as the professional version; this version only allows projects with up to 20 devices. It is intended for training centers and their customers.
3. *Demo*: this version is free of charge but can be used to design networks with three devices at most.

In case of a user with a single PC-dependent license, there is also a *supplementary* version available as an additional license for the full professional version running on a second PC, for example, a laptop

used at the construction side. In addition to ETS, the KNX Association also offers the following software tools or libraries:

- *iETS server*: it is a software interface between KNX and IP adopted for connecting iETS clients (such as ETS4) to the KNX network. With iETS, the installer can access the system remotely by means of ETS, enabling remote programming or diagnostics via IP.
- *Falcon Driver Library*: it is a high-performance DCOM (Microsoft Distributed Component Object Model) based library enabling Windows-based PC KNX bus access. Falcon offers an API for sending and receiving telegrams across the KNX network and supports the communication through RS232, USB, and Ethernet.
- *Interworking test tool (EITT)*: this tool is used by developers and test laboratories for testing, troubleshooting, and monitoring the interworking and system stack compliance of KNX products. EITT is also a powerful tool for the analysis and simulation of the KNX network protocol.

Also KNX members offer a number of KNX-related software packages. In particular, several ETS plug-in modules (named ETS Apps) have been developed, allowing to extend the functionality of ETS, for example, for graphical project designs, data exchange, or efficient project engineering. In fact, any new, or existing, software can be adapted to the ETS App interface and integrated in ETS4 by using the related SDK (software development kit), without the need to completely recompile the software.

Finally, noteworthy is a Java library for KNX access, named *Calimero* [9], offering a clean and lean interface and allowing free client access to KNX networks and a basic KNX server functionality. It is designed to operate also on resource-constrained systems (i.e., mobile and embedded devices) as it requires low memory and CPU. In addition, it is fully compliant with the popular Java Standard Edition (J2SE) environment commonly deployed on home computers, and this ensures a widespread employment of it. It is important to notice that Calimero is an open-source software distributed according to the GNU GPL license.

#### 58.4.4 Basic Installation

In order to illustrate the process of setup and configuration of a KNX network, a simple example is considered. The project design of a KNX system initially does not differ from a typical electrical project. In the preliminary stages, several aspects must be clarified by the planner such as the type and use of the installation, the building system components to use, and their functions and special requirements stipulated by customers. Subsequently, product databases may be downloaded and imported in ETS4 in order to create a new project. Then the network configuration must be defined, for example, building structure, bus topology, and GA levels. The project engineer selects the KNX devices with the corresponding application to insert into the network, assigns them an IA, and sets the parameters according to the requested features. As an example, a network is proposed consisting of a simple TP line (1.1) connected to a backbone IP line (0.0), having six devices connected: a KNX/IP router, a switch and a dimmer actuator, a KNX module with PBs, a shutter controller, and a weather station for outdoor environments (Figure 58.10). The IAs are automatically assigned by ETS4 in ascending order in the respective current line; however, they can be modified at any time by the user. The selected devices are displayed in the tree structure on the left panel. Double-clicking on each device, the properties panel will be displayed containing further information about the product and the parameters that can be modified by the installer. Moreover, selecting a device in the tree view, the related GOs will be shown below it. In the proposed configuration, the weather station (1.1.5) exposes several GOs associated to rain, temperature, wind force, and brightness sensors.

Afterward, GAs can be created. In each project, a different pattern for the definition of GAs can be used. For example, for three-level addresses, the main group can specify floors or rooms, the middle group can specify the functional domains (e.g., switching, dimming), and the subgroup can define

articulated operations named scenarios (e.g., turn on/off a specific lamp in the house or open/close the living room according to the weather conditions). The GAs are listed in the GA window, shown in Figure 58.11. In order to ensure that sensor and actuator devices may know which GOs should communicate with each other to realize a given function, the objects of each device are assigned to the GAs.\* In the example, the rain sensor of the weather station is connected to the shutter controller by means of the same GA, so when rain is detected, the shutters will be automatically closed.

In this way, all devices are fully configured and the final network topology is defined. In conclusion, the network configuration should be checked before the commissioning of the project. Obviously, it is also possible to deviate from this sequence according to the project requirements. Some steps can be omitted for smaller projects, whereas additional steps could be needed in larger ones.

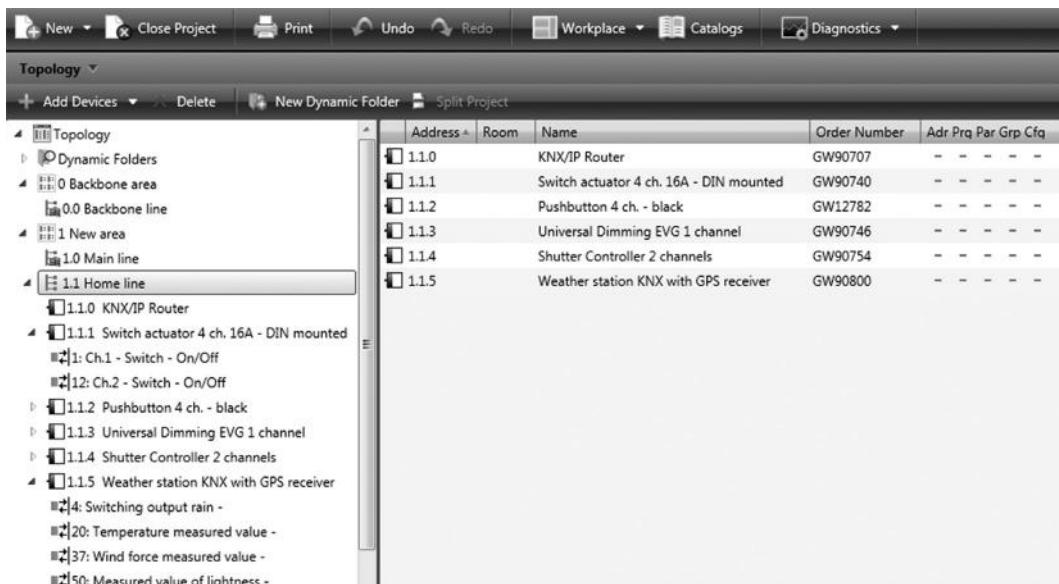

FIGURE 58.10 ETS4 topology panel.

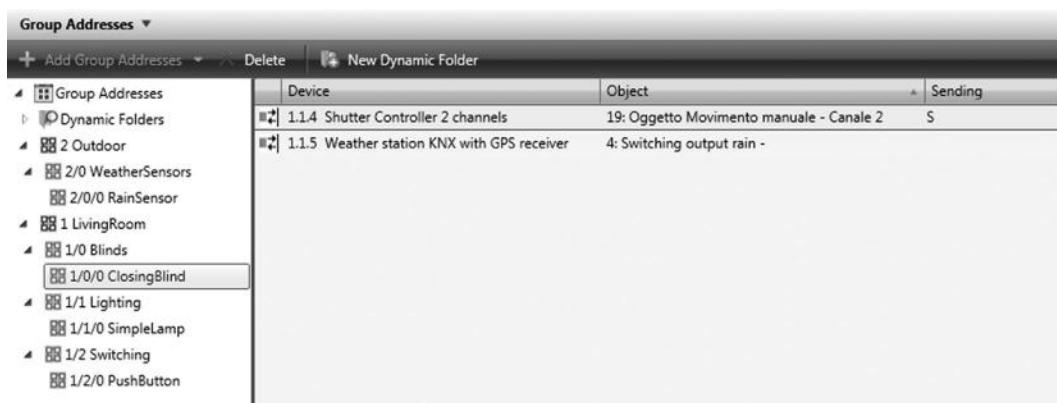

FIGURE 58.11 ETS4 GA panel.

\* In a group address, it is only possible to create connections between group objects of the same type (e.g., 1 bit, 1 byte). The group address receives the type of the group objects with the first assignment.

## 58.5 Research Perspectives

---

The basic goal of HBA [10] is to improve people's comfort, increase safety and security, reduce energy consumption, and minimize the overall ecological footprint. For this purpose, a more effective management and coordination of building appliances and subsystems is required. In particular, *ambient intelligence* (AmI) [11] proposes a multidisciplinary research vision aiming at defining frameworks and techniques for smart environments, where people are surrounded by intelligent and unobtrusive microcomponents, capable of being sensitive and responsive, recognizing user profiles, and self-adapting behavior accordingly. Devices should communicate and interact autonomously, without the need for direct user intervention, also making decisions based on multiple factors, including contextual information, sensory data patterns, and user presence and preferences. They should be coordinated by intelligent systems acting as supervisors.

At present, EIB/KNX and other current standard HBA systems and technologies are still far from that vision, because they cannot grant such flexibility. As seen in previous sections, they can essentially set static functions and features configured during system setup; explicit interaction with the user is required for all except the most elementary cases. Context-aware dynamic information management and decision-making about users, devices, and services are not yet supported. In order to enable intelligent HBA infrastructures, capable to adapt and control building appliances autonomously, smart environments have to be conceived according to results coming from pervasive and mobile computing, artificial intelligence theory, and agent-based software design [12]. Consequently, AmI research is closely related to studies for effective discovery and coordination in volatile and resource-constrained scenarios.

In latest years, four major research directions were pursued to improve intelligence, effectiveness, and usability of HBA systems:

1. Improve user interaction with HBA systems.
  2. Integrate different HBA technologies in a common application layer.
  3. Model HBA frameworks as *multiagent systems* (MASS).
  4. Use semantic technologies to enhance information management and decision-making capabilities.
1. Several approaches proposed more advanced and user-friendly device management with respect to current standard technologies. Nevertheless, they still rely only on direct command-based user interaction, through local or network-based interfaces. In particular, [13] introduced a method to control home devices either locally (through an AJAX web application) or remotely (via web services), allowing the user to issue either direct commands to devices or set routines that should be executed periodically. The proposal is not tied to any particular HBA standard. The framework devised in [14] is focused on a low-cost ZigBee home automation system. Also in this case, devices can be controlled directly by the home occupants by means of a ZigBee remote control, while the ZigBee *Home Automation* network exposes a *home gateway* on the Internet, so that the home can also be controlled remotely from a PC.
  2. Due to the diversity of HBA technologies, a further aspect widely investigated is the integration of different HBA technologies in a common application layer. Some works achieved limited integration of domotic subnetworks based on different technologies by means of custom gateways. For example, in [15], a gateway is proposed between KNX and ZigBee *Home Automation* application profile. Several proposals [16,17] adopt web service technologies as unified abstraction layer to integrate various communication protocols and mobile service discovery via UDDI (Universal Description, Discovery, and Integration) and UPnP (Universal Plug and Play) in automation contexts. Standard web service description and orchestration languages based on XML are adopted, only allowing syntactic match between users' needs and service/resource attributes, lacking semantic characterization. As a consequence, the improvement in service discovery and composition capabilities with respect to basic HBA protocols is not so relevant to justify the increased architectural complexity.

3. HBA is characterized by the lack of hard real-time constraints and the need for high flexibility and reconfiguration capabilities. As pointed out in [18], such kinds of environments are very well suited to be modeled by means of MASs. Agents can meaningfully represent entities (devices), contexts (rooms, floors), or people, emphasizing interaction capabilities such as communication, concurrency, cooperation, coordination, conflict resolution, and negotiation. Many proposals exist in literature for structuring HBA systems through MAS: while early research focused on agent-based direct control of home appliances, recent MAS proposals concern high-level, complete HBA control systems. In order to achieve greater interoperability, a major goal is to provide a unified view of the home environment and a flexible application model. Particularly, in [19], a platform was proposed to allow an easy integration of multimodal user interfaces in heterogeneous device networks. The MAS was implemented using Java Agent Development Framework (JADE) SDK, whereas IP-based UPnP was exploited as discovery protocol. In [20], a service-oriented smart home architecture was defined, where each component is designed as an agent. When the home is about to perform a service for a user, it compares service requirements with the environment situation to find out rooms whose status and resources are ready for service activation. Similarly, in [21], the use of BDI (belief–desire–intention) agents was proposed to automate service composition tasks, providing transparency from the user standpoint. In latest years, the MAS model has been proposed also for *BEMS* (*Building Energy Management Systems*), due to the growing interest in *smart grid* technologies [22] and in reducing energy consumption via *demand-side management* [23]. An agent-based BEMS typically supports *active load management* techniques [10] and exploits *smart metering* via energy-efficient network protocols [24]. Such approaches *put the human back into the loop* [23], that is, they take into account user profiles and requests in order to maximize both energy efficiency and customer satisfaction. In [25], a *multiagent comfort and energy system* was designed for management and control of both building systems and occupants. It coordinates appliances and users, for example, suggesting changes to occupant meeting schedules. A MAS for energy management in commercial buildings was proposed also in [26]: Agents communicate and negotiate with human occupants to save energy; optimal policies are generated considering multiple criteria—for example, energy cost and personal comfort—as well as uncertainty in occupant preferences.
4. Knowledge representation and reasoning (KRR) technologies allow greater generality and more flexible reuse of models concerning the aforementioned approaches, because *ontologies* provide a conceptual framework to express and share formal and structured descriptions of services and appliances, while general-purpose reasoning procedures can be used for semantic-based service composition in different HBA scenarios. *DomoML* [27] was the first specific proposal of a building automation ontology suite. Reinisch et al. [28] acknowledged the relevance of semantic-enhanced approaches upon current HBA standards, for cost and efficiency motivations; they introduced a theoretical ontology-based framework for the integration of different HBA protocols at the application level. In [21], the use of intelligent agents was proposed to automate service composition tasks. Nevertheless, a very elementary ontology was derived from attribute-based service descriptions in UPnP and Bluetooth service discovery protocols. As a consequence, the approach lacked adequate expressiveness of user, device, and service profiles. In [29], the first self-contained prototype was presented including a reasoning module able to manage and coordinate heterogeneous devices by means of logic rules processing. Classical rule-based inferences are not enough in heterogeneous and dynamic AmI contexts. In order to execute a rule, conditions it imposes must be fully matched by the current system state. Unfortunately, experience shows that full matches are quite unlikely in real-life scenarios, where objects, subjects, and events are featured by different heterogeneous descriptions, often partially in conflict among them. Semantic-based matchmaking frameworks as the one in [30], which exploit standard and nonstandard inference services and allow to match requests and resources based on the meaning of their descriptions (also providing classification and

logic-based ranking), are more effective. Beyond obviously good matches, such as *exact* or *full* ones, they enable so-called *potential* or *intersection* matches (i.e., those matches where requests and supplied resources have something in common and no conflicting characteristics) and *partial* or *disjoint* matches (i.e., cases where requests and available services have some conflicting features) that can also be considered useful in scenarios when nothing better exists. In [31], the exploitation of KRR technologies, originally conceived for the semantic web, was proposed to overcome restrictions of common HBA systems. An enhancement to ISO/IEC 14543-3 EIB/KNX standard has been devised in a knowledge-based and context-aware computing framework for building automation, supporting semantic annotation of both user profiles (i.e., needs, moods, features) and device capabilities (i.e., services/resources of home appliances). The integration of a semantic microlayer within the KNX protocol stack enabled novel resource discovery and decision support features in HBA making them autonomous and decentralized while preserving full backward compatibility. Machine-understandable metadata characterize both home environment and user profiles and preferences. Thanks to the integration of semantics at the application layer, each object/subject joining a KNX network can describe itself and advertise managed services/resources. By means of a matchmaking process—based on inference procedures in [30]—the most suitable available services/functions for adapting the ambient to a given request or event can be easily detected. Annotations are expressed in ontological formalisms derived from description logics (DLs) [32]: DIG [33], a more compact equivalent of OWL-DL (OWL Web Ontology Language, W3C Recommendation, February 10, 2004, <http://www.w3.org/TR/owlfeatures/>), has been adopted in particular. In order to reduce the size of semantic annotations referred to both device features and user profiles, an encoding algorithm [34] is exploited for efficiently compacting XML-based ontological languages, generating a header and a body for each encoded document. Furthermore, an IO named *generic profile of the device* (GPD) has been introduced to describe general device features, for example, type, manufacturer, or model. A single GPD is associated to a given device. A *specific profile of the device* (SPD) object has been also defined to describe individual functionalities and operating modes of a device. Multiple SPDs can be associated to the same device, one for each different service/function it exposes. Furthermore, a user-transparent and device-driven interaction is enabled as opposed to current static configuration approaches. At network layer, KNX support for IP communication through KNXnet/IP is leveraged to extend the management of building control beyond the local bus, while IEEE 802.11 and Bluetooth are exploited for wireless communication with the user. The work was extended in [35] with a multiagent approach exploiting semantic-based resource discovery and orchestration in HBA. The semantic annotation of user profiles and device capabilities is used to (1) determine the most suitable home services/functions according to implicit and explicit user needs and (2) allow device-driven interaction for autonomous adaptation of the environment to context modification.

### 59.1 Introduction

For home and building automation technologies, two main trends can be observed. The first one arises from the ongoing demand to improve the energy efficiency of buildings. The reason for this trend can be found in decades of continuous increase in the energy prices. Commercial buildings being responsible for about 23% of the worldwide energy consumption are the focus of research on how energy efficiency can be improved and how renewable energy sources can be used to cover the energy demands of buildings [1]. An extensive introduction of the building automation systems in commercial buildings and urban complexes is going to be decisive in achieving the ambitious energy goals that have been set by several regional and national governmental institutions.

Taking into account the continuous urbanization taking place in the Asia-Pacific region that grows annually by the size of a 2 million metropolitan city, the role of buildings including energy consumption is getting increasingly important. In order to improve the energy efficiency of buildings, the various domains of building automation covering heating, ventilation, air-conditioning, cooling, as well as lighting and shading need to cooperate in a cross-domain manner. The use of heterogeneous technologies that are either tailored to specific domains or only addressing one specific layer of a multi-tiered automation system is a commonplace in contemporary buildings (cf. Chapter 55).

Furthermore, building automation services need to be integrated into processes that have a larger scope than the local building. The interaction with smart grids to enable demand-side management or load shifting requires an integration that spans multiple buildings or even a complete region. This requires services that manage multiple buildings and sites and perform real-time data analysis that demands extensive computational resources. Here, cloud computing can provide the required flexibility.

This leads to the second main trend that can be found in building automation systems, which is the adoption of the Internet Protocol (IP) and wireless technologies. Although IP technology is well established at the management tier of automation systems, it is still not treated as a first-class citizen at the

lower levels of the automation hierarchy. State-of-the-art technologies like KNX or LonWorks, as introduced in Chapter 55, use IP to tunnel their custom network layer, transport layer, and application layer technologies. IP technologies ease the integration with enterprise and IT systems and can be one enabler for crossing the borders between different automation technologies. However, the adoption of IP technologies does not necessarily require integration with the Internet, although this would allow to fully exploit the potential of having IP in place. Rather, IP can also be operated in closed networks, still leaving the main advantage of using mature technologies with several implementations and tools available.

Also, building management can benefit from the cloud computing. For instance, building maintenance can be taken care of by services and tools offered by a third party. Software-as-a-Service (SaaS) paradigms allow to move the energy management, operation, and maintenance of buildings from the site to a third party.

Although IP technologies ease the integration of the heterogeneous and distributed systems, several issues arise if these technologies are to be used in the field and automation tier. The main problems are the strong resource demands on memory, processing power, and bandwidth that have to be addressed. Nevertheless, the ease of integration through the use of IP technologies for commercial buildings is the main driver for the successful deployment of smart grids and smart cities. Moreover, the application of IP within residential homes is beneficial for coupling together home appliances, consumer electronics, and home energy management systems, ending up in the vision of *smart living*.

Future trends in building automation also tackle the wide-spanning area of the *Internet of Things* (IoT) [2] that was initially characterized by radio-frequency identification (RFID) components and the use of the Electronic Product Code (EPC) to identify physical objects. Since IP does not provide much more than a network protocol to interconnect different devices, the layers mentioned earlier are of utmost importance for building *interoperable* systems feasible for the IoT. The use of Web-based communication is a possible way to provide these upper protocol layers. The term *Web of Things* [3] can be used to summarize these efforts that aim at building interoperable systems that adhere to the paradigms that made the World Wide Web successful.

## 59.2 Application Areas

---

In the future, home and building automation systems will be used in novel application areas that require the interconnection of heterogeneous infrastructures and information systems. Selected areas and their related communication protocols are summarized in the following sections.

### 59.2.1 Smart Living

The term smart living generally denotes a residential dwelling where automation technologies take over the automatic control of (at least) parts of the building services in so-called smart homes. It shares its roots with building automation but, nowadays, needs to be regarded as an independent application and research area [4]. In order to differentiate it from *classic* building automation, it is often referred to as home automation or sometimes domotics. Apart from the core automation domains heating, ventilation, and air-conditioning (HVAC) and lighting/shading, a smart home also interconnects household appliances as well as consumer electronics and entertainment devices. Moreover, security and safety components as well as equipment from the *Ambient Assisted Living (AAL)* domain (e.g., sensors monitoring human vital parameters) are integrated into a smart home system.

Research is related to ongoing work in the area of ambient intelligence where systems should be sensitive and responsive to people and the environment. Thereby, computing devices are fully integrated into the physical environment and people are using them without being aware of it. This concept is denoted by the term ubiquitous computing. Unfortunately, smart homes are often regarded as a future vision that seems to be practically available only in some decades of time. In practice, however, the technological and scientific foundations have long been developed so that a realization of smart

homes is already practically feasible today. Still, the commercial breakthrough of the smart home is awaited. However, several demonstration projects addressing smart homes have already been put into practice (e.g., PlaceLab, Georgia Tech Broadband Institute Residential Laboratory, T-Com Haus, inHouse, iHomeLab). They illustrate different approaches regarding the concept of a smart home and also provide valuable information on the challenges as well as lessons-learned information for the design of upcoming smart home concepts and systems. Nevertheless, in many cases, existing prototypes cannot fully achieve their promises. Their systems are too complex for a practical use, seldom tailored to pervasive energy savings and often not characterized by real smartness. A smart home system needs to combine many different parts (e.g., novel control strategies that operate on additional knowledge and are executed autonomously) so that the overall solution is more than the mere sum of its parts [5].

For this reason, a smart home cannot be seen as an isolated instance that solely interacts with its inhabitants. It incorporates with different kinds of devices and adopts information of its environment in order to realize *smart* applications. Thereby, the IoT allows direct communication among devices (i.e., *machines*). Since machines do not have the human capabilities of interpreting different types of information, precise foundations of semantics have to be assigned to the objects, their data, and functionalities. Ontology frameworks that emerged within recent research work of the IoT community (e.g., SensorML, DomoML, or the ThinkHome ontology) can provide such a foundation.

### 59.2.2 Smart Metering and Energy Management

Smart meter devices are the cornerstone of energy management systems and a new energy grid (see next section) and will facilitate the power authorities to deal with real-time power consumption values. Here, the integration of devices resting upon the (Wireless) M-Bus standard defined in EN 13757 will play an important role [6]. However, also other approaches have to be considered, like the International Electrotechnical Commission (IEC) 62056 where the Device Language Message Specification (DLMS) and the Companion Specification for Energy Metering (COSEM) have been published. Also, Smart Message Language (SML) provides a communication protocol for meter devices [7]. Within the North American market, ANSI C12.18 gained importance [8].

While energy management systems usually aimed at optimizing the local energy consumption of a building, in the context of upcoming smart grids, also the external systems are in the scope of this optimization. For commercial buildings, substantial energy savings can be achieved. In the residential area, there is still a strong potential for the deployment of home energy management systems. The key criteria are the global optimization of the user comfort and energy efficiency. For this optimization task, information technology is exploited to host and execute control algorithms that are capable of multi-criteria optimizations. Minimum inputs for these algorithms are goals of the global level, the states of the underlying automation systems and their devices, as well as information on the state of the environment. This mandatory context awareness as well as the optional availability of predictions of future environmental states (e.g., anticipated user presence, predicted weather situations) are foundations of energy management systems. Decisive to the widespread deployment of energy management systems will be the rising costs of energy, regulations mandating energy efficiency, flexible pricing schemes, and the need to protect the environment. Still, strong inhibitors are the low savings potential for residential customers, high initial investment costs, the heterogeneity of technologies, and the risk aversion of utilities that are reluctant to go beyond pilot deployments [9]. Security and privacy issues may impede the deployment.

The IoT and the use of interoperable protocols can be a solution to the problem of the underlying heterogeneous smart (metering) technologies. The key application for the home and building automation systems will be energy demand response, which is the adjustment of the electric energy consumption in reaction to external parameters such as pricing signals or the grid stability. For large commercial customers, demand response is well-known and might even be performed in a manual way. However, specialized protocols for the automated demand response such as Open Automated Demand Response

(OpenADR) [10] make the deployment more attractive. Thus, a strong market growth is to be expected within the next decade for demand response in the commercial and residential area.

### 59.2.3 Smart Grids and Smart Cities

The term smart grids reflects the need of adding information and communication technologies to the existing power grid in order to successfully integrate variable renewable energy sources and to increase the grid's stability. Traditional power grids adhere to the paradigm that the production has to follow the consumption pattern of energy consumers. Usually, centralized power plants generate the energy that is distributed to the consumer using high-voltage transmission grids as well as medium- and low-voltage distribution grids. Renewable energy sources like photovoltaic and wind power or small- and middle-sized power decentralized power plants lead to revolutionary challenges put on the electricity grid.

Within smart grids, the IEC 61850 [11] standard series will play an important role in the design and operation of power utility automation systems. While the focus of Edition 1 of the standard series concentrated on substation automation systems, most parts of the standard series have been revised in Edition 2 where the focus was broadened to interconnected power utility automation systems in general. IEC 61850 defines technical aspects of automation system communication, such as communication protocols and data objects, but also aspects on the design, configuration, and operation of power utility automation systems are specified. The standard covers communication within a substation, as well as inter-substation communication and communication between control centers and substations. IEC 61850 uses a two-layered approach for defining its communication services: Abstract Communication Service Interface (ACSI) defines all communication services in an object-oriented way, while several Specific Communication Service Mappings (SCSMs) map these abstract services to specific communication protocols. Examples for SCSMs are the client/server protocol Manufacturing Messaging Specification (MMS) and the real-time protocols Generic Object Oriented Substation Events (GOOSE) and Sampled Measured Values (SMV).

Buildings are a fertile ground for the demand-side management. The heating and cooling processes deployed in commercial buildings can be used to provide the required flexibility with respect to the energy consumption. Distributed generation puts stress on the distribution grid since the energy flow can now be reversed. Smart meters and advanced metering infrastructure allow to measure in real-time energy consumption and the power quality. They also allow data analysis and provide feedback to the customers on energy consumption. The IoT and its protocols can be one of the key factors in the successful development and deployment of smart grids [12]. Smart cities—focused on the urbanized area—have a similar goal: to increase the energy efficiency and optimize the usage of renewable energy sources. In addition to the built environment and the energy grid, they include other systems and infrastructures, like telecommunications, traffic management, or the health, safety, and security domains [13].

## 59.3 Future Internet of Things Protocols

---

There are several technologies and protocols that are relevant for the future IoT that will interconnect billions of devices equipped with embedded intelligence or so-called smart objects. One way to realize such an infrastructure is to reuse the IP that proofed its reliability and scalability. Besides the use of *plain* IP, Web technologies like *Web services* revolutionized the landscape of information systems and their integration within different applications. Thus, the following subsections provide an overview on these protocols.

### 59.3.1 6LoWPAN

6LoWPAN is an acronym for IPv6 over Low-power Wireless Personal Area Networks (LoWPAN). Its idea is to deploy IP even on most constrained devices with limits regarding memory and processing power

that are wirelessly connected with narrow bandwidth and strong requirements on energy efficiency [14]. 6LoWPAN is not a fully specified protocol stack; it is more a framework of standards that respectively address several issues of the IoT. As stated in [15], several problems have to be covered if IPv6 is used on top of Institute of Electrical and Electronics Engineers (IEEE) 802.15.4 networks [45]:

- IPv6 connectivity: IPv6 connectivity is desirable since LoWPANs will consist of many devices. IPv6 provides the required address space and mechanisms for stateless auto-configuration. Furthermore, this allows the seamless connectivity with the Internet.
- Topologies: Different topologies needed to be supported within a LoWPAN including mesh and star topologies. Routing may happen within the local mesh at the link layer or on a more global level between different IP networks that may use other links. Furthermore, the resource demand of routing protocols needs to be taken into account with a routing overhead balanced regarding topology changes and power conservation.
- Packet size: IPv6 demands the maximum transmission unit (MTU) to be at least 1280 bytes. However, for IEEE 802.15.4, the standard packet size is 127 bytes. Further, the overhead of the header and, optionally, some link layer security features needed to be considered, leaving a remaining size of about 81 bytes that can be used by upper layers (i.e., payload).

IPv6 provides its own fragmentation mechanism for packets that are larger than the minimum MTU of 1280 bytes but relies on the link layer to be able to transmit packets of this size. 6LoWPAN takes care of this gap and provides a fragmentation format. Packets are split into multiple fragments that can be reassembled at the receiving node. It defines an 11-bit `datagram_size` field that is transmitted in every fragment and reflects the size of the resulting reassembled packet limited to 2047 bytes. A 16-bit `datagram_tag` field together with the sender and destination link layer addresses and datagram size is used to distinguish between different packets. An 8-bit `datagram_offset` provides the position of the fragment within the packet and counts in 8 byte units.

In general, protocols should be designed to allow the exchange of data or control commands within one IEEE 802.15.4 frame to have optimal efficiency.

- Limited configuration and management: Since devices within a LoWPAN have limited resources, usually no user interfaces are available. Thus, it is required to keep the configuration and management efforts as low as possible. In the best case, the protocols support bootstrap mechanisms without manual configuration.
- Service discovery: Services delivered by nodes within a LoWPAN need to be discoverable. Efficient protocols are required to supply such mechanisms to advertise and to search for certain service types. 6LoWPAN by itself does not define any service discovery protocol. However, for basic node discovery mechanisms, IPv6 neighbor discovery or the optimized version for LoWPANs can be used [16]. For application-layer-specific discovery requests, the multicast domain name system (mDNS) or the domain name system service discovery protocol can be applied.
- Security: Security is a key issue if sensors and actuators are connected wirelessly by IP. Using IEEE 802.15.4 as link layer option, basic security is provided by using the Advanced Encryption Standard (AES). However, within 6LoWPAN, no details on the key exchange and key management are specified. The bootstrapping process is not described and applications need to take care about it by themselves.

6LoWPAN provides an adaption layer that makes it possible to use IPv6 on constrained links. A popular link for 6LoWPAN is, for example, provided by IEEE 802.15.4 networks. Additionally, efficient mechanisms for multicast and unicast routing are specified, which facilitate a special neighbor discovery approach.

### 59.3.1.1 6LoWPAN Frame Format

Since IEEE 802.15.4 does not define a field for identifying the carried protocol, 6LoWPAN provides this information by using a dispatch byte as first element of the protocol header. The first 2 bits are used to

group the possible dispatch values. All values starting with 00 are reserved for non-6LoWPAN frames. A value of 01 identifies a regular 6LoWPAN frame, 10 is used to identify a mesh header, and 11 is taken for fragmentation headers.

For addressing within 6LoWPAN, a relation between link layer addresses and network layer addresses is necessary. While IEEE 802.15.4 uses either 64-bit EUI addresses or 16-bit short addresses in conjunction with 16-bit network IDs, 6LoWPAN uses IPv6 addresses. Furthermore, a lot of information sent within the IPv6 header is redundant for subsequent packets that are exchanged between two communicating nodes. The full address space of 128 bits of IPv6 is usually not needed if the packets are transmitted within a 6LoWPAN network. 6LoWPAN addresses this issue by using header compression. Header compression can work either *end-to-end* or *hop-by-hop*. Since the full IP header is required to perform routing, *hop-by-hop* is a more attractive solution since it keeps the header compression as a local aspect between two adjacent nodes. 6LoWPAN aims at *stateless* compression, which has the advantage of not having any synchronization problem and simple algorithms. The 16-byte IPv6 addresses are the largest part in the IPv6 header and 6LoWPAN provides a stateless header compression for link-local addresses. Unfortunately, for compressing global routable addresses, at least some state information is required; therefore, a context-based header compression is also available.

### 59.3.1.2 Stateless Header Compression

For stateless header compression, two schemes are specified in [17]. HC1 is used to compress IPv6 headers and HC2 to narrow down User Datagram Protocol (UDP) headers.

The HC1 header contains two flags identifying the source address encoding (SAE) and the destination address encoding (DAE). These flags contain one bit for the prefix and the interface identifier (ID). If set to 0, the according part of the address is transmitted; if set to 1, the part is elided. For the prefix, this can only be used for link-local addresses (FE80::/64). For the interface ID, a 1 indicates that the address can be derived from the layer 2 address. Another optimization is to leave away the traffic class and the flow label of the IPv6 header that are in the most common cases set to 0. The C flag indicates this optimization. The two-bit next header (NH) flag is used to indicate the NH, which is limited to the options sent in-line, UDP, Internet Control Message Protocol (ICMP), or Transmission Control Protocol (TCP). The final bit indicates whether an HC2 header is present or not. Furthermore, the IPv6 version flag is never transmitted since this is an obvious IP version 6 in 6LoWPAN. The payload length can be inferred and is also elided.

The HC2 header only consists of three-bit flags. The first two bits are used to control the compression of the source and destination port that is limited to the port range between 61616 and 61631 (0xFFBn), which allows to compress the port to use only the last four bits. The L flag is most of the time set and allows to leave away the payload length that can be derived.

The best case header compression that can be achieved with stateless compression is impressive, although it has to be mentioned that this case only applies for rather limited local interaction scenarios.

### 59.3.1.3 Stateful Header Compression

In cases where globally distributed nodes need to communicate, the optimizations used in stateless header compression cannot be applied. In order to allow compression of the global routable address information, some kind of *context* is required, that is, kept synchronized between a sender and receiver. The stateful header compression as stated in [17] is again separated into two compression headers. The first is the compression for the IP header (LOWPAN\_IPHC) and the second one is the optional compression scheme for the NH (LOWPAN\_NHC).

### 59.3.1.4 Neighbor Discovery

IPv6 neighbor discovery (IPv6 ND) is an essential part of IPv6 as it provides the functionality to discover routers, perform address resolution, and duplicate address detection and redirection of messages. It can be further used to discover the used network prefix and other parameters. IPv6 ND relies on IPv6 links that

usually form a single broadcast domain and provide transitivity. In this context, transitivity means that if node A can communicate using the link with node B and node B can communicate to node C, then node A can also communicate with node C using the link without any intermediaries. 6LoWPANs provide a nontransitive link; therefore, the IPv6 ND—heavily using multicasting—does not operate well, as the realization of efficient multicasting is still an ongoing topic. To address this issue, the 6LoWPAN working group proposed an optimization for IPv6 ND that finally resulted in Requests for Comments (RFC) 6775 Neighbor Discovery Optimization for 6LoWPANs [16]. It lists several optimizations and extensions to IPv6 ND:

- Unsolicited router advertisements are avoided by a new host-initiated refresh of router advertisement information.
- For EUI-64-based IPv6 addresses, there is no duplicate address detection; for DHCPv6 assigned addresses, it is optional.
- A new address registration mechanism between hosts and routers avoids the use of multicast neighbor solicitation messages.
- A new router advertisement option supplies context information used for header compression.
- New messages for duplicate address request and duplicate address confirmation are used in features for performing duplicate address detection.
- A new mechanism to distribute prefixes and context information is available.
- New and optimized protocol constants are introduced.

### 59.3.1.5 Routing

Routing is a crucial aspect of IP-based network communication. For LoWPANs, approaches for unicast and multicast routing in IPv6-based wireless networks are defined.

For unicast (i.e., point-to-point [P2P]) communication, two different routing approaches are applicable. On the one hand, routing can be performed at the data link layer by the underlying mesh network (i.e., *mesh-under*). In this case, the adaption layer ensures that a pairwise communication is possible. However, it is not specified which routing mechanism is applied. On the other hand, a routing protocol at the network layer can be taken that addresses the special demands of wireless sensor and actuator networks (i.e., *route-over*).

For this purpose, the Routing Protocol for Low power and Lossy Networks (RPLs) as specified in RFC 6550 [18] is used. The routing mechanism is based on destination-oriented directed acyclic graphs (DODAG). Every graph has exactly one destination node (root), where every path in the graph finally leads to. The graph is stored in a distributed way, whereas the building process is initiated by the root node. For the computation and maintenance of the graph, ICMPv6 messages are used. Generally, messages are sent upward in the graph, but it is also possible that the root node sends messages to its children. RPL operates either in a non-storing mode or in a storing mode. In the case of P2P traffic, all downward traffic in the non-storing mode has first to reach the DODAG root. For the storing mode, a routing node processes the Destination Advertisement Objects (DAO) messages and constructs downward routes. This improves the P2P traffic by allowing a packet to be transmitted via a common ancestor between the source and the destination before reaching the DODAG root.

Immediate communication among nodes in different paths of the tree is not possible. Thus, some routes are far more expensive in terms of the used metric than the optimal one. If such links are frequently used, the overall performance drops. In order to overcome this issue, multiple instances of RPL can be defined. Each instance constructs its own DODAG using a different metric or a different root node; however, an RPL node has to belong to at most one DODAG within an RPL instance.

The storing mode can be operated with multicast or without multicast support. With multicast support, DAOs are used to relay group registrations up toward the DODAG root. In contrast to unicast traffic in which a packet is forwarded only to a single child node, multicast traffic is forwarded to all nodes that have registered to a multicast group. Multicasting routing states are therefore installed on each router between the listeners and the DODAG root.

A different approach is provided by Multicast Protocol for Low power and Lossy Networks (MPLs) [19] that is at the time being still in draft state. MPL avoids the creation and maintenance of a multicast forwarding topology. It uses the Trickle algorithm [20] for controlling packet and control information transmissions. Trickle optimizes the propagation of information efficiently and mainly specifies when messages need to be transmitted, without defining a concrete frame format or even the overall purpose the Trickle algorithm is used for. The basic idea is that when two neighbors are consistent (i.e., share the same state information), the message exchange rate between them is slowed down exponentially. For this purpose, the so-called trickle timer is used. If a node receives consistent information, it increases this timer. If an inconsistency is detected, the trickle timer is reset. This dynamic behavior prevents from wasting messages and allows to propagate changes within milliseconds.

MPL forwarders subscribe to multicast groups and are responsible for the dissemination of MPL multicast packets. An MPL domain consists of a set of connected forwarders that define the degree of the multicast distribution process. The behavior of the forwarders regarding which packets to buffer and which ones to transmit is defined by MPL. For the distribution, a proactive propagation mode and a reactive propagation mode are defined. In the proactive mode, the forwarder transmits the message based on the Trickle algorithm without discovering that a neighboring forwarder has not received the message. In the reactive mode, control messages are used by neighboring forwarders and buffered multicast packets are only sent, if it is discovered that they have not yet been received by other forwarders.

The main difference between RPL- and MPL-based multicasting is that in the case of RPL, a multicasting topology is maintained, while in case of MPL, only a per-packet state is preserved. This leads to several advantages and disadvantages of the mechanisms regarding scalability, performance, and complexity. A thorough evaluation is provided within [21]. Since MPL is in a draft state, the protocol can be expected to be improved.

### 59.3.2 ZigBee IP

ZigBee IP (ZIP) [22] is an upcoming technology in the context of Wireless Sensor and Actuator Networks (WSAN). It is specified by the ZigBee Alliance [23] and addresses recent developments in Web-based technologies. ZIP completely differs from the *original* ZigBee version [47]. In contrast to ZigBee that uses IEEE 802.15.4 addressing, ZIP is based on IPv6. However, ZigBee as well as ZIP are based on the IEEE 802.15.4 physical layer (PHY) and media access control (MAC). ZIP is quite similar to 6LoWPAN. While 6LoWPAN is a collection of possible IoT standards, ZIP strictly specifies communication modes and referees to dedicated standards. Thus, the ZigBee Alliance states that ZIP is the *first open standard for IP-based wireless mesh networks*.

#### 59.3.2.1 ZigBee IP Protocol Stack

ZIP is based on IEEE 802.15.4-2006 [24] that defines the PHY and data link layer and supports communication in different frequency bands. While the 2.4 GHz frequency band can be used globally, there are two sub-GHz bands that are restricted to specific regions. Immediately above, the *6LoWPAN adaption layer* resides in the ZIP communication stack. As stated in Section 59.3.1, IPv6 requires an MTU of at least 1280 bytes, but IEEE 802.15.4 allows only packet sizes of 127 bytes. Thus, the adaption layer is responsible for compressing and decompressing IPv6 headers as well as fragmenting and reassembling IPv6 packets. For packet fragmentation, ZIP refers to RFC 4944 [25] with the additional requirement that fragments of an IPv6 packet are transmitted and received in order. Since already one IPv6 address is as long as an IEEE 802.15.4 packet, the header has to be compressed and decompressed according to RFC 6282 [17]. Thereby, a ZIP device must support all defined compression modes and shall use the most effective one. IPv6 headers can be compressed in a stateless as well as in a stateful way as described in Sections 59.3.1.2 and 59.3.1.3, respectively. The adaption layer further handles neighbor discovery as specified in RFC 6775 [16]. This mechanism allows a node to determine its immediate neighbors. In contrast to conventional networks, wireless links have special properties that imply requirements concerning neighbor

discovery. Thus, ZIP refers to RFC 6775 [16] that optimizes the common neighbor discovery mechanism of IPv6, whereby ZIP requires that even optional mechanisms of the standard are supported.

The network layer implements the IPv6 protocol suite with special optimizations for low-rate wireless networks. Since ZIP is based on IEEE 802.15.4, two different types of addresses are possible. On the one hand, a device has to be uniquely identified by a EUI-64 address [26], while on the other hand a device can be identified by a combination of a 16-bit short address and a 16-bit personal area network id (PAN-ID). To derive an IPv6 interface ID from a EUI-64 address, link-local unicast addresses (cf. [27]) with a prefix of 64 bits are used. Similarly, a link-local unicast address with a prefix of 64 bits can be further derived from a concatenation of the PAN-ID, 16 zero bits followed by the 16-bit short address. Both address types have to be compressed in a stateless way by the *adaption layer*. Furthermore, a global unicast address can also be derived from the short address. Thereby, a unique prefix has to be defined and the address has to be checked for uniqueness. ZIP also facilitates IPv6 multicast communication. For this reason, *subnet-local* addresses are used (i.e., scope value 3, cf. RFC 4291). The network layer is further responsible for routing. In contrast to 6LoWPAN where routing can alternatively be performed at the adaption layer, ZIP uses the RPL as specified in RFC 6550 (i.e., *route-over*) [18]. For multicast routing, a special multicast forwarding mechanism called MPLs is used in ZIP according to an Internet Engineering Task Force (IETF) draft standard [28]. These basic properties of the mechanisms are described in Section 59.3.1.5.

### 59.3.2.2 Security

The transport layer of ZIP supports connectionless UDP as well as connection-oriented TCP services. Besides network encryption according to IEEE 802.15.4, the main security mechanism resides at this layer. The security suite of ZIP is based on *Protocol for Carrying Authentication for Network Access (PANA)* as described in RFC 5191 [29], which acts as carrier for other security mechanisms and additional security-related material. For example, security information for configuring IEEE 802.15.4 security mechanisms are distributed by the authentication server. PANA is based on UDP and is therefore capable of multihop transmissions. Thus, a joining device not necessarily is directly reachable by the authentication server. Mutual authentication between a joining node and the authentication server is established by the *Extensible Authentication Protocol (EAP)*. At highest level, Transport Layer Security (TLS) authentication is used, which is why EAP-TLS must be used for carrying TLS data. TLS provides two different types of authentication: one is based on preshared keys and the other one is based on elliptic curve cryptography in conjunction with an AES-based mode of operation.

### 59.3.2.3 Topology

A ZIP network consists of devices of different types. Initially, a network contains exactly one ZIP coordinator that acts as PAN coordinator according to IEEE 802.15.4. Additionally, a ZIP router and ZIP hosts can join the network depending on their hardware resources and capabilities. While a ZIP router is able to forward packets in the mesh network, ZIP hosts are associated with a ZIP router only and are not capable of routing.

### 59.3.3 Constrained RESTful Environments

Web services, especially RESTful Web services [30], are a key technology for integration in enterprise technologies. The IETF working group on constrained RESTful environments\* (CoRE) aims at a framework for resource-oriented applications that brings down the advantages of REST to constrained IP networks. These networks are constrained in the sense of providing limited bandwidth and reliability and having nodes with limited computing capacities and strong energy constraints. Moreover, these devices tend to be not online all the time and may have limited wake up times. LoWPANs are one

---

\* <https://datatracker.ietf.org/wg/core/>.

example of such network types. The framework is tailored to limited classes of applications that are working on simple resources like sensors and actuators found in a typical automation system setup and the application domains range, for example, from home and building automation systems to energy management systems.

Within the CoRE framework, several standardization drafts emerged. The Constrained Application Protocol (CoAP) [31] is a messaging protocol to interact with resources on constrained devices and is the most mature standardization draft of CoRE that will soon become an IETF standard. CoAP defines a similar request/response interaction protocol like Hypertext Transfer Protocol (HTTP), but due to the high resource demand of HTTP and TCP, it provides several optimizations for the protocol header and uses UDP instead of TCP. This opens the possibility of further message exchange patterns like asynchronous communication or group communication but forces CoAP also to deal with the reliability issues when UDP is used as transport layer protocol. Complementary to the messaging protocol, there are standard drafts for observing resources and block-wise transfer, and finally a link format that allows to describe the resources that are provided by a CoAP device.

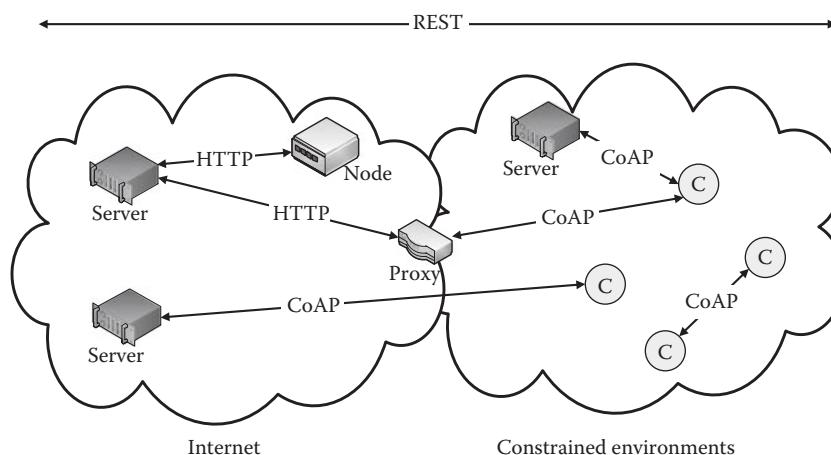

The architecture of CoRE targets a seamless integration with the existing Internet and the Web. Figure 59.1 provides an overview of the architecture of CoRE.

### 59.3.3.1 CoAP Architecture

CoAP uses a client/server interaction model where nodes may act at the same time as server and client. At transport layer, UDP is used. Since UDP is packet oriented and furthermore provides no functionalities to ensure reliability, several extensions to CoAP compared to HTTP are required. CoAP defines four message types, which are confirmable, non-confirmable, acknowledgment, and reset. These messages are provided in a sublayer and used for a request/response interaction semantics to the application layer, which does not have to deal with the messaging. All requests are sent to a uniform resource identifier (URI) that uniquely identifies the target resource.

For requests, four methods are defined: GET to retrieve the representation of the identified resource, POST to process the request by the identified resource or to update the identified resource, PUT to create or update the identified resource, and DELETE to delete the resource identified.

CoAP uses a 4-byte binary header followed by binary options and the payload. Each message contains a message ID in order to detect duplicate messages and for optional reliability mechanism. CoAP marks messages as confirmable if an acknowledgment should be provided by the server. In this case, the server responds with an acknowledgment. If the acknowledgment is not received, the client retransmits

**FIGURE 59.1** CoRE architecture.

the message for several times until an acknowledgment is returned. In order to avoid congestion, an exponential back-off mechanism is used. For some use cases, reliable messaging is not required; in this case, only one message is passed from the client to the server, which makes the communication more efficient but unreliable.

The request/response semantics of CoAP are similar to HTTP. The request contains the method or response code and the optional information such as the resource URI and the payload media types. A token is used to match responses to requests and can use up to 8 bytes. The token should be generated with strong randomization mechanisms in order to prevent easy spoofing of response messages. Requests can be marked confirmable or non-confirmable, and if possible, response messages can be piggybacked in the acknowledgment message.

Due to the use of UDP, CoAP further provides asynchronous communication abilities allowing a client to subscribe to a resource and to be notified about changes without polling permanently for updates. In this case, the observe option can be specified for the GET request. The client then continuously receives updates until a reset request is sent.

### 59.3.3.2 Message Format

A CoAP message starts with a fixed-size 4-byte header, consisting of a 2-bit flag indicating the CoAP version number, followed by a type ID (T) that maps to the different message types that are possible. An 8-bit field is used for specifying the message code. All possible values are maintained within a code registry. Finally, the 16-bit message ID is part of the fixed header. The message ID is used for message exchange purpose and reliability as described earlier. Afterward, a variable length token with the size between 0 and 8 bytes is used for mapping requests and responses. Subsequently, 0 or more options are closed by a 1-byte payload marker. Each option is identified through a number and has a variable length and an option value. The mechanism for specifying options is rather sophisticated due to optimizations but is also quite flexible. The option number is in the most basic case expressed through a 4-bit delta value that is accumulated while the header is processed and a 4-bit length field that provides the length in bytes. Reserved values for the option number delta and length allow to use up to 16-bit fields for identifying the option number and the length. One example for an option is the URI path that identifies a resource.

## 59.4 IoT Protocol Stacks and System Architectures

---

The previous section presented several upcoming standards of relevant communication protocols for the IoT. Typically, these protocols are tailored to a very specific functionality at a certain layer of the ISO/OSI reference model. For providing an alternative to existing home and building automation systems, a full system stack is required that allows two nodes to communicate with each other or, in a more advanced case, even a complete system architecture. The following subsections overview selected standards and technologies that address this issue.

### 59.4.1 Open Building Information Exchange

The Open Building Information Exchange (oBIX) as already presented in Chapter 55 can provide missing application layer services and semantics for the IoT, especially when it comes to building automation systems [32]. This can be seen in the recent standardization activities around oBIX that gained substantial momentum.

By 2010, the current working draft of the oBIX specification proposed a binary message encoding for the usage within 6LoWPAN networks. However, the performance issue of using HTTP and TCP remained. In the latest oBIX 1.1 committee specification that was released for public review, this shortcoming was addressed by new protocol bindings and encodings that make oBIX more suitable for the IoT and a deployment in constrained environments.

#### 59.4.1.1 IoT Protocol Bindings and Message Encodings

In the latest oBIX 1.1 specification [50], the protocol bindings and encodings moved to separate specification documents and include a new REST protocol binding to CoAP. This allows to take advantage of the communication features of CoAP. Alternatively to the former oBIX watch concept, objects can be observed using the CoAP observe feature. In that way, a client does not need to poll for updates. Instead, they are pushed by the server that makes this kind of conversion more efficient. Furthermore, new message encodings for JavaScript Object Notation (JSON) and the Efficient XML Interchange (EXI) format have been defined. The JSON encoding has become recently quite popular in the IoT community since it is slightly more lightweight than Extensible Markup Language (XML) and easy to process in Web browsers using JavaScript. EXI is an attractive alternative to a proprietary binary encoding as it is as efficient regarding message size and also based on an open standard. If schema-informed EXI is used, the message encoding efficiency compares to the oBIX binary encoding and is therefore well suited for the use within LoWPANs. With these improvements, oBIX can be directly deployed on constrained sensors and actuators and directly integrated in the IoT through technologies like 6LoWPAN and CoAP.

#### 59.4.1.2 oBIX 2.0 Outlook

The current standardization activities within oBIX are mainly driven through the requirements identified by the IoT. Also, oBIX has been recognized as a relevant technology providing interoperability within smart grids by the National Institute of Standards and Technology (NIST) [33]. The work plan for oBIX 2.0 is yet to be defined but several goals are already determined.\* oBIX 2.0 should be a main technology in the IoT, and therefore peer-to-peer communication services should enrich the optimized protocol bindings. Besides this, the focus is put on so-called enterprise services. Specific contracts for the energy domain should enrich the core contract sets and allow the easy integration with Energy Interoperation standard that subsumes OpenADR 2.0. Furthermore, the requirements of the Energy Market Information Exchange standard should be addressed. Reporting and advanced history services are also on the roadmap. Additionally, it is planned to enrich current alarming services by a powerful standardized way to specify alarm logic. Building information models will play an essential role. Moreover, the integration toward enterprise scheduling will be addressed to schedule interactions within building systems. Finally, oBIX 1.1 does not support a custom security framework. This is going to be solved by oBIX 2.0 with a special attention on how access control can be achieved and aligned with enterprise services.

#### 59.4.2 OPC UA

OPC as introduced in Chapter 55 was originally designed for reading, writing, and monitoring of control data. Therefore, different kinds of access schemes were defined such as OPC Data Access or OPC Alarms and Events. However, using classic OPC in modern automation systems leads to several disadvantages. First, OPC is based on Microsoft's technology (Distributed) Component Object Model (COM/DCOM), which limits its use to Windows-based systems. Furthermore, COM/DCOM has additional drawbacks like limited support for routing and security as well as incompatibility between different Windows versions. Another major drawback is its rudimentary data model where only very restricted information models can be created. Complex data structures, for example, are not provided by these OPC standards.

To overcome the drawbacks of these so-called classical OPC specifications, the OPC Foundation [48] decided to define a new specification that is referred to as *OPC Unified Architecture (OPC UA)* [34]. It is also standardized as IEC 62541 [35]. To eliminate the dependency on Windows, OPC UA is based on a service-oriented architecture (SOA). To achieve this, OPC UA uses Web services or a TCP-based protocol for data exchange that both enable full platform independence. In addition to this new communication

---

\* <http://www.newdaedalus.com/articles/2013/3/26/work-plan-for-obix-20.html>.

concept, another key feature within OPC UA is the support of a powerful and extensible information model that can be used to model any kind of information and data.

#### 59.4.2.1 Information Modeling in OPC UA

The comprehensive information modeling capabilities of OPC UA can be used to provide a standardized, well-defined way to model the data that are originating from different technologies. In order to model information in OPC UA, a so-called address space model is introduced that provides the following features [36]:

- The address space model supports object-oriented mechanisms allowing the definition of type hierarchies and inheritance.
- The modeling concept allows a definition of models that consist of full-meshed nodes.
- Information models are defined on server side, which entails that clients do not need to be aware of the models since they can be retrieved from the server.
- Type information and type hierarchies can be accessed by clients since they are exposed like normal data.
- A key concept of OPC UA information modeling is that the base information model can be extended by defining own models on top of the existing one.

Information modeling in OPC UA is based on defining *nodes* and *references* between them. Nodes are used to model any kind of information. This includes the representation of data instances or the definition of data types. Each node belongs to exactly one of the following *node classes*:

- **Base NodeClass:** This node class represents the base class from which all other node classes are derived.
- **Object NodeClass:** Objects are used to represent real-world entities like system components, hardware and software components, or even whole systems.
- **ObjectType NodeClass:** This node class holds type definitions for objects.
- **Variable NodeClass:** Variables are used to model values of the system. OPC UA distinguishes between data variables (e.g., data points that represent physical values of the process under control) and properties (e.g., metadata that further describes nodes).
- **VariableType NodeClass:** This node class is used to provide type definitions for variables.
- **DataType NodeClass:** The **DataType NodeClass** is used to provide type definitions for the values of variables.
- **ReferenceType NodeClass:** This kind of nodes is used to define different reference types.
- **Method NodeClass:** Methods are used to model callable functions that initiate actions within a server.
- **View NodeClass:** A view summarizes a subset of the nodes of the address space. Views are used to make only parts of the address space visible to clients.

Depending on the node class, a node has several attributes that characterize its properties. Some attributes are common to all nodes like the **NodeId** (uniquely identifying a node within the address space), the **NodeClass** (defining the node class), the **DisplayName** (localized text that can be used by a client for displaying the name), and the **BrowseName** (identifies a node when browsing the address space). Other attributes are only available for certain node classes. For example, variables have the attribute **Value** that represents the value of the variable and the attribute **DataType** that indicates the data type of the **Value** attribute.

The list of attributes cannot be extended by the user. Adding additional semantics to nodes has to be done by introducing a type hierarchy and by adding references to other nodes. A key concept within OPC UA is the modeling of *complex type definitions* for objects and variables. Such a complex type is an object or variable that embeds other nodes as subcomponents. The assignment of these subnodes to their parent node is done by using references.

Another powerful modeling mechanism is the use of *references*. References are always defined from one node to another—references are therefore always one-to-one relations. References can be defined in a symmetric or asymmetric way and further be divided into hierarchical or non-hierarchical. Hierarchical references can be used to introduce topologies and hierarchies within the model. Typical examples of standard OPC UA hierarchical references are `Organizes` (used to introduce a general hierarchy of nodes) and `HasComponent` (used to reference a complex type to its subnodes). An example of a standard OPC UA non-hierarchical reference is `HasTypeDefinition` that allows referencing an object or variable to its type definition. OPC Foundation [34] provides further details about modeling mechanisms in OPC UA and a full list of all attributes.

One of the most important features of OPC UA is that it already defines a set of standardized information models. The OPC UA base information model provides basic object, variable, reference, and data types as well as a set of predefined objects and variables. On top of this basic model, four additional information models are defined:

1. OPC UA Data Access (Part 8): This model specifies basic concepts to model data points of automation systems.
2. OPC UA Alarm and Conditions (Part 9): Within this part, concepts for alarm handling and defining alarm conditions are available.
3. OPC UA Programs (Part 10): OPC UA methods are only useful for invoking operations that immediately finish after execution. For operations that require a longer execution time, OPC UA programs shall be used.
4. OPC UA Historical Access (Part 11): To store and access historical data within the information model, the concepts covered within this part can be used.

#### **59.4.2.2 Services and Communication in OPC UA**

OPC UA is completely based on the client/server model—the communication is performed in *sessions*. To gain access to data, an OPC client establishes a connection to one or more OPC servers. In OPC UA, devices can choose one of two different transport protocols for communication. The first one is based on WS-I Basic Profile 1.1 [37] where Simple Object Access Protocol (SOAP) and HTTP are used. The second one is a binary TCP-based protocol that has been developed by the OPC Foundation.

Since OPC devices are mainly located at the management level where the network may be shared with other application domains, a security model has been introduced in OPC UA. To secure the communication, a *secured channel* is set up during session establishment. This secured channel is provided by the OPC communication layer that is located between the transport layer and the application layer. The secured channel uses cryptographic techniques to guarantee data confidentiality, freshness, and data origin authentication. Entity authentication is provided during session establishment with the help of certificates. Authorization and access control to the control data and services, is left up to the application.

Based on these secure transport protocols, OPC UA defines different services that are used by clients to communicate with the servers and vice versa. These services are grouped into so-called service sets. Typical service sets are the `Attribute Service Set` that contains services to read and write attributes of nodes as well as the `Session Service Set` that consists of services to open and close a session. For a complete list of all services specified by OPC UA, see OPC Foundation [34].

#### **59.4.3 MQTT**

Message Queuing Telemetry Transport (MQTT) follows a publish/subscribe integration approach. It aims to be lightweight, simple, and open. MQTT is developed by International Business Machines Corporation (IBM) and is now moving toward becoming an Organization for the Advancement of Structured Information Standards (OASIS) standard.

The main features of the protocol are [38]:

- One-to-many message distribution and decoupling of information sources and applications
- Payload agnostic message transport
- TCP/IP for network connectivity
- Three qualities of service for message delivery
- Small transport overhead
- Notification mechanism for abnormal client disconnection

MQTT follows a data-centric design paradigm. Information systems that need to interact with each other do not use a direct communication; instead, a broker is used as middleware and topics identify the information of interest. MQTT clients can then subscribe to topics and publish new messages to topics. In that way, a one-to-many interaction is possible and the communicating systems are decoupled through the broker. A drawback of this architecture is that the broker becomes a single point of failure and a bottleneck for scalability.

#### 59.4.3.1 Message Format

The MQTT message format uses a fixed 2-byte header. There is a 4-bit field identifying the message type, where 14 message types are defined. The message types range from connection-related messages like connect, disconnect, ping, and acknowledgment messages over to messaging related types like publishing and subscription management. The remaining flags are used for the duplicate delivery (DUP), quality of service (QoS), and retain flags. The DUP flag is used to indicate the retransmission of messages, the QoS sets the level of assurance (at most once, at least once, exactly once), and the retain bit holds semantics if a message is persistently stored at the broker and also transmitted to subscribers that enroll on the topic after the message has been published. A second byte represents the remaining length of the payload. There, 7 bits are used to encode the length in bytes and 1 bit is used as continuation bit to extend the remaining length representation for a variable number of further bytes.

Depending on the message type, several variable headers are defined and come between the fixed header and the message payload. For example, the topic name is presented as variable header in a publish message and can take up to 32.767 characters. Within the subscribe message, multiple topics can be placed in the payload.

#### 59.4.3.2 MQTT for Sensor Networks

MQTT for sensor networks (MQTT-S) [39] specifies optimizations that allow to use the MQTT protocol within sensor networks. It is adapted to the requirements on constrained networks regarding computing resources and limited bandwidth and device energy. The main adaptions are the following:

- Multiple connect messages combined with other message types to reduce the number of messages.
- Short 2-byte-long topic ID instead of long character-based identification. A registration mechanism allows to register names for topic IDs and to query by name at the broker.
- Predefined topic IDs and short topic names.
- Discovery mechanism for brokers and gateways.
- Keep alive mechanism for sleeping clients.

The overall architecture of MQTT-S is outlined in Figure 59.2. The architecture consists of four components. The original MQTT broker is left unchanged by MQTT-S, but three new components are added which are clients, forwarders, and gateways. The clients use the optimized MQTT-S protocol and the forwarders simply relay the protocol unchanged, which might happen at the border of a LoWPAN to a network with more bandwidth and reliability. Finally, the gateway does the translation between MQTT-S and MQTT.

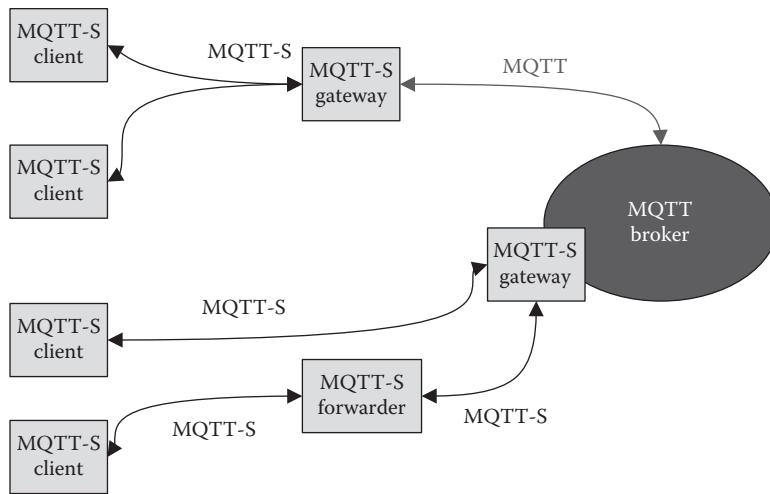

FIGURE 59.2 MQTT-S architecture [39].

#### 59.4.4 IPSO Application Framework

The Internet Protocol for Smart Objects (IPSO) application framework defines the required application layer to provide interoperability among sensors and actuators using CoAP for message exchange. The IPSO Alliance is an organization that promotes the use of IP directly on smart objects ranging from home over building automation systems to smart appliances and other M2M applications, for example, for energy management systems.

The application framework defines the interfaces and the resource representation of smart objects equipped with IP. The framework does not aim to be a standard and intends to complement existing application-layer-specific standards like oBIX or ZigBee Smart Energy Profile 2.

Certain resource types are grouped into function sets. A function set has a resource type parameter that can be used for discovery and comes with a recommended root path. The subresources are organized below the root path. The root path is a recommendation but resources might be represented also using different addressing schemes.

Path templates are defined that contain index parameters like {#}, which provide means for identification within multiple instances of one resource type. The resource type is described through a namespace and a type ID. This information is also used for the rt field if the CoRE link format description is requested.

The framework currently supports two namespaces, namely, ipso and ucum. The ipso namespace is used for namespaces that are defined with the application framework. ucum refers to the Unified Code for Units of Measure (UCUM) specification, which is used for referencing standard unit types. The interface specification is based on REST interfaces and references the basic core resource types of Shelby and Vial [40].

The available data types are the basic XML schema data types or the data types defined by Sensor Markup Language (SenML) [41]. For the message encoding, it is possible to use either text/plain encoding or application/senml+json. However, an encoding using XML or more efficiently EXI is also possible.

As interaction model, a classic client/server communication model is used, based on either HTTP or CoAP. For discovery, only a kind of *lobby* mechanism is provided that describes the resources using the CoRE link format and returns links to those resources when querying the path / .well-known/core; additionally, a device may register its resources at a resource directory [42].

##### 59.4.4.1 Function Sets

Table 59.1 provides an overview of the function sets defined by the application framework. Each function set covers a certain domain or specific functionality and comes with a root path and a base

**TABLE 59.1** IPSO Application Framework Function Sets

Function Set	Root Path	Resource Type
Device	/dev	ipso.dev
General-purpose IO	/gpio	ipso gpio
Power	/pwr	ipso.pwr
Load control	/load	ipso.load
Sensors	/sen	ipso.sen
Light control	/lt	ipso.lt
Message	/msg	ipso.msg
Location	/loc	ipso.loc
Configuration	/cfg	ipso.cfg

resource type. A function type can be seen as a complex type containing further subresource types. These resource types are more equivalent to the concept of a data point, since for those types, a certain interface, data type, and (in case of numerical values) a unit are defined.

The device, configuration, and location function sets cover operational and meta-information of the smart object like the manufacturer, serial number, and name or the location and allow to modify the configuration. The General purpose input-output (GPIO) function set covers generic digital and analog inputs and outputs. The other function sets like power, load control, sensors, and light control are more domain-specific and come with specific types and resource representations. For example, within the sensor function set, a motion type is defined for motion sensors, or within the light control function set, a subtype for dimming is specified. Finally, the message function set can be used to express status, alarming, and display messages.

#### 59.4.4.2 Data Formats

The data types used by the application framework to specify the subtypes within the function set are illustrated in Table 59.2; also, the mapping to the plain-text encoding and to SenML fields are described. If no additional metadata is required, the plain-text encoding provides an efficient way to exchange information. In this encoding, the data fields are represented using ASCII and the according XML schema type definitions. SenML provides a simple information model for representing sensor devices and corresponding measurements. Each message represents one single object with attributes that hold an array of entries. An entry consists of attributes like a unique ID within the sensor, the measurement time, and the value. One goal of SenML is to keep metadata as much as possible out of communication and to rely on out-of-band exchange for the required metadata.

#### 59.4.5 ZigBee: Smart Energy Profile 2

With the recent development of ZIP, the ZigBee Alliance also revised the Smart Energy Profile (SEP) used with the *original* ZigBee. In cooperation with the HomePlug Alliance [43], the ZigBee Alliance [23] introduced the Smart Energy Profile 2 (SEP2) [44]. Both versions are application layer information

**TABLE 59.2** IPSO Application Framework Data Formats

Data Type	Text/Plain Format	SenML Field
b (boolean)	xsd:boolean	Boolean value (v)
s (string)	xsd:string	String value (sv)
e (enum)	xsd:integer	Value (v)
i (integer)	xsd:integer	Value (v)
d (decimal)	xsd:decimal	Value (v)

representation and interaction models. While SEP is based on the ZigBee information modeling framework as introduced in Chapter 55, SEP2 implements a RESTful architecture based on HTTP. The communication interface is defined using Web Application Description Language (WADL), a machine-reachable description language. The application payload is encoded in either XML or EXI. Although SEP2 is designed to be used in conjunction with ZIP, the use of standard technologies (i.e., HTTP, XML) allows of using different IP-related transmission technologies such as WiFi or Ethernet. Since different—possibly unsecured—transmission media can be used, SEP2 specifies additional application layer security mechanisms. Besides device authentication, SEP2 provides methods for authorization with fine-grained access control for specific resources.

SEP2 defines services in form of function sets and resources for domain-specific applications. Thereby, sets and resources for metering, pricing, and billing are specified. Further domains are demand response and load control as well as prepayment. An important domain deals with distributed energy resources. Additionally, a group of common resources and function sets is specified for timing network management and configuration.

## 59.5 Conclusion

---

Home and building automation technologies are the target of a rapidly proceeding technology revolution driven by the recent research activities around smart grids, smart cities, and the IoT. Besides new protocols to be deployed, integration and interoperability remain key challenges to be solved. A clear trend toward the use of IP and Web technologies can be observed that will finally lead to a convergence of control and data network infrastructures. New protocols are available, but the definition of a complete system is to be defined, yet. There is ongoing work on different approaches and system architectures that have a different level of maturity. Several standards are still in a draft state and open issues exist. Nevertheless, vendors are already starting to produce devices equipped with such communication stacks, but it will take more time until a broad industry acceptance can be seen with large-scale deployments that go beyond research or pilot installations.

### 60.1 Introduction

---

Automatic meter reading (AMR) can be considered as the predecessor of AMI (advanced metering infrastructure), and it allows utilities to perform some basic readout functions of a customer's meter. It does not allow control of the meter itself (e.g., disconnect or the uploading of new tariff tables), let alone enable demand-side management. Together with new generation challenges (distributed energy resources [DER] and intermittent), the next logical step will be the emergence of AMI systems under distributed control: the smart grid.

The rise of the smart grid is shaping up to follow a gentle evolutionary trajectory. New wind farms, solar installations, and substations will be equipped with distributed control and monitoring features, enabling utility automation. At the consumer side, the installation of smart meters will trigger a (slow) adoption of *energy-aware* devices that can communicate with it.

#### 60.1.1 Smart Grid Communication Architecture

Figure 60.1 shows a generic smart metering system outlining the basic system components. It is very similar to the *system components and interfaces* defined in the Open Meter project and the *metering installation description* from the DSMR document. A short overview of the main components:

*Electricity meter and communication hub:* This device functions as the gateway to the smart grid.

Most of the time, the house's main electricity meter will be integrated with it, as well as an externally controllable breaker switch (e.g., for contract control). Being also a communication hub, the device will communicate with other metering devices and home appliances connected to a home area/automation network (HAN).

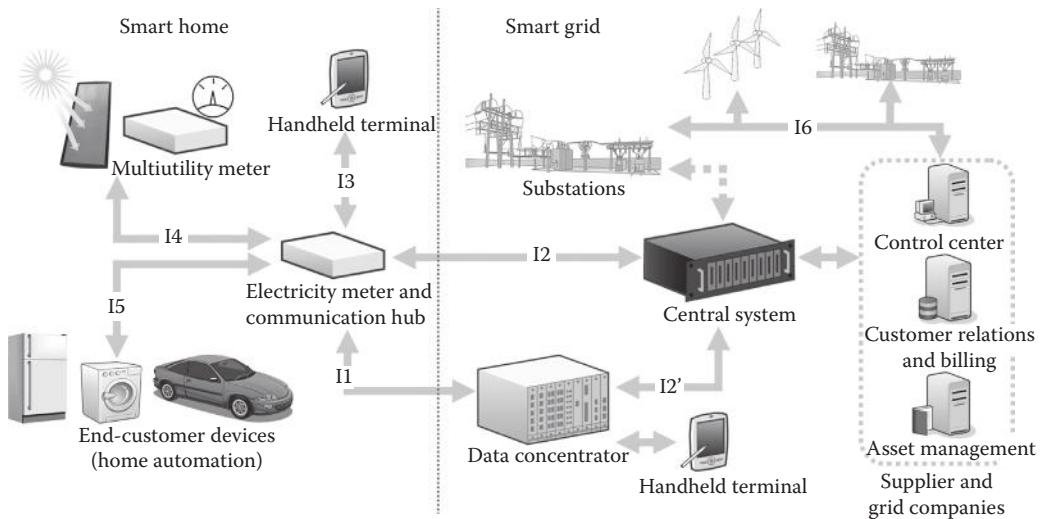

FIGURE 60.1 Smart grid system architecture.

**Multiutility meter:** A meter measuring, for example, gas, water, or heat, or an electricity submeter such as for a residential PV installation.

**End-customer device:** Appliances that communicate with the hub using a HAN. Examples include heating and ventilation air conditioning (HVAC) units, lighting and major appliances, and also plug-in (hybrid) electric vehicles (P(H)EVs).

**Data concentrator:** In between the smart meter and the central system, an intermediate data concentrator can be present. Its main purpose is to manage the connected meters, aggregate the data, and act as a relay for the central system.

**Central system:** The task of the central system is to provide the core communication functions of the smart grid. It interfaces with the supplier and grid companies, which can query customer meters for billing purposes or issue tariff commands and demand response alarms. It is possible that the central system will be operated by new service providers, which then grant access to the various market players. Eventually, the control center of the transmission system operator and distribution system operator is still responsible for the management of the legacy grid infrastructure as well as its centralized and distributed energy sources.

**Handheld units (HHUs):** An extra port on the meter/hub and concentrator allows service technicians to locally read and change parameters during installation or maintenance. It is also useful in case problems arise that cannot be remedied remotely.

The relevant communication channels and relations that arise are marked interface I1–I6. The protocols introduced in this chapter are dealing with the interactions I1–I5 (see Section 60.3).

## 60.2 Available Standards

In this section, a short introduction to each analyzed standard is presented. The relevant criterion for selection was the *openness* of the standard. Because of the smart grid context, interoperability and extendibility must be guaranteed across different devices and manufacturers. Therefore, only open standards have been considered in this overview.

A rough referencing of the protocol to the OSI layer position is shown in Figure 60.2. For example, if it mostly concerns hardware aspects (such as IEC 61334-5 or IEC 62056-21) or does it also specify a data model (e.g., Distribution Line Message Specification [DLMS]/COmpanion Specification for Energy Metering [COSEM]) or both (such as KNX and LonWorks).

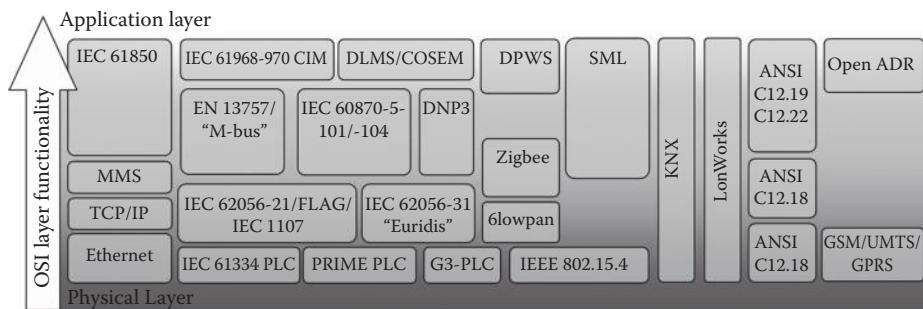

FIGURE 60.2 OSI layer placement of the analyzed standards.

### 60.2.1 IEC 61334-5 PLC

This IEC suite of standards was developed at the end of the 1990s by IEC working group 57 and defines several narrowband power line communication (NB-PLC) systems. The full name is “Distribution automation using distribution line carrier systems.”

While IEC 61334-5 is mostly used with S-FSK, the standard contains a suite of different lower layers (numbered 61334-5 Part 1–5):

- Part 1: Spread frequency shift keying (S-FSK) in the CENELEC A-band (9–95 kHz). This allows for a few hundreds of kbps using about 100 mW of transmit power.
- Part 2: Frequency shift keying (FSK).
- Part 3: Spread-spectrum adaptive wideband (SS-AW).
- Part 4: Multicarrier modulation (MCM).
- Part 5: Spread spectrum—fast frequency hopping (SS-FFH).

The upper OSI layers (network layer, application layer, and DLMS protocol) are also specified (in IEC 61334-4), but their use is optional.

A typical narrowband PLC deployment consists of a concentrator close to the MV/LV transformer, where it is coupled to a backbone network (Figure 60.3). All communication is initiated by the concentrator or gateway, which means that meters down the line can access the medium only when requested by the concentrator. Once the data are in the concentrator, it can be forwarded to the management center.

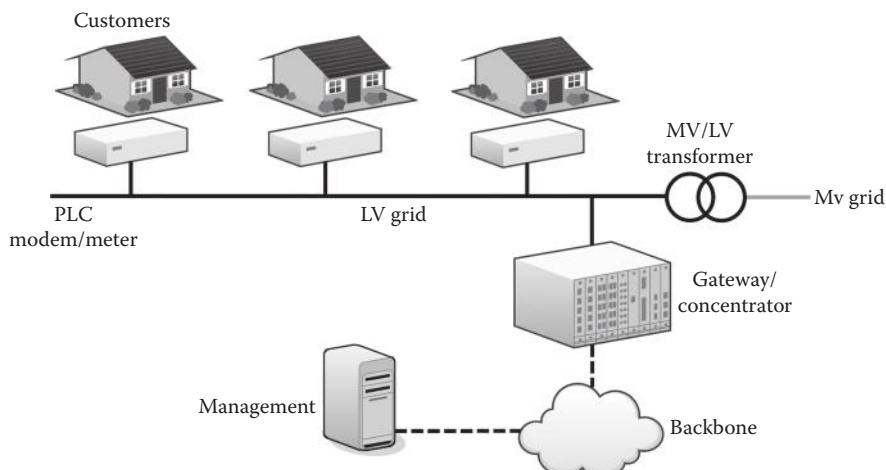

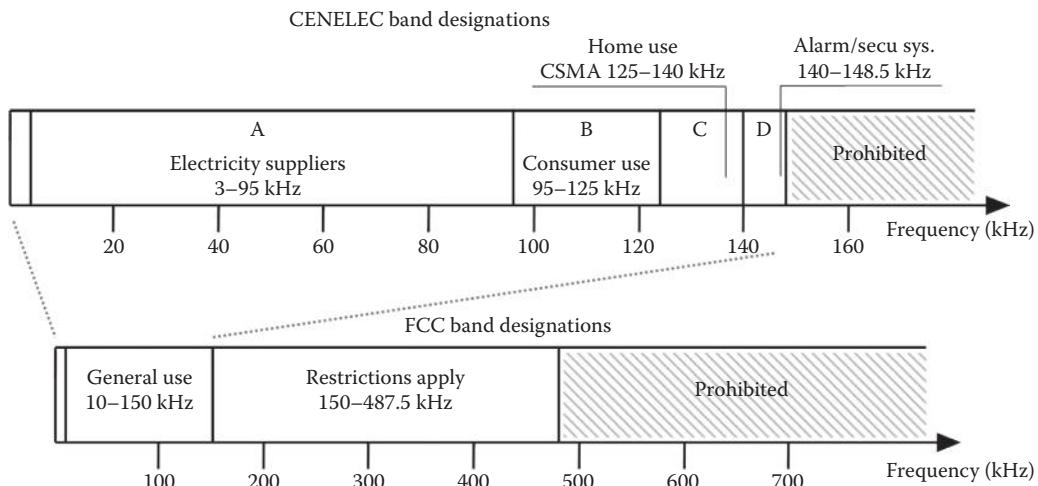

FIGURE 60.3 Overview of typical narrowband PLC deployment.

**FIGURE 60.4** Comparison of CENELEC and FCC EMC regulations regarding the use of PLC.

Because of the allowed frequency range (3–148.5 kHz in Europe) and limited transmission power, the available bandwidth is quite low (up to a few kbit/s). Also, the small packet size makes IEC 61334-5 not very suitable for, for example, TCP/IP communication as this combination would result in unacceptable fragmentation and delays. However, this standard is robust, mature, and widely used.

In the United States and Asia, the regulation is different. The FCC and ARIB allow PLC devices to work in the frequency band from 3 to 500 kHz. A comparison of the CENELEC and FCC regulation is depicted in Figure 60.4.

Recent narrowband PLC technologies such as PRIME (2009) and PLC G3 (2011) are based on more sophisticated orthogonal frequency-division multiplexing (OFDM) techniques to provide higher data rates. Both of these technologies are under consideration for the physical and medium access layers of the upcoming IEEE 1901.2 standard.

Also worth mentioning is the installation of filters that isolate the LV loads from the outside grid or the different feeders in the LV grid to improve SNR ratios and the use of multiple gateways per line segment.

Despite the difficulties, PLC technologies are at an advantage when viewed from the perspective of the utility company. They already have full access to the network infrastructure, which means more control and less dependence from third parties.

### 60.2.2 IEEE P1901.2/PRIME PLC/PLC G3

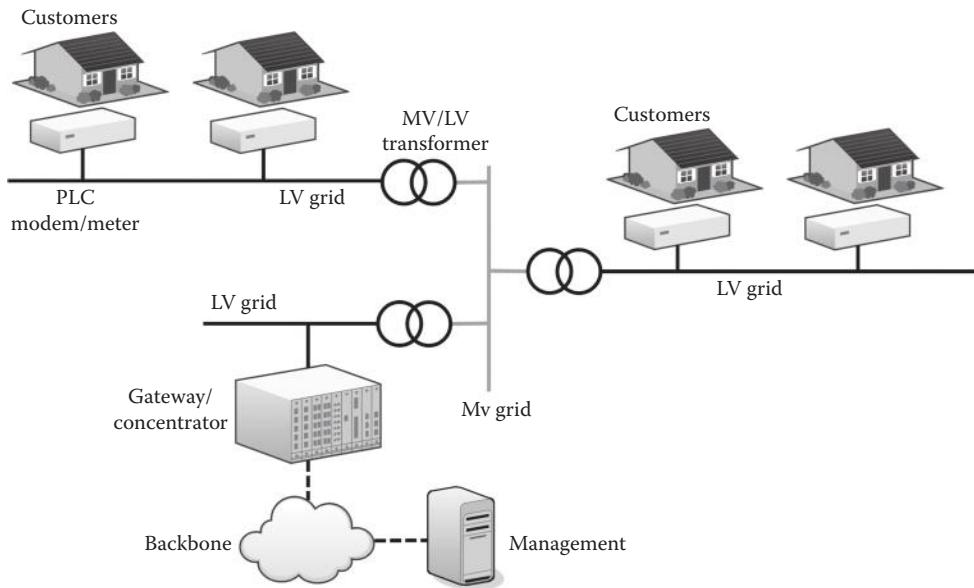

In March 2010, the IEEE authorized a project *Draft Standard for Low Frequency (less than 500 kHz) Narrow Band Power Line Communications for Smart Grid Applications*.

The goal of this standard is to define the physical and medium access layers for a low-frequency (below 500 kHz and inside CENELEC A-band) NB-PLC protocol operating on AC and DC electric power lines. Typical applications include smart meters, electric vehicle charge stations, intrahome networking, and additionally lighting and photovoltaic converter communications.

IEEE P1901.2 is intended to be usable

- On the low-voltage lines <1000 V (e.g., between the transformer and consumer's meter)
- Through the transformer from low-voltage to medium-voltage grid (1000 V–72 kV)
- Through the transformer from medium-voltage to low-voltage grid

In North America, the low-voltage segment between the house and utility may extend 3–4 m. In such scenarios, putting a concentrator before the MV/LV transformers would not be cost-effective, making

**FIGURE 60.5** Overview of a typical IEEE P1902.1 PLC deployment.

transformer crossing an interesting capability. It enables the concentrator to be placed where it can aggregate data from more locations (Figure 60.5).

Multikilometer rural communications and/or data rates up to 500 kbit/s should be possible depending on the application. The standard ensures coexistence with broadband power line (also part of IEEE 1901) devices by minimizing emissions in bands >500 kHz.

Two technologies are under consideration for the physical and medium access layers of the upcoming IEEE 1901.2 standard, PRIME and PLC G3. Both drafts are based upon the use of OFDM, whereas IEC 61334 is based on the use of FSK on a single carrier frequency.

### 60.2.2.1 PRIME

PRIME stands for power line-related intelligent metering evolution and defines the lower layers of a PLC narrowband system that operates within the CENELEC A-band, between 42 and 89 kHz. A maximum data rate of 128.6 kbit/s can be attained under good circumstances or 21.4 kbit/s using its most robust encoding scheme. An IPv4 convergence layer allows the transfer of TCP/IP traffic, and a security profile based on 128-bit Advanced Encryption Standard (AES) allows secure authentication and data encryption. Simplicity, low cost, and flexibility are the main goals in the design of the PRIME system. An overview of the layers in the PRIME system is shown in Figure 60.6.

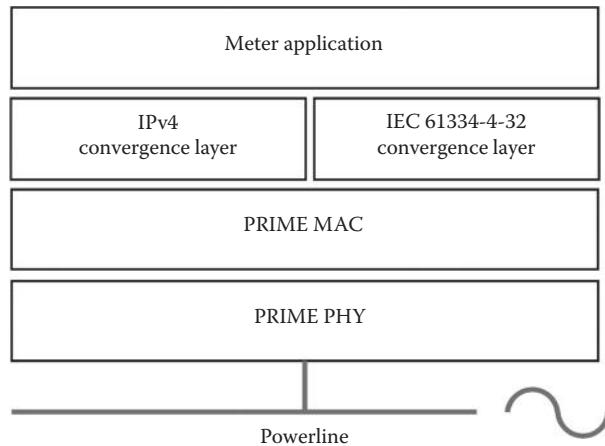

The main coordinator behind this technology is the Spanish utility Iberdrola, which started a pilot project back in 2009. As of May 2013, the PRIME Alliance reported that over 2M meters using this technology have been installed.

Work is progressing on a PRIME extension that operates with frequencies up to 500 kHz (for use outside Europe). PRIME FCC bands will span from 40 to 490 kHz, allowing for maximum data rates of 1 Mbps. The relevant PHY parameters are to be defined by end of April 2013.

Additionally, a COSEM Profile Task Force has been formed with the scope of defining an optional, common DLMS/COSEM profile for PRIME.

### 60.2.2.2 G3-PLC

In 2010, ERDF announced its plans to develop and implement an automatic metering management (AMM) system to manage the complete electricity supply chain, from electricity suppliers all the way

**FIGURE 60.6** PRIME layers. (Derived from PRIME Project, PRIME technology whitepaper: PHY, MAC and convergence layers, 2008, Available at [http://www.iberdrola.com/webibd/gc/prod/en/doc/MAC\\_Spec\\_white\\_paper\\_1\\_0\\_080721.pdf](http://www.iberdrola.com/webibd/gc/prod/en/doc/MAC_Spec_white_paper_1_0_080721.pdf).)

to the consumers. The system provides two-way communication using OFDM-PLC between meters installed at the customers' premises and the concentrator, communicating in a master-slave setup.

During 2010, after a successful experimental field test, over 250,000 *Linky* meters supporting PLC-3G were installed by ERDF. In 2011, the G3-PLC alliance was founded to promote the technology. The alliance includes meter vendors such as Landis+Gyr and chip manufacturers Maxim, STMicroelectronics, and Texas Instruments.

G3-PLC supports the portion between 35.9 and 90.6 kHz of the CELENCE-A band. Using the *normal mode* modulation schemes, data rates of up to 33.4 kbit/s are supported. In *robust mode*, additional error detection and correction is added, reducing throughput to about a fourth of that. There is a potential to use this standard to support communication in frequencies up to 180 kHz, in the FCC band, using an extension proposed by Maxim (G3-FCC). Data rates up to 400 kbit/s are then possible.

G3-PLC coexists with S-FSK and other legacy PLC technologies by notch filtering on the S-FSK carrier frequencies and seamlessly supports DLMS/COSEM (IEC 62065). Data security is provided through 128-bit AES and support for IPv6 enables PLC-G3 to converge IPv4 and IPv6 devices and networks in an efficient manner.

### 60.2.3 ANSI C12 Protocol Suite

Back in 1996, a number of partners from industry and utility companies developed two ANSI standards for the readout of electricity meters. In ANSI C12.19, standard meter data and tables are described, together with the basic requirements for reading and writing these tables (referred to as services), independent of the transport protocol. In ANSI C12.18, a low-overhead protocol for the ANSI Type 2 Optical Port (ANSI C12.13) for on-site meter reading is described (Figure 60.7). It can be compared to IEC 1107-FLAG in Europe and is basically the first protocol for the transport of C12.19 table data.

In 1999, C12.18 was adapted for remote access over telephone modems, as C12.21, making it one of the early solutions for AMI projects. Both are essentially session-based serial point-to-point protocols and known as "Protocol Specification for Electricity Metering" (PSEM). Communication takes place in a request/response manner, in which both sides can initiate request commands.

C12.21 also adds authentication enhancements due to the fact that the person reading the meter is not necessarily on-site. Subsequent data reads and writes are done unencrypted though, making C12.21 not well-suited for use over the Internet.

**FIGURE 60.7** An Elster A3 Alpha Meter showing the D-shaped ANSI Type 2 Optical port. (Copyright Elster Metering, Elster A3 Alpha Meter, [Online] 2013, Available at [http://www.elstersolutions.com/en/product-details-na/73/en/A3\\_ALPHA\\_meter](http://www.elstersolutions.com/en/product-details-na/73/en/A3_ALPHA_meter) (Accessed on August 2, 2013).)

In both C12.18 and C12.21, specific media (optical and telephone) are specified. The goal of C12.22, added in 2007, is to describe transport of C12.19 meter tables using PSEM messages, using already existing communication networks such as TCP/IP over Ethernet, SMS/GSM, and so on. Typically, C12.22 uses TCP as its transport protocol. The commonly used TCP port for C12.22 traffic is 1153.

C12.22 makes it possible to chain request commands and support communications over shared media. It also provides for both session and session-less communications, which reduces the amount of packets and complexity (e.g., in the case when using SMS over GSM). AES encryption is also specified as an option.

Some countries such as Australia and South Africa have adopted both IEC 1107 and ANSI standards for metering, and a variant called open smart grid protocol is used by Echelon in their AMI solutions.

#### 60.2.4 IEC 62056-21/IEC 61107

Similar in purpose to ANSI C12.18 and 19, this standard is aimed at meter reading and programming using a directly connected handheld device, but is also used over modem connections. In 2002, IEC 1107 was incorporated into IEC 62056 as *IEC 62056-21 Electrical metering—Data exchange for meter reading, tariff and load control—Part 21: direct local data exchange, 2002-05*. It was originally part of IEC 1107:1990.

Together with Euridis, IEC 1107 is one of the physical layer standards provided by IEC 62056. Part 21 contains the third edition and describes a bidirectional optical interface along a specification with data rates, character format, and transmission protocol. This standard is mainly used in Europe.

Optical probes used for IEC 1107 are sometimes called FLAG probes, after an earlier interface by Ferranti and Landis+Gyr. While the protocols are the same, FLAG is a subset of IEC 1107 and is more specific regarding the media. The hardware of the interface is identical though, and IEC 1107 optical probes will work on FLAG meters.

It is also possible to use the IEC 1107 protocol over other media than optical, such as a two-wire system similar to EIA-485, inductively coupled loops, modems, or even Internet protocols. Multiple devices can be connected to a shared communications bus as well, for example, in an apartment building. Different operating modes are specified, labeled from A to D, all based on ASCII but differing in baud rate, directionality, and security. A special mode E allows the use of DLMS/COSEM via High-Level Data Link Control (HDLC) (see IEC 62056-46).

The mode is negotiated between the readout unit and the meter. More than one mode can be supported: nowadays, support for Mode C and Mode E with DLMS/COSEM is common practice.

As one of the first meter data exchange standards, IEC 62056-21 is widely used today. However, it does not use a data model or uniform memory mapping. Therefore, meter communication requires manufacturer-specific information, limiting interchangeability, unless DLMS/COSEM is used in Mode E.

Every manufacturer has their own three-letter identification code, whose list is maintained by the FLAG Association and the DLMS User Association.

### 60.2.5 SITRED/Telegestore/Meters and More

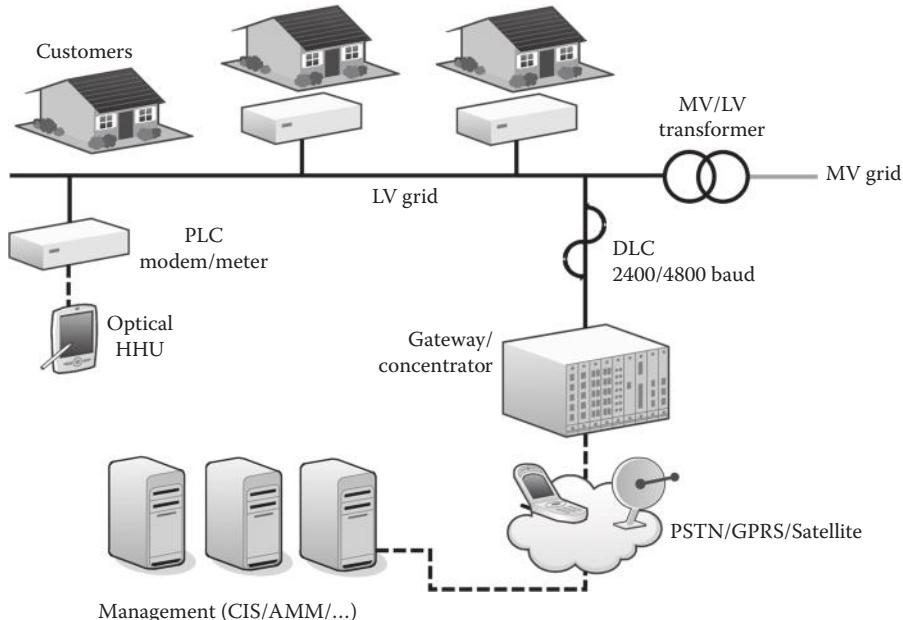

At the beginning of the 1990s, Italy's largest distribution company, ENEL, developed a transmission system called SITRED to read and manage meters remotely, using distribution line communication. A large test comprising 80,000 installations proved that remote management via the LV network was technically viable, but the use of Ferraris meters equipped with electronics was not cost-effective enough.

At the end of the 1990s, technology had advanced enough, and ENEL concluded that changing all the low-voltage meters for electronic ones would soon be profitable, and in October 1999, the Telegestore project was started.

#### 60.2.5.1 Architecture

At the consumer side, fully electronic meters communicate with a concentrator situated close to a transformer via PLC (Figure 60.8). The concentrator communicates with the acquisition center through an access server using GSM, PSTN, or satellite. Local access is also provided through an RS-232 and IEC 1107 Mode C optical port.

The central management system does all the customer relationship management, including remote contract management (disconnection, tariff plans, etc.), monthly billing, and demand-side management.

**FIGURE 60.8** Overview of the Telegestore architecture. (Derived from Botte, B. et al., *18th International Conference and Exhibition on Electricity Distribution*, 2005, pp. 1-4.)

**FIGURE 60.9** Enel Single Phase Smart Meters as installed during the Telegestore project. (Copyright Enel, Smart Metering Diffusion, [Online] 2013, Available at [http://www.enel.com/en-GB/innovation/smart\\_grids/smart\\_metering/spread.aspx](http://www.enel.com/en-GB/innovation/smart_grids/smart_metering/spread.aspx) (Accessed on August 2, 2013).)

For the communication between concentrator and meters, two protocols (using narrowband PLC) are used:

- ENEL's own SITRED protocol, based on a simple narrowband FSK-based solution (similar to IEC 61334-5-2, in CENELEC band A). It uses a carrier frequency of 82 kHz and is relatively reliable throughout their whole diverse grid. The attainable speed is only about 2400–4800 baud, but the cost of transceivers and coupling devices is limited.
- An enhanced version of LonTalk PLC, using two carriers at 86 and 75 kHz. Depending on the noise level, the system can switch between the two.

LonTalk and SITRED differ in the PHY and MAC layers, but the same proprietary application layer is used on top of both, ensuring transparency for the acquisition center. The details on this application layer are sparse, but apparently, it allows autodiscovery of meters and network autoconfiguration.

During the peak of deployment, more than 40,000 m were installed a day by about 4,000 workers (Figure 60.9). Installation and initialization takes 15–30 min using an HHU after which the control center commissions the meter via the data concentrator. The latter detects the communication path and the phase to which the meter is connected without topology information, in order to assign the meter's real address. The control center reaches 97%–99% of the meters on the first connection attempt. This is not very high with such an installed user base (30 million meters and 350,000 data concentrators).

By the end of 2006, about 29.8 million meters had been installed. Eventually, ENEL announced to make its system open to the market and started the *Meters and More* alliance together with Spanish utility Endesa and IBM to further promote the technology.

With *Meters and More*, focus is being put on making energy data available in the home, via the smart meter. This would enable new applications, such as in-home energy displays and appliances that react to the current or future tariff. In 2009, Enel performed a field test in 1000 households with in-home displays to analyze the impact on customer behavior.

### 60.2.6 SML (SyM<sup>2</sup> Project)

The Smart Message Language (SML) is a communication protocol for data acquisition and parameterization developed by the German utility companies RWE, EON, and EnBW. The main idea

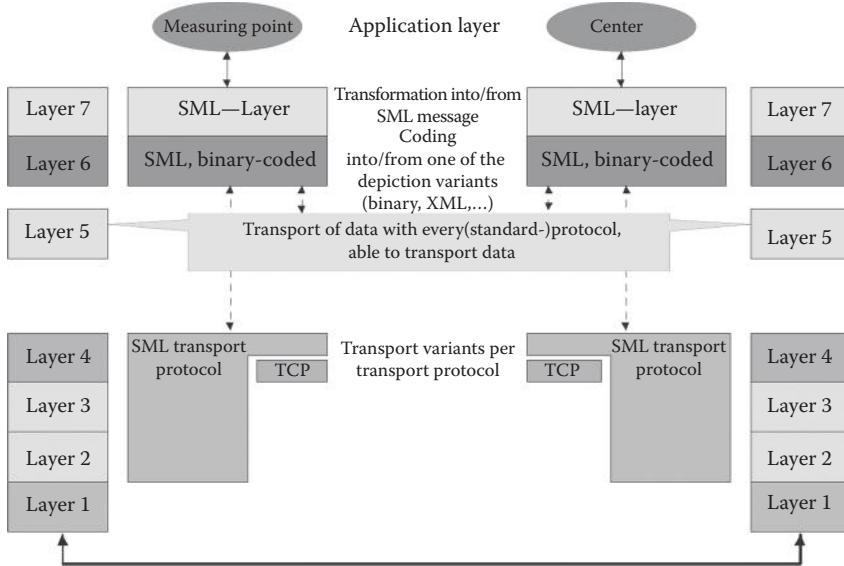

FIGURE 60.10 SML communication model overview, from the SML 1.02 specification document.

is to have a simple structure that is usable in low-power embedded devices (Figure 60.10). Therefore, SML message can be transported over stateless, secure communication paths, and both push and pull operations are supported (not limited to a fixed client–server model).

SML is tailored toward electricity metering and has to be viewed alongside the SyM<sup>2</sup> project. This is a joint venture between RWE, EON, and Landis+Gyr to develop an industry standard specification for load profile meters in Germany.

#### 60.2.6.1 Application Layer

The application layer defines a file and document structure to carry a useful payload between the measuring point and, for example, the data collection center.

SML messages can be grouped together in self-contained information units called *files* that are independent of the transport technology used. An SML file is always structured as a chain of SML messages and can be segmented to reduce the size. An SML message must be either a Request or Response message and contains tasks and assigned attributes (including a transaction ID and a group number to process messages in a particular sequence or simultaneously).

The SML documentation does not refer to encryption, because it only provides a framework for the transmission of signatures. The encryption method itself is determined by the selected application. This is typically defined in a so-called companion specification, such as Sym<sup>2</sup> or Multiutility Communications Controller.

#### 60.2.6.2 Presentation Layer

In the presentation layer, SML provides two options: SML binary coding and XML encoding. The binary coding is optimized to be data efficient, where the XML format is human readable but takes up much more data volume. The SML binary encoding is detailed in Section 6 of the specification. It is based on a classic type–length–value structure. The type and length are grouped together in one single byte for most cases.

#### 60.2.6.3 Transport Layer and Below

In typical metering applications, SML messages are transported using TCP/UDP transport layers over IP networks. However, for (unsecured) serial links such as GSM/PSTN or direct readout links, the SML transport protocol is available.

First of all, SML is focused and tailored specifically toward electricity metering and has to be viewed alongside the SyM<sup>2</sup> project. SYM<sup>2</sup> is a set of specifications for a modular smart meter, with a strong focus on clock synchronized and signed meter data, and interchangeable communication modules.

SML only defines a message structure but does not specify an object model, nor does it specify what functions should be supported. There are also no interface classes such as in COSEM. SML does however support the Object Identification System (OBIS) codes as maintained by the DLMS User Association. However, SML may specify additional functionality for which no OBIS codes exist. Thus, the use of companion specifications is necessary (such as SyM<sup>2</sup>).

SML is under consideration as messaging method for DLMS/COSEM, as IEC 62056-5-3-8. At the moment, SML is not used outside of Germany. In the rest of Europe, DLMS/COSEM has received wider industry support and is already an IEC standard.

Additionally, it was decided (BSI-TR-03109-1) that SML has to be supported by the Smart Meter Gateway with the smart meters in Germany, but it is only mentioned for the communication with the local meters (LMN), not in the protocol stack for the WAN communication.

## 60.2.7 EN 13757/M-Bus

EN 13757 (Meter bus) is a European standard for the remote interaction with utility meters (originally electricity and gas, called *meters* in the specification) and various sensors and actuators (*other*), which was developed by the University of Paderborn and Texas Instruments.

M-Bus is primarily focused at the special requirements of simple remotely or battery-powered systems. When interrogated, the meters on the bus deliver the data they have collected to a common master, such as a utility's handheld computer. Alternatively, data can also be collected by transmitting them over a PSTN modem line.

Several physical media are supported including twisted pair and wireless M-Bus (in the ISM band). The twisted pair medium typically operates at 2400–9600 baud, and a single segment can be up to a few kilometers long. Noteworthy is the support for DLMS/COSEM in the lower layers.

The DSMR and German Technische Richtlinie BSI TR-03109-1 both specify wired and/or wireless M-Bus as the means of communication between a metering installation and other (gas, water, etc.) meters, albeit with improved security (AES instead of DES). As this standard is already widely used in meters and reasonably future proof, it is almost indispensable for local data exchange in the smart grid architecture.

### 60.2.7.1 Structure

M-Bus uses a reduced OSI three-layer structure, as shown in Table 60.1, consisting of the following.

#### 60.2.7.1.1 Physical Layer

Several physical media are covered, such as twisted pair baseband signaling (EN 13757-2) and *local bus* accordingly (EN 13757-6).

Using the twisted pair system (Figure 60.11), signaling from master to slave takes place by voltage-level changes (up to  $\pm 42$  V). The slaves thereby act as constant current sinks. Range is up to a few kilometers, and typical data rate is 2400–9600 baud, but up to 38,400 baud is supported.

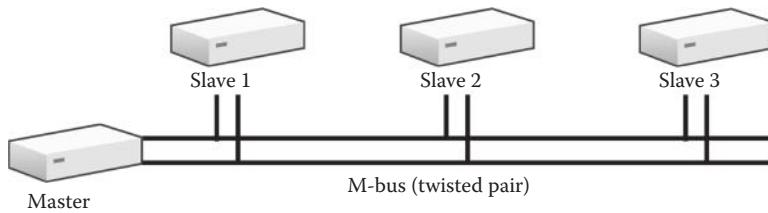

Meters that are connected with the twisted pair media can also be powered through these, plus the wires can be interchanged without damage to the connected equipment.

The wireless version (EN 13757-4) operates in the ISM band of 869–980 MHz for short-range devices. This allows data exchange up to about 15 m, extendable by using relaying methods (specified in EN 13757-5).

Several types of communication are defined: Mode S (stationary mode), Mode T (frequent transmit mode, where the meter periodically transmits its data), and Mode R (frequent receive mode). They differ

**TABLE 60.1** Parts of the EN 13757 Standard

ISO Layer	Type of Layer	Functions	Standard Part
Application layer	Application-oriented layers	Data structures, data types, actions	EN 13757-3
Presentation layer		Empty	
Session layer		Empty	
Transport layer	Transport-oriented layers	Empty	
Network layer		Routing (optional)	
Data link layer		Transmission parameters, telegram formats, addressing, data integrity	EN 13757-2
Physical layer		Cable type, bit representation, bus extensions, topology, electrical specification	EN 13757-2 EN 13757-4

**FIGURE 60.11** Master–slave M-Bus twisted pair system.

by transmission speed (4.8 to 100 kchip/s\*), coding, bandwidth, and some other technical aspects. The physical layer and data link layer of KNX-RF were defined jointly with the wireless MBUS standard, and S-mode corresponds with KNX-RF.

Recently, new modes have been added to Wireless M-Bus: C-mode (*compact mode*; derived from the T-mode but reduced complexity) and N-mode (at 169 MHz and high power, for long-range meter reading +1 km). There are also extensions following the meter standardization work in the Netherlands (NTA 8130), Denmark, Germany (Open Metering Specification), and France.

#### 60.2.7.1.2 Link Layer

A link layer based on the format class FT1.2 (defined in EN 60870-5-1) and a telegram structure based on EN 60870-5-2. This standard, also known as IEC 870-5, defines the transmission protocols for tele-control equipment and systems (also used in SCADA communication). The M-Bus protocol derives from this standard but does not use all the IEC functions.

#### 60.2.7.1.3 Application Layer

The dedicated M-Bus application layer as defined in EN 13757-3 can have an either fixed or variable data structure and can transport either the dedicated layer specified in EN 13757-3 or DLMS/COSEM type of data. The maximum length of a telegram is recommended to be 255 bytes, as longer messages could lead to problems in modem communication. The upper limit for characters in the variable data blocks is therefore limited to 240 bytes.

Encryption is mandatory. EN 13757-3 (Section 60.5.10) defines DES encryption for the M-Bus telegrams, which is nowadays considered as insecure. Authentication is not supported. The Dutch DSMR

\* In systems using spread-spectrum signals, a single data bit is transmitted using a sequence of symbols or chips. The chip rate thus refers to the symbol rate of the physically transmitted signal and is generally lower than the effective data bit rate.

project deviates from the standard and specifies that the preferred encryption is AES (Advanced Encryption Standard; Federal Information Processing Standard [FIPS] 197).

DLMS/COSEM devices such as electricity meters can be set up as M-Bus masters (using M-Bus client objects). M-Bus protocol parameters are mapped to attributes, and M-Bus functions are mapped to methods. Then, data can be exchanged with M-Bus slaves, such as gas, heat, or water meters, and stored in COSEM objects. The objects are then suitable to be collected by the DCS (Data Collection System). The clients can also send commands to the M-Bus devices. It should be noted that this is not the same as the DLMS/COSEM support in the M-Bus protocol itself. The extensions resulting from the DSMR specifications are likely to be included in the next revision of EN 13757.

### 60.2.7.2 Conclusion

M-Bus is a specification mainly targeted at local in-house data exchange. It can be implemented with a twisted pair cabling system or using a wireless system in the ISM band. M-Bus is optimized to be able to work on simple battery-powered devices with modest requirements. The lower layers of M-Bus support DLMS/COSEM and DLMS/COSEM devices can be set up as M-Bus masters, making the two very compatible.

### 60.2.8 DLMS/COSEM and IEC 62056

DLMS originally stands for the Distribution Line Message Specification and is an application layer specification, aimed at messaging between (energy) distribution devices. It is an international standard established by IEC TC 57 and published as IEC 61334-4-41.

Later on, this standard became the Device Language Message Specification and integrated into the IEC 62056 series of standards. It specifies general concepts for the modeling of object-related services, communication entities, and protocols for energy metering.

COSEM stands for COmpanion Specification for Energy Metering and provides an object-oriented interface model of communicating metering equipment, based on OBIS (Object Identification System) codes.

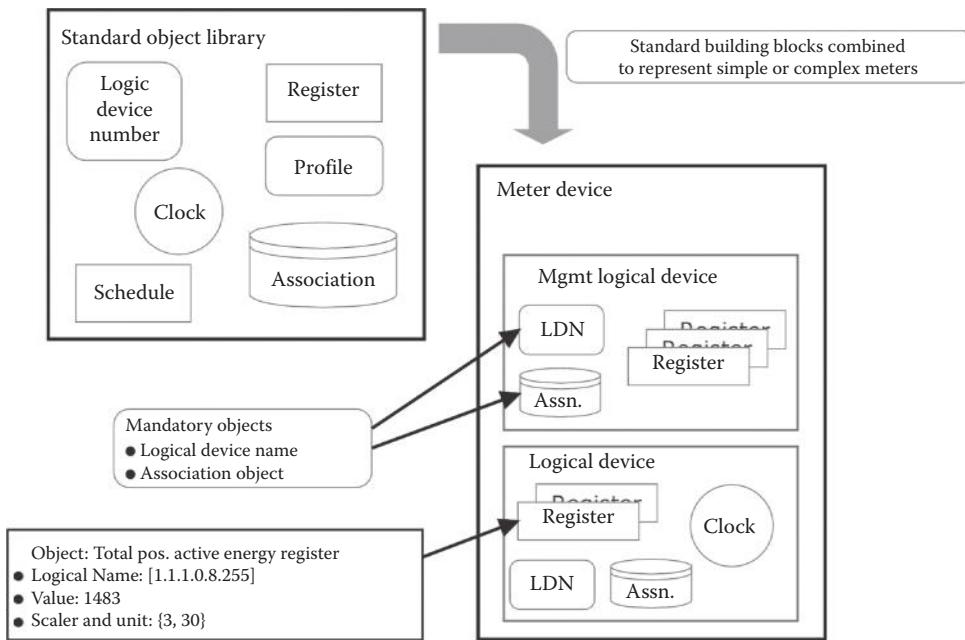

Finally, xDLMS is an extension to the original DLMS and describes how to access attributes and methods of COSEM objects. The original DLMS standard was IEC 61334-4-41 and did not provide a meter data model or a naming system. When combined with COSEM, as DLMS/COSEM, only a part of the original DLMS standard is used, but a few extensions were added to make more efficient use of the COSEM data model. This is what constitutes xDLMS.

The full specification of DLMS/COSEM is divided over four *colored books* that are maintained by the DLMS User Association:

1. The Blue book details the data model, comprising the COSEM interface classes and the OBIS codes for the various energy types. This specification is standardized by the IEC and CEN.
2. The Green book specifies the protocols that can support DLMS and refer to various ISO, IEC, NIST, and Internet standards.
3. The Yellow book specifies the conformance and certification test plans for the COSEM object model and the communication layers.
4. The White book contains a glossary of terms.

#### 60.2.8.1 COSEM Data Modeling

In order to structure the information and functionality of some physical metering equipment and to control access to it, COSEM standardized building blocks can be combined to model a metering device in a hierarchical structure. There are four groups of COSEM interface classes, relating to storage, access control, time and scheduling, and communication.

**FIGURE 60.12** Combining COSEM standard building blocks to represent meter functionality.

For example, a meter is modeled as a physical device that contains one or more logical devices (LDs). Each LD has a number of interface objects, holding the data in the form of attributes and presenting the functionality of the LD as methods. Methods can be used to examine or modify attributes.

In a physical device, at least a *Management LD* is mandatory. In turn, each LD should at least contain an *LD Name*, a unique identifier for each and every LD worldwide, and an *Association object* to control the access to the objects. Thus, by combining standard objects, complex metering systems can be built. A residential meter will contain on order of a few 10 objects, while an industrial meter could contain more than 100 objects.

Using this system, a wide variety of interoperable products from different manufacturers, from simple to very complex metering equipment, can be supported. An example is shown in Figure 60.12.

A more complex example would be a concentrator handling data for a number of meters. Sticking to the DLMS/COSEM meter model, each set of metering data is handled by an LD implemented in a physical device.

#### 60.2.8.1.1 Management LD

The management LD is the LD, which must always be present in the physical device and for which the upper HDLC address 0x01 is reserved. It holds a list of LDs that are inside the physical device and should at least be accessible for a public client using the lowest security level. This ensures that a device with an unknown structure can be *discovered*.

#### 60.2.8.1.2 LD Name

The *LD name* is used for a worldwide unique identification of each LD and is an octet string of up to 16 octets. The first three octets uniquely identify the manufacturer of the device. It is assigned by the DLMS UA in cooperation with the FLAG Association. The manufacturer is responsible for guaranteeing the uniqueness of the octets that follow (up to 13 octets).

#### 60.2.8.1.3 Association Objects

Access to the objects in a device is controlled by association objects, which provides the list of objects available, authentication rules, and access rights. Associations are established between a client and an LD. They are identified by the pair of client and LD addresses.

#### 60.2.8.1.4 Profile Objects

To efficiently store and process tables of data, such as tariff profiles or logged voltage events, COSEM provides profile objects. Such profiles can be freely parameterized, and the objects have attributes and methods to describe the contents and ways to deliver the data.

### 60.2.8.2 Messaging and Referencing

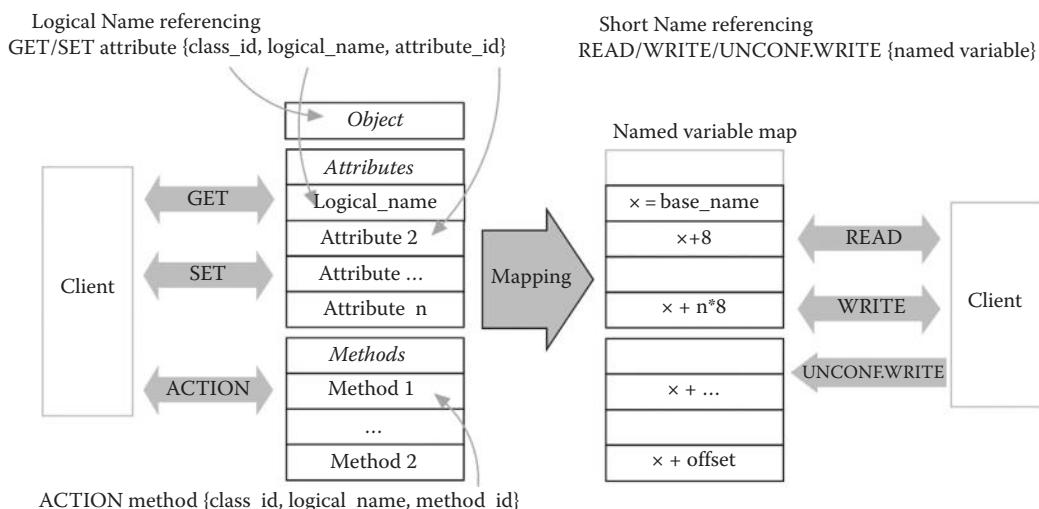

The role of the messaging system is to transform COSEM object information into messages that can be transported by the lower layers. This transformation is performed by the DLMS services, according to a client-server concept. Herein, the DCS acts as a client to the meter and requests certain abstract services (read/write/action) while the LDs in the meter act as servers and respond to those requests.

To access any information modeled with COSEM, such as attributes and methods of objects, they have to be referenced. In the metering equipment (server), the COSEM application layer provides two mechanisms to access attributes: Short Name (SN) referencing and Logical Name (LN) referencing (Figure 60.13). SN referencing has been inherited from the original DLMS standard. The DCS (client) application layer can only use LN referencing.

#### 60.2.8.2.1 Short Name Referencing

With SN referencing, attributes and methods of COSEM objects are mapped to DLMS named variables during the design of the meter. Each named variable is identified with an SN, which is a 16-bit unsigned integer. Attribute 1, the LN of the object, is mapped to a DLMS named variable identified by a base name. There are no general rules defined for assigning base names.

The map with named variables can be retrieved from the meter after which access using SN referencing is provided by the DLMS read/write services.

**FIGURE 60.13** Accessing objects/attributes/methods using Logical Name referencing (left) or Short Name referencing (right).

#### 60.2.8.2.2 LN Referencing

With LN referencing, attributes and methods are accessed via the LN of the object, by specifying the indexes of the attributes or methods. LNs are defined according to OBIS.

When a meter is read using LN referencing, the necessary attributes of certain objects are accessed using an xDLMS service and transformed into a series of bytes, called Application Protocol Data Units (APDUs). OBIS naming is used to identify COSEM objects to make them self-describing. Standard codes for electricity, cold water, hot water, gas, heating, and cooling are defined in the DLMS UA Blue book. A full list of standard OBIS codes and valid combinations of standard values in each group is maintained by the DLMS User Association.

To support future functionality, specific elements such as new OBIS codes, attributes, methods, and interface classes are allowed. However, the information on such elements has to be made available by the manufacturer. Obviously, for standard features, manufacturer-specific *hacks* are not allowed.

#### 60.2.8.3 OBIS Codes

Names of objects are specified by OBIS codes. The list of codes follows a hierarchical structure, using six value groups, in which the meaningful combinations are standardized (Figure 60.14). The OBIS system has its origins in the EDIS system.

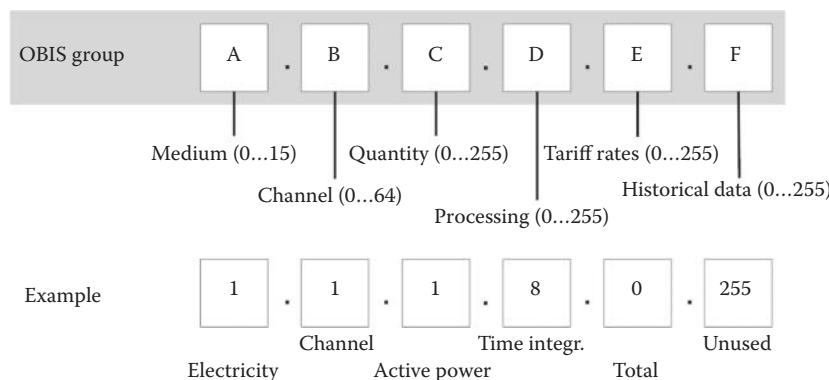

The value group A defines the media (energy type) that the metering is related to (with A = 0 for abstract values). Value group B identifies the measuring channel. Value group C defines the physical quantity measured, while value group D identifies processing methods and country-specific codes. Value group E is typically used for identifying rates. Value group F is used for identifying historical values. Groups B-D have code space for manufacturer-specific identifiers. Some value groups may be suppressed if they are not relevant to an application, for example, by setting group F value to 255.

For example, the LN of a register object holding the total positive active energy could be 1.1.1.8.0.255, while the one holding total positive reactive energy could be 1.1.3.8.0.255.

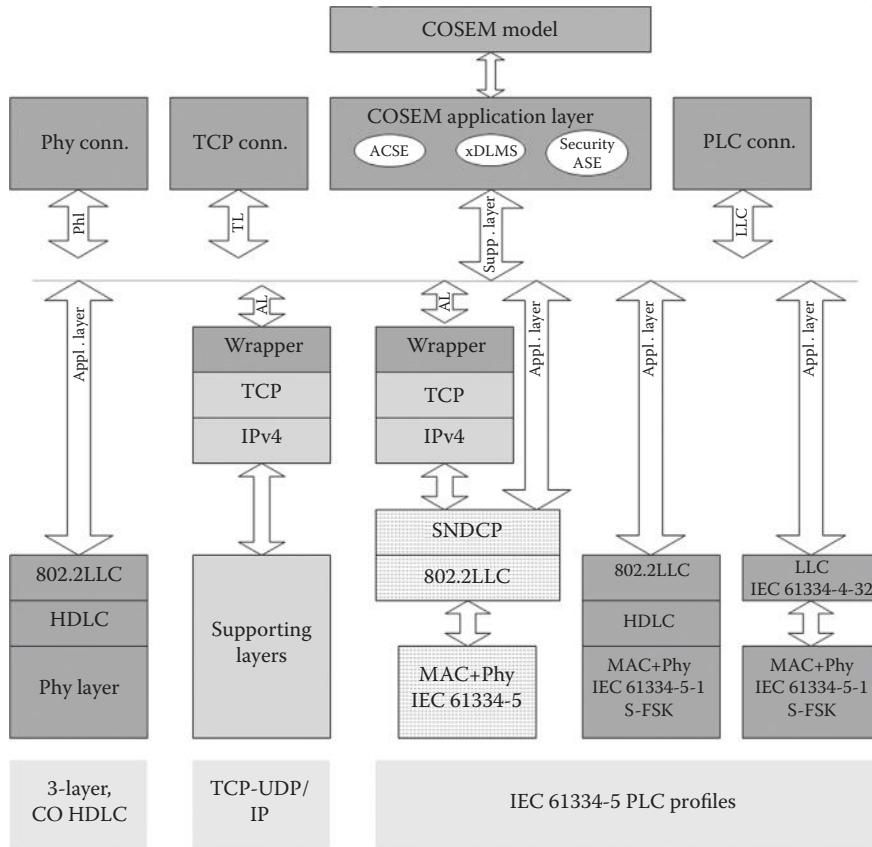

Billing data are modeled as physical quantities and processed as energy (integration) and demand (averaging) quantities. Energy and demand registers can be allocated to tariff schemes and stored over several billing periods.

#### 60.2.8.4 Communication Profiles

In reality, data communication takes place through a communication protocol stack and via the communication media. As in the OSI system, the communication process is divided into independent layers, and various lower layers can be used below the application layer. A combination of the

**FIGURE 60.14** Structure of the OBIS naming system.

**FIGURE 60.15** DLMS/COSEM communication profiles. (From the DLMS/COSEM Architecture and Protocols document, DLMS User Association, Companion specification for energy metering: Architecture and protocols, 2009.)

layers, with always the same application layer on top working directly with the application process, is called a communication profile.

As the communication protocol stack (called a profile) is completely independent of the application layer, the servers and clients may independently support one or more communication profiles to communicate over various media. The COSEM model, used for modeling the application process and the application layer, remains the same.

The DLMS services are defined in a verbal form and are formally using the ASN.1 standard. The information is then turned into bytes using the A-XDR standard (a performance-optimized version of BER). The resulting APDUs are transported by the lower protocol layer over the selected media.

DLMS/COSEM specifies a number of possible communication profiles, some of which are shown in Figure 60.15:

- The three-layer HDLC-based connection-oriented profile. HDLC is a bit-oriented synchronous data link layer protocol. The profile supports data exchange over certain local ports such as RS232, optical links, current loops, and GSM/PSTN connections. Also see IEC 62056-21 *Mode E*.
- A TCP/IP-based communication profile, to support data exchange over the Internet and GPRS connections.
- The PLC profile, as specified in IEC 61334.
- An M-Bus/EN 13757 profile.
- The Euridis/IEC 62056-31 profile, using twisted pair cables.

The Dutch metering project\* specifies that the communication between the residential metering installation and the Central Access Server will use DLMS/COSEM (see DSMR-M 40) and will transfer data either by GPRS, PLC, or Ethernet (see NTA 8130). This implies the use of the TCP/IP profile.

#### 60.2.8.5 Security

DLMS/COSEM provides controlled access to the meter's data with the association objects. Based on these, different clients can be offered a different view of the meter's objects, under the appropriate authentication mechanism. This can be very useful in the deregulated market setting, where multiple parties need access to some part of the meter's data.

There are three authentication mechanisms, negotiated during association establishment:

1. *Lowest-Level Security*: No identification takes place. This is used when no security is required or to establish an association between a public client and the management LD of the server, in order to be able to retrieve the resources of an unknown device.
2. *Low-Level Security*: The server identifies the client, by checking a secret password held by the server. This password can be different for all physical devices, LDs, and associations. Low-Level Security is used when there is no risk of eavesdropping of the communication and replay attacks.
3. *High-Level Security*: Both the server and the client identify the other partner. It is a four-step process during which client and server exchange challenge strings.

In addition to the authentication mechanisms, encryption can be used. This is provided by the xDLMS service element of the application layer.

#### 60.2.8.6 M-Bus Integration

DLMS/COSEM devices such as electricity meters can be set up as M-Bus masters (using M-Bus client objects). M-Bus protocol parameters are mapped to attributes, and M-Bus functions are mapped to methods. Then, data can be exchanged with M-Bus slaves, such as gas, heat, or water meters, and stored in COSEM objects. The objects are then suitable to be collected by the DCS. The clients can also send commands to the M-Bus devices.

#### 60.2.8.7 Conclusion

DLMS/COSEM is positioning itself as the all-round contender for smart grid communication. The support for DLMS/COSEM in a lot of other standards (such as M-Bus, IEC 62056-21, -31, and recently ZigBee), projects (Dutch DSMR), and existing meters illustrates this.

### 60.2.9 IEC 61968 Part 9: System Interfaces for Meter Reading and Control

The Common Information Model specified by the standards IEC 61970 and IEC 61968 is a semantic model that describes the components of an electrical system and their interrelations. It consists of many parts that specify format, for example, exchange of power system network models, and describe processes like asset management, work scheduling, and customer billing. Basically, it consists of the definition of an *information model* (UML-based canonical model), *contextual profiles* (context-specific subsets), and their implementation schemas (XML/RDF).

Part 9 specifies the exchange of information between the AMR metering and other systems and business functions within the Enterprise Resource Planning (ERP) of the utility enterprise. Specific communication protocols (e.g., TCP/IP) are not defined by this standard. It can be used also for

---

\* The document "Dutch smart meter requirements" (DSMR) is an elaboration of the NTA 8130, commissioned by the Dutch grid companies (ENBIN) and aimed at meter interoperability. Also, requirements have been added, mainly with respect to installation and maintenance, quality, and performance.

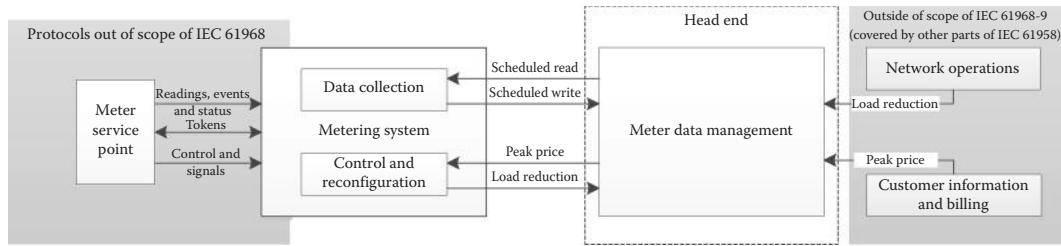

FIGURE 60.16 Simplified IEC 61968-9 reference model with relation to other parts of the standard.

communicating metered quantities of gas or water infrastructure. Information is modeled by a set of messages that support reading and control functions of smart meters. Typical uses are

- Meter reading and control
- Meter events
- Customer Data Sync and Switching

From the common reference model point of view, the smart meter is an *end device*, with a *unique id*. It can be considered as a *physical asset*, which receives *control requests* and collects and *reports* measured values. The smart meter is part of a *business process* including customer and respective contracts, energy market, aggregators, and other ancillary service providers.

The reference model specifies the following functionalities for meter reading and control:

- Metering system includes data collection, control, and reconfiguration.
- Meter data management.
- Maintenance.
- Load management including load control and load analysis.
- Meter asset management.
- Meter administrative functions.

In detail, the relations of the reference model are depicted in Figure 60.16.

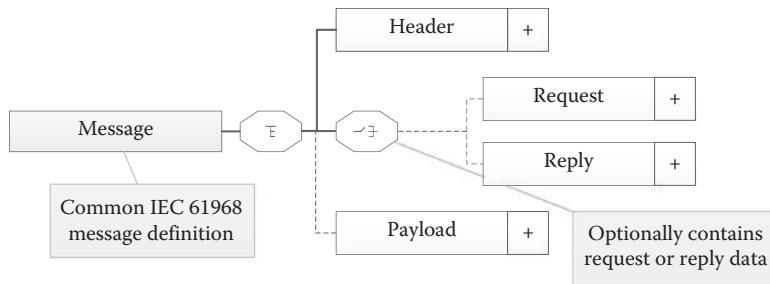

### 60.2.9.1 Message Structure

The message profile according to IEC 61968 (Figure 60.17) is basically structured in the header, containing meta-information and the payload. It can also contain data defining either a request or a reply.

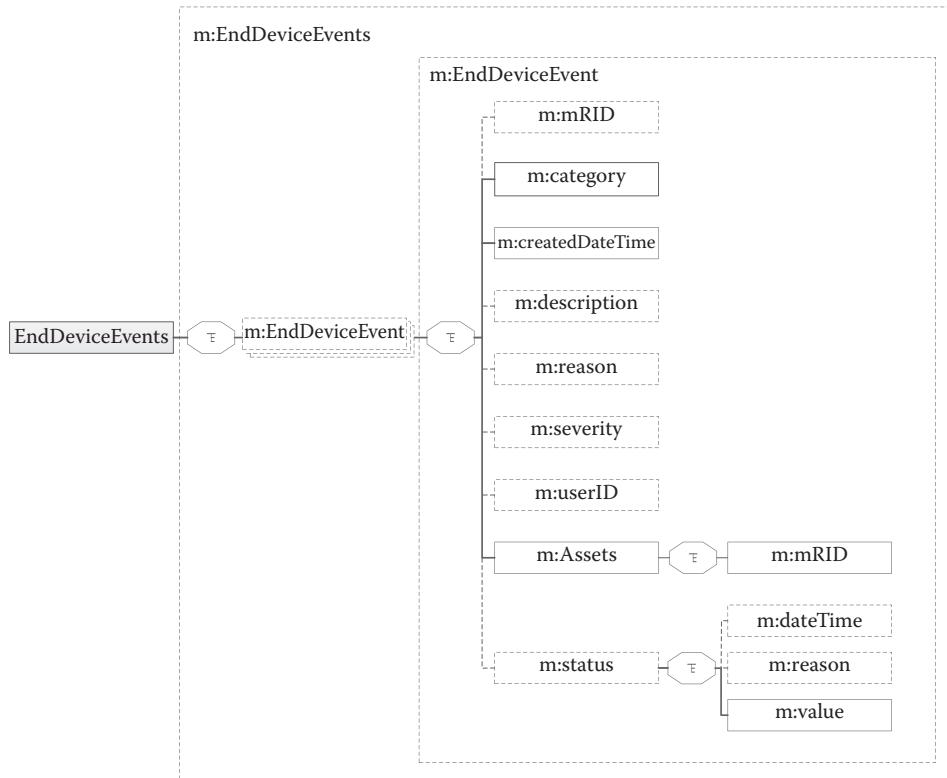

The message types specified include messages for

- CustomerMeterDataSet
- MeterAsset
- MeterAssetReading
- EndDeviceControls
- EndDeviceEvents
- MeterReadings
- MeterReadSchedule
- MeterServiceRequest
- MeterSystemEvents
- EndDeviceFirmware

The EndDeviceEvent is shown in Figure 60.18 as an example for a message type. The reason of the event is also specified and includes, for instance, a sustained outage, a high- or low-voltage threshold, a distortion meter, and a revenue.

**FIGURE 60.17** Common message definition by IEC 61968.

**FIGURE 60.18** Example message “EndDeviceEvents.”

#### 60.2.9.2 IEC 61968-9 and DSLM/COSEM

An extension of CIM has been proposed to include the DSLM/COSEM object model (e.g., physical device and LD) in CIM. IEC 61968 specifies the communication within the ERP to the head-end of the metering system, while the meters can be compliant to DSLM/COSEM. This means, in case of a request from the ERP, that the head-end has a DSLM/COSEM protocol session with the meters, where the IEC 61968 message can provide all the details for addressing the meter and the objects and attributes of interest.

#### 60.2.10 IEC 62056-31 *Euridis*

Euridis is a standard (IEC 1142) for remote and local meter reading introduced at the beginning of the 1990s. In 1999, it was integrated into IEC 62056 as part 31 (*IEC 62056-31 Ed. 1.0:1999 Electricity*

*metering—Data exchange for meter reading, tariff, and load control—Part 31: Using local area networks on twisted pair with carrier signalling).* Euridis is mostly used in francophone countries, and it is estimated that about 10 million meters communicate using Euridis.

Euridis uses a twisted pair cabling system, the local bus, onto which all meters in a building can be linked. It uses OOK (On-Off Keying) amplitude modulation on a 50 kHz carrier. A magnetic coupler then allows connecting an HHU for readout or programming, in a master–slave configuration (referred to as primary and secondary stations). The bus can be up to 500 m or 100 devices and allows a data rate of 1200 baud half-duplex. Functions are provided to perform a complete automatic identification of the stations on the bus.

EURIDIS also provides authentication features upon connection and simple encryption scheme for the data exchanges.

The original Euridis specification does not include a data model. However, at the beginning of 2009, the Euridis+protocol stack was announced, supporting DLMS and allowing data rates of 9600 baud, while retaining backward compatibility.

## 60.2.11 Other Standards with Relevance to Smart Metering

### 60.2.11.1 KNX

KNX is the result of the joint effort of three European consortia working on home and building control, namely, BatiBUS, EIB, and EHS. At the beginning of 2002, a first specification of KNX was made public, which was primarily based on EIB, extended with new communication media and configuration mechanisms originally developed for BatiBUS and EHS. KNX was made into standard ISO/IEC 14543-3-x in November 2006.

KNX defines a hierarchically structured bus (implemented using twisted pair, radio frequency, power line, or IP/Ethernet, or a combination) to which all devices are connected. Devices are sensors and actuators needed for the control of building management equipment such as lighting, blinds, security/monitoring systems, energy management, HVAC systems, metering, audio/video control, and white goods. All their functions can be controlled, monitored, and signaled via a uniform system without the need for any extra control centers.

The KNX specification encompasses the following concepts (Figure 60.19):

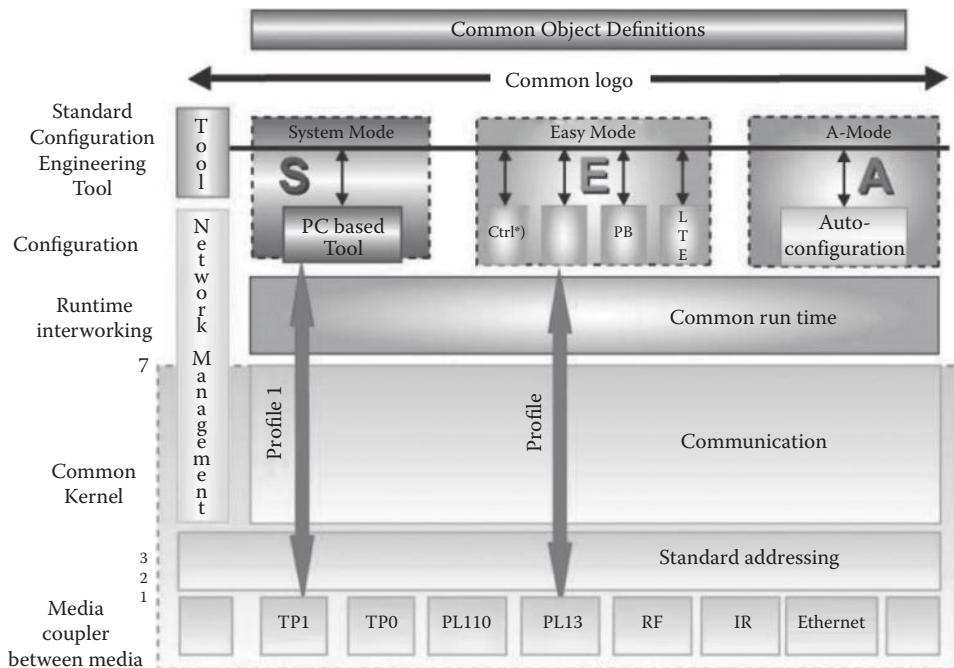

- Interworking and Distributed Application Models for the various tasks of home and building automation
- Schemes for configuration and management (configuration modes, E, S, and A), typically with the PC-based ETS tool
- A communication system, with a set of physical media, a message protocol, and communication stack models
- Device models, summarized in profiles

The KNX specifications are spread over 10 volumes, with volume 3 *System Specification* handling the bulk of the hardware and software implementation. The other volumes cover general architecture, information on specification tests and certification, conformance tests, device profile definitions, etc.

#### 60.2.11.1.1 Application and Interworking Models

A central idea in the KNX Device Network is the data point. Data points can be inputs, outputs, parameters, etc., and implement standardized data point types. They represent the process and control variables of the system.

When a local application in a device (e.g., such as a sensor) writes a value to a *sending data point*, the communication system sends a write message with the corresponding address and the new value.

Ctrl, Controller Approach; LT, Logical Tag (e.g., Code Wheel); PB, Push Button approach; LTE, Logical Tag extended

**FIGURE 60.19** The KNX model. (From Konnex Association, KNX system architecture V3.0, 2009, Available at [http://www.knx.org/fileadmin/downloads/03-KNXStandard/KNXStandardPublicDocuments/03\\_01\\_01Architecturev3.0.zip.](http://www.knx.org/fileadmin/downloads/03-KNXStandard/KNXStandardPublicDocuments/03_01_01Architecturev3.0.zip.))

A *receiving data point* with this same address will inform the local application of the new value, which in turn can then take an action. This action could be an internal state change, updating one of its own *sending data points* or modifying some output in an actuator.

The principal way to realize data points is with group objects. Group objects are accessed via multicast group addressing. Thus, one or more sensors emit a value, and many actuators listen on a given group address. In this way, local applications in a number of devices, with linked data points, combine to form a distributed application.

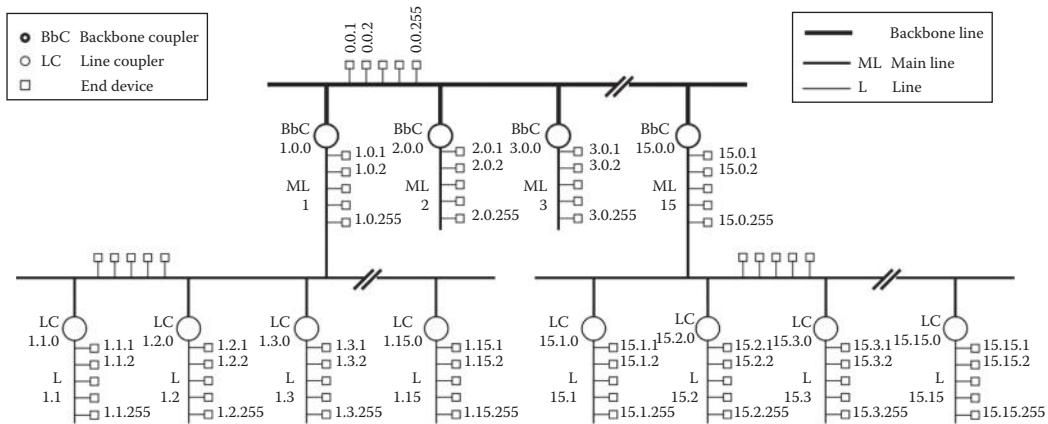

KNX is not limited to grouping devices, as each device can also publish several of its own data points that can be grouped independently into network-wide shared variables.

#### 60.2.11.1.2 Communication System

The logical topology of a KNX installation is structured into a backbone line, main lines, and lines (Figure 60.20). During commissioning, each KNX device is assigned a unique 16-bit *individual address* that reflects the position in this topology. A KNX network contains a single backbone line, to which up to 15 main lines are attached, which in turn allow up to 15 lines to be connected. The connections between the lines are done by couplers.

A *subnetwork* is any part of this topology with the same main line number and the same line number. The backbone line, any main line, and any line are subnetworks.

The KNX end devices can be connected anywhere in this topology, and up to 255 KNX end devices can be addressed in any subnetwork. This results in a maximum 65,536 devices in a backbone line. While different physical layers can be mixed within a KNX network, a subnetwork is the smallest part of the topology that can be implemented with one single physical layer type; it cannot be split.

**FIGURE 60.20** Logical topology of a KNX system. (From Konnex Association, KNX logical topology FAQ, 2005, Available at <http://www.knx.org/fileadmin/downloads/03-KNXStandard/KNXStandardPublicDocuments/FAQLogicalTopology.pdf>.)

#### 60.2.11.1.3 Physical Layers

As mentioned, KNX can be used on top of a number of media:

- **Twisted pair:** There are two twisted pair media specified; TP0, with a bit rate of 4800 bits/s, has been taken over from BatiBUS, and TP1, with an bitrate of 9600 bits/s, has been taken over from EIB. Devices can be powered over the bus.
- **Power line:** Again, two variants are specified—PL110 (operating at 110 kHz, from EIB) and PL132 (at 132 kHz, from EHS).
- **Wireless:** KNX-RF operates in the 838 MHz ISM band. Separate wiring is needed for power, making KNX-RF not widely used. The physical layer and the data link layer of KNX-RF were defined jointly with the wireless MBUS standard, and S-mode complies with the KNX-RF standard. KNX-RF and wireless M-Bus S-mode are equal on the PHY and MAC layer but differ on the higher layers.
- **KNX over IP:** Using UDP (unicast and multicast) allows the use of Ethernet, Bluetooth, Wi-Fi, etc. Usable for high-bandwidth applications.

#### 60.2.11.1.4 Configuration and Management

For the configuration, KNX specifies three modes: system (S), easy (E), and automatic (A). System mode allows sophisticated building setups but needs a separate configuration master (such as the association's own ETS software) and trained installers. Easy mode is meant for installers with basic KNX knowledge, and such devices can only be partly reconfigured. Automatic mode is suitable for end-user installation. Some devices support more than one configuration mode. The KNX standard also has predefined sets of features for many common applications, called profiles.

KNX aims to provide a complete solution for home and building automation and is backed by a lot of manufacturers worldwide. It must be noted that most KNX success stories about reduced energy consumption involve a complex interaction of KNX-enabled boilers, lighting, etc., making the installation costs very high, especially for retrofitting.

#### 60.2.11.2 LonWorks/LonTalk

The heart of the LonWorks technology (Local Operating Network) is the proprietary LonTalk protocol, developed by Echelon. Development of the LonWorks platform began in 1988, and the technology was heavily marketed to the utility industry.

The goal of LonWorks is to make it easy and cost-effective to build open control systems, but before 1996, the LonTalk protocol was only available by using Echelon's proprietary Neuron chip. This guaranteed interoperability. After becoming an open standard (with EIA 709.1 *Control Networking*), the LonMark Interoperability Association became responsible for the certification of interoperable products.

The LonTalk protocol itself is a layered, packet-based, peer-to-peer communications protocol designed to be medium independent but was originally intended for twisted pair and PLC medium. Just as KNX, LonTalk implements a form of network variables (NVs). The application program in a device does not need to know where input and output NVs come from or go to as this is the task of the LonWorks firmware.

Altogether, LonWorks is similar to KNX but is used in a much wider range of applications, well outside the home and building space (e.g., train controls). In 1999, LonTalk was submitted for ANSI standardization, and at the end of 2008, the ISO and IEC made the LonTalk technology into standard ISO/IEC 14908-1 to -4.

More recently, Echelon started marketing its Networked Energy Services (NES), which is an integrated (smart meters, data concentrators, and system software) smart metering solution using the power lines as communication medium, based on LonWorks. The AMM system deployed in Sweden by Vattenfall and E.ON is using Echelon's NES.

### 60.2.11.3 BACnet

BACnet stands for Building and Automation Control Networking and is developed by the BACnet Committee since 1987. In 1995, it was adopted by the American Society of Heating Refrigeration and Air-Conditioning Engineers and became ISO standard 16484-1 to -5 in 2003.

BACnet is an entirely nonproprietary system, with typical applications in the HVAC, lighting, and security domains. A number of network technologies can be used, including Ethernet, LonTalk, ARCnet, ZigBee networks, and BACnet/IP. The latter allows the use of BACnet over virtually any medium.

#### 60.2.11.3.1 Concept

All data in a BACnet system are represented using an object-oriented approach, resulting in objects, properties, and services.

An object contains information relating to physical inputs and outputs, or nonphysical concepts like software, or a group of set points. Objects provide a set of properties that are used to get information from the object or give information and commands to an object. The BACnet specification has a list of standard objects, with predefined properties and behavior.

For example, a temperature sensor might be represented as a BACnet Analog Input object. This object would contain a *Present\_Value* property that contains the current reading, and possibly Min and Max values.

BACnet specifies 123 properties of objects, of which *name*, *type*, and *identifier* have to be present in every object. Some properties can accept writes, while others can only be read.

The act of reading or writing a property is called a *service*, which, following a client-server model, is carried out by the server on behalf of the client. There are 32 standard services in the specification.

BACnet has a Smart Grid Working Group (SG-WG) focused on enabling buildings to interact in the grid. Standard BACnet objects such as the Load Control Object can already be used to track consumption and execute preprogrammed actions accordingly. The BACnet/web services (WS) specification allows external applications to interact with a building automation system and is used in the OpenADR project. The group has also developed definitions for a standard meter object as well as energy profiles (for load, generation, and storage status).

The BACnet Committee has also added ZigBee as a possible data link layer, and the ZigBee Commercial Building Automation Task Group is defining a way to tunnel BACnet traffic through ZigBee networks.

LonWorks and BACnet have overlapping scopes, but the latter has become the first choice at the system management level.

#### 60.2.11.4 ZigBee (Smart Energy Profile)

ZigBee is a low-power wireless communications technology designed for monitoring and control of devices and is maintained and published by the ZigBee Alliance. Home automation is one of the major market areas. ZigBee works on top of the IEEE 802.15.4 standard, in the unlicensed 2.4 GHz or 915/868 MHz bands.

An important feature of ZigBee is the possibility to handle mesh-networking, thereby extending the range and making a ZigBee network self-healing.

The ZigBee Smart Energy Profile (numbered 0x0109) was defined in cooperation with the Homeplug Alliance in order to further enhance earlier HAN specifications. The profile defines device descriptions for meter reading, demand response, meter prepayment, etc.

A collaborative effort between the ZigBee Alliance and the DLMS UA was announced to define a method to tunnel standard DLMS/COSEM messages with metering data through ZigBee Smart Energy networks. In 2011, the smart energy profile was updated to version 1.1, with additions related to dynamic pricing and tariff blocks, prepayment, and enhancements to allow tunneling of other protocols (such as DLMS).

In April 2013, the Smart Energy Profile 2 was published. This profile focuses on IP-based (6LoWPAN) energy management and is not directly compatible with the 1.1 profile. Noteworthy is the support for very large size multidwelling units (where direct wireless connections between meters in a basement and the HAN device in an apartment may not be possible) and features to control PHEVs.

Considering the low power requirements, robustness, availability of cheap ZigBee *kits*, and the specific profile for metering applications, ZigBee has a lot of potential in HANs.

#### 60.2.11.5 Homeplug (Command and Control)

The Homeplug 1.0 standard was published in 2001 by the Homeplug Power line Alliance and allows communication over power lines at 14 Mbps half-duplex. In 2005, it was succeeded by Homeplug AV, allowing over 100 Mbps and meant for HD multimedia applications.

In 2007, version 1.0 of Homeplug Command and Control was announced, providing a PHY and MAC specification for low-speed (up to 5 kbps), low-cost PLC usable in house-control applications (lighting, HVAC, security, and metering) and meter reading. Work on network, transport, and session layers is still reported ongoing. Device profiles will provide a description language to define supported services and actions. A transfer rate of about 5 kbps when using 128 byte packets (at application level) is possible.

Currently, no Homeplug C&C products have hit the market, and it is uncertain whether this technology will be further developed.

#### 60.2.11.6 6LoWPAN

The 6LoWPAN is a standard from the IETF designed from the ground up to be used in small sensor networks, on top of low-power wireless (mesh) networks, specifically IEEE 802.15.4 (thus directly competing with ZigBee). Implementations of 6LoWPAN should easily fit into a few kB of memory. Highlights include support for the Zero-Conf and Neighbor Discovery capabilities of IPv6 and stateless header compression that allows the packets to be as small as 4 bytes. 6LoWPAN could realize the main concept of the *Internet of Things* by making it feasible to assign an IP address to the smallest of devices, sensors, and actuators.

#### 60.2.11.7 DPWS

DPWS stands for Devices Profile for Web Services, and its goal is to integrate devices with Internet WS. DPWS 1.1 was approved as an OASIS Standard in June 2009. The full protocol stack is composed of several web standards, such as WSDL, XML, SOAP, and a host of WS standards. DPWS is similar to Universal Plug and Play but puts more focus on WS technology. DPWS enables secure WS messaging, discovery, description, and eventing on embedded, resource-constrained devices.

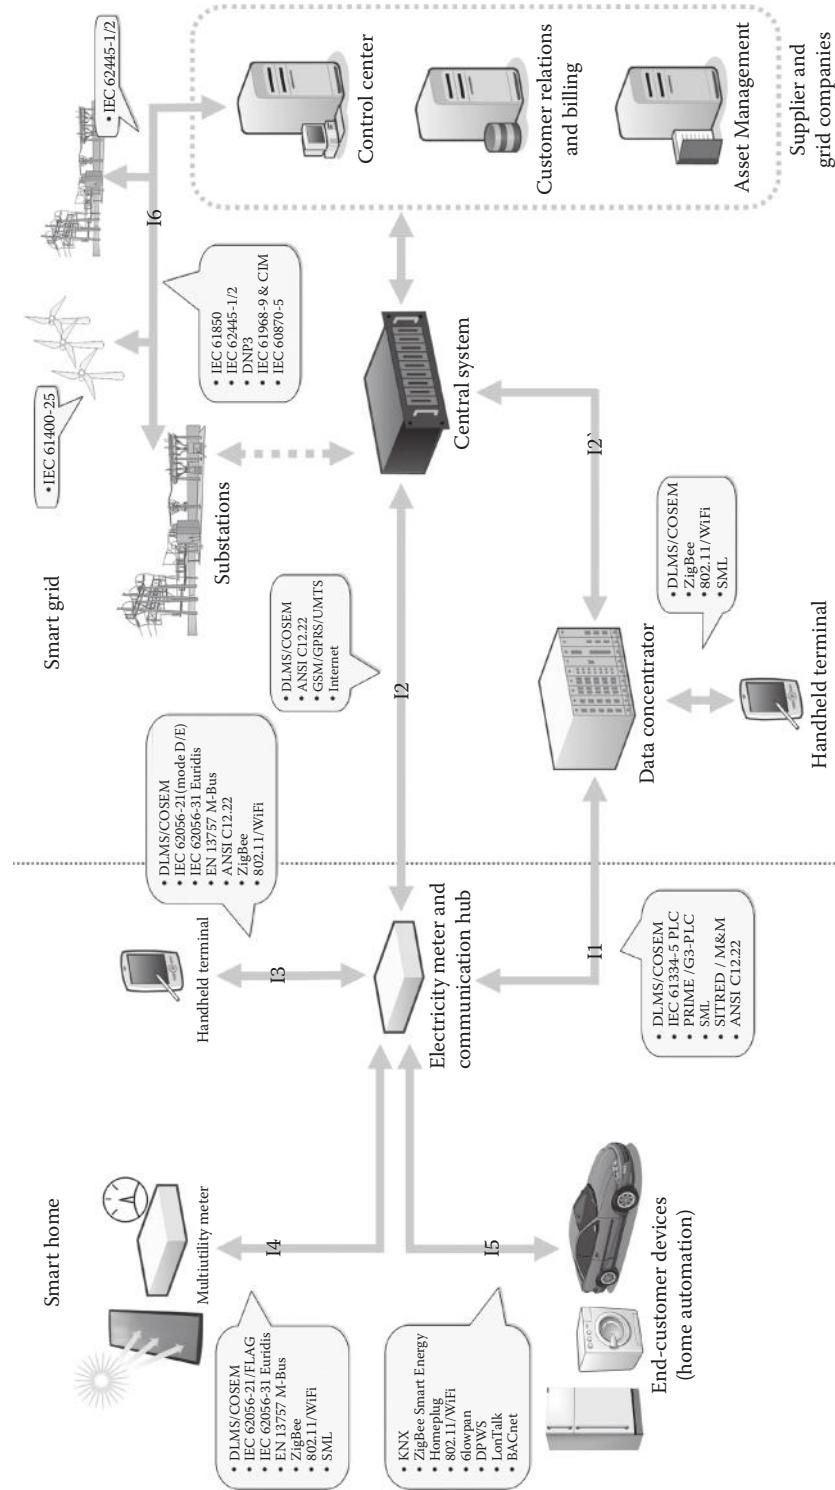

FIGURE 60.21 Placement of the analyzed standards in the smart grid architecture.

## 60.3 Suitability in the SG Architecture

In Figure 60.21, most of the legacy systems are situated within the dotted area marked as *supplier and grid companies*, and the transmission and substation systems pictured above them. On the lower levels of the net, command-and-control systems are less common. In a typical system for smart meter, we find the following interfaces:

- Interface I1: The communication between a data concentrator and a consumer's electricity meter. Data concentrators are used when a direct connection from the central server to the meter is not possible (e.g., PLC systems) or practical. An HHU can be connected for maintenance.
- Interface I2: Direct communication between the meter and the central system. This will typically be based on GPRS/UMTS/LTE or an already available broadband Internet connection.
- Interface I3: Connection between the meter and a local terminal (for installation and configuration). It is comparable to the case of the data concentrator, with wireless functionality making cost-effective *drive-by meter reading* possible.
- Interface I4: Communication between the central meter and secondary meters (e.g., domestic solar panel arrays) or multiutility meters for gas, water, or heat.
- Interface I5: Communication between the meter and a HAN for home automation and domotics, enabling advanced demand response and load-shedding functionality. In-home displays and controllers will communicate with the meter via this interface.
- Interface I6: Communication for command and control of DER and control centers. These protocols were not covered in this chapter.

## 60.4 Conclusions

The rollout of smart meters that are currently under progress in many countries necessitates the need for interoperable and future-proof solutions that are available today. In this chapter, an overview was given of communication standards relevant to AMR and smart meters. Of course, many more technologies are out there, but most of them lack wide acceptance and flexibility or are still nascent or vendor controlled. The latter is especially true in connection with home and building automation space.

When talking strictly about meter data exchange itself, the leading standard would be DLMS/COSEM. As an application layer protocol, it can be used over virtually any medium, and more importantly, commercial solutions are available today.

### 61.1 Introduction

---

The area of power system automation has developed over more than 100 years. Compared to other automation application areas, the automation pyramid is rather large, spanning from field-level controls such as voltage and frequency control at generation units up to wide-area monitoring systems with phasor measurement units and cross-nation SCADA systems for transmission networks. However, due to stability of the architecture and operation principles of power grid over many decades, the job to be done by power grid automation and its underlying communication protocols did not change a lot over long periods. This left room for improvements that became available with technology innovations. The introduction of high-bandwidth wide-area communications was one of these technical improvements.

In recent years, requirements have changed dramatically. The massive integration of renewable energies into the existing infrastructure has changed operation paradigms of transmission and distribution power grids. Automation infrastructure is needed more urgently than ever before. This results in a paradigm shift, where automation systems, which in the past were usually considered as secondary infrastructure, become a central role in the electricity system. Typical tasks for these systems are remote access of field

devices, substations, etc., or metering data for billing purposes on the enterprise side. New protocols have developed, dealing, for example, with large-scale meter readings, communication with electric cars, or management of demand response. Compared to the well-established automation protocols, there are manifold approaches and competing solutions with very different levels of standardization.

The typical power system automation architecture starts from operation centers, connecting the user interfaces of the SCADA systems via a wide-area network (WAN) connection typically isolated from other communication networks such as enterprise local-area network (LAN) or Internet with substations and associated field devices (sensors, switches, and protection devices). A wide range of protocols are used within this architecture: IEC 60870-5 within the WAN, Modbus, DNP3, IEC 61850 within substations, RS485, RS232, wired connections, field buses on the field level, and many others. In the following, a light will put on the most widely used candidates among these protocols. There is, however, usually just a very simple paradigm on the application layer: each data point is connected from its physical position like a virtual connection to the SCADA system.

In parallel with such substation automation systems, dedicated infrastructure for remote metering and wide-area sensor networks (e.g., phasor measurement units) are in operation. These systems are usually physically separated from each other for security and dependability reasons. Further, at the control center level, many centralized IT systems exist for applications like billing or energy trading.

A number of communication-related challenges have to be resolved in future smart grids, such as interoperability (see, e.g., the common information model [CIM]), security, and infrastructure costs. Most of these challenges are not caused by the centralized parts, but happen at the interface between centralized and distributed controls. First of all, the smart grid automation system is far from being homogeneous. The IEEE Guide for Smart Grid Interoperability describes the smart grid as a system of systems [26]. Many of the relevant subsystems already exist today. Others are currently emerging and driven by new smart grid use cases (such as electric mobility operators or load aggregators). From the functionality side, there is a strong trend toward interconnection of currently separated systems (e.g., metering infrastructure and grid operation networks) in order to use meters as field sensors. Also from an economic viewpoint, setting up dedicated infrastructure for different applications is not favorable. Currently, the rollout of smart grid technologies is being held back by significant infrastructure costs. Multiple-use and modular extension capabilities are key factors to reduce investment costs and to avoid stranded costs. However, from a security and dependability viewpoint, this convergence of infrastructure is not always ideal. Most discussions and contributions in the area of power grid communication systems are currently driven by this conflict.

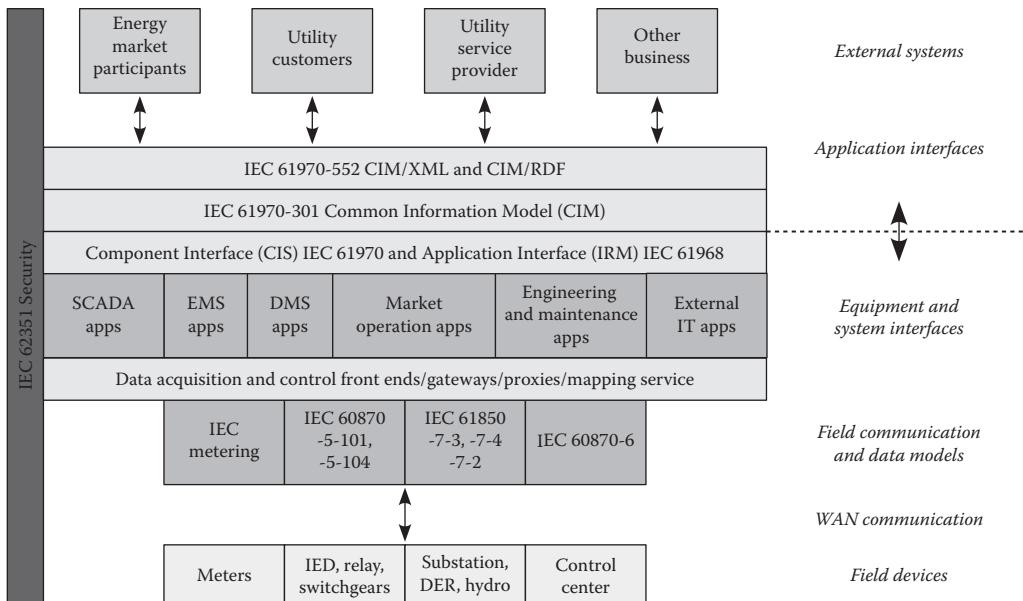

## 61.2 IEC Seamless Integration Architecture

---

As already mentioned in the introduction, the area of power system automation is characterized by the usage of various approaches and communication protocols. The interoperability and data exchange between the different solutions, automation systems, and control devices is a highly important requirement.

The International Electrotechnical Commission (IEC) describes in the technical report (TR) IEC TR 62357 “Power system control and associated communications: Reference architecture for object models, services and protocols” [25] of the Technical Commission (TC) TC 57 “Power Systems Management and Associated Information Exchange” different IEC standards families and proposals, which provide the basis for the implementation of a Seamless Integration Architecture (SIA) for the power generation, transmission, and distribution domain. Moreover, this IEC TR should also help to identify inconsistencies in the usage of these standards and to identify open gaps, which should be filled by the development of new IEC standards in the power and energy domain. An overview of the IEC SIA is provided in Figure 61.1.

IEC TR 62357 describes all existing object models, services, and protocols and their interrelation, which have been suggested by the IEC TC 57 for the domain of power generation, transmission, and

**FIGURE 61.1** IEC TR 62357: TC 57 Seamless Integration Architecture. (From Appelrath, H.-J. et al., *Future Energy Grid*, Springer DE, 2012; IEC TC 57, IEC/TR 62357: Power system control and associated communications—Reference architecture for object models, services and protocols, Technical Report IEC/TR 62357, International Electrotechnical Commission, Geneva, Switzerland, 2003.)

distribution. It covers interfaces, data models, exchange formats, and communication protocols from the field up to the business process layer. This includes the following core IEC standard families for the realization of smart grids:

- IEC 61970/61968: The CIM provides a kind of domain ontology for power transmission and distribution systems represented in UML.\* In addition, it defines also an exchange format and protocol for network model data using XML† and RDF.‡ Further details of this important energy systems approach are given in Section 61.3.
- IEC 61970: Deals with the information exchange of energy management system (EMS) used for the automation of power transmission grids. It defines especially an application programming interface (API) for EMS.
- IEC 61968: Similar to IEC 61970, this standards family covers the information exchange between distribution management system (DMS) and also defines a corresponding API for these kinds of automation systems.
- IEC 61850: Covers the interoperability of substation and power utility automation systems by the definition of an object-oriented modeling approach and high-level communication protocols. Moreover, it defines an XML-based description language—called Substation Configuration Language (SCL)—for the modeling of the automation equipment and corresponding devices.
- IEC 62351: Defines security concepts and mechanisms for protecting critical infrastructure in the power and energy domain against cyber attacks.

In addition, the IEC 60870-5 remote control approach (for details, see Section 61.4) and the IEC 60870-6 for intercontrol center communication (details see Section 61.5) as well as the well-known functional

\* Unified Modeling Language.

† eXtensible Markup Language.

‡ Resource Description Framework.

safety standard IEC 61508 for programmable electronic devices have also to be taken into account for the domain of smart grid systems.

Summarizing, this IEC TR provides the state of the art for the standard-compliant realization of smart grids [10,25]. Similar interoperability and integration approaches and related architectures are also targeted by the NIST *Conceptual Reference Model* [4] and the IEEE Guide for Smart Grid Interoperability [26].

## 61.3 Common Information Model

---

### 61.3.1 IEC CIM

CIM is defined by a series of documents summarized under the three standards for “Energy Management System Application Program Interfaces EMS-API” (IEC 61970), “Application Integration at Electric Utilities—System Interfaces for Distribution Management” (IEC 61968), and “Framework for Energy Market Communication” (IEC 62325).

A typical application of CIM is the exchange of a power system model data between companies and applications, or other interapplication-related integration issues. The standard basically defines three fundamental parts:

1. *Information model*: A canonical model that defines semantic relations between the objects of the power system. It is modeled in UML and managed in SPARX Enterprise Architect® UML modeling tool.
2. *Contextual profiles*: Specific subset of the CIM, for example, Common Power System Model (CPSM).
3. *Implementation models*: Rules for coding CIM in XML/RDF schemas, for example, schema for power system model exchange or schema for messages.

A semantic information model defines the basic vocabulary or terms of the objects. It defines an ontology that represents the knowledge, business concepts, relationships, and a set of rules. The knowledge can be organized in a discrete layer for independent use by other systems and thus is more scalable, maintainable, and manageable.

The context-specific use is restricted by the profile. It restricts the information model and thus is standardized to provide interoperability.

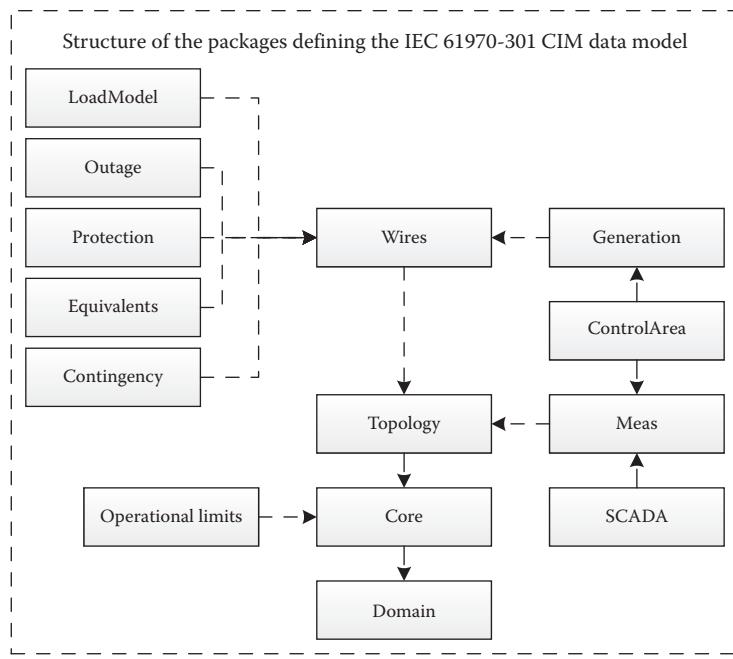

The message syntax is needed to implement the format of the exchanged information. It has to obtain the rules of the format and is covered in different part of the standard.

Besides the data model, the standard series specify interface architectures, general guidelines, implementation profiles, and common services for, for example, data access and exchange, as well as examples.

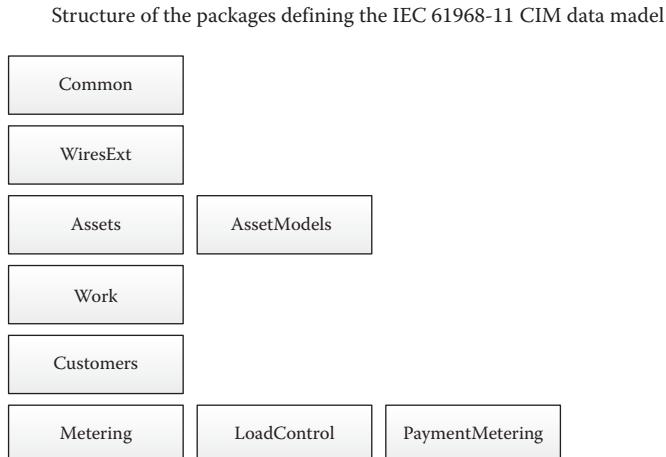

### 61.3.2 CIM Data Model

The CIM core data model is specified by parts of three standards:

1. IEC 61970-301 describes a semantic model or domain ontology of all power system components of an electrical system and their relationship. Physical aspects and complex relations of EMS can be modeled with the classes defined in the packages depicted in Figure 61.2.
2. IEC 61968-11 extends it with other aspects of power system information such as asset management, workforce scheduling, or customer billing. Information exchange requirements for distribution systems, which extend the base model, are modeled with the classes defined by the packages depicted in Figure 61.3.
3. IEC 62325-301 describes the framework for energy market communications. Dealing with the market transaction for energy exchange and market operation (both for the US and EU markets) can be modeled with the packages depicted in Figure 61.4.

**FIGURE 61.2** IEC 61970-301 CIM base data model. (From IEC 61970, Common Information Model (CIM)/Energy Management, Part 1-405, 2013, [www.iec.ch](http://www.iec.ch).)

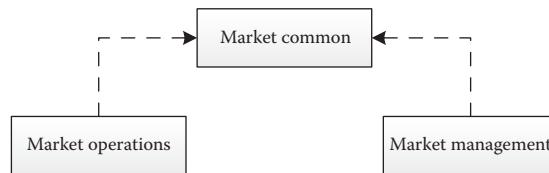

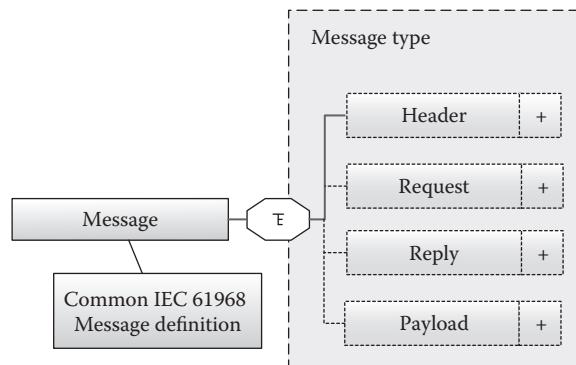

**FIGURE 61.3** IEC 61968-11 CIM base data model. (From IEC 61968, Common Information Model (CIM)/Distribution Management, Part 1-13, 2013, [www.iec.ch](http://www.iec.ch).)

### 61.3.3 Component Interface Specification

This part of the standard series deals mainly with interoperability: system integration issues and their implementation. From application-independent services and interface definition language (IDL), application-specific information exchange model to the mapping to specific technologies (e.g., web services [WS] and XML) are defined in the part 400 documents [46].

Structure of the packages defining the IEC 62325 CIM data model

**FIGURE 61.4** IEC 62325-301 CIM base data model. (From IEC 62325, Framework for Energy Market Communications, Part 1-502, 2013, www.iec.ch.)**FIGURE 61.5** IEC 61968-11 Generic message structure. (From IEC 61968, Common Information Model (CIM)/Distribution Management, Part 1-13, 2013, www.iec.ch.)

### 61.3.4 CIM Profiles

Profiles represent a subset of the CIM model. Since CIM is a very large model, these subsets limit the scope to an application-specific scenario, contextual or domain model [46].

Examples of profiles are as follows:

- CPSM (IEC 61970-452). Execute EMS applications of power flow and state estimation.
- Planning Profile Model for transmission planning power flow. Used to exchange info about contingency, load forecast, scheduling, and operation limits.
- Dynamic stability analysis. Handling of dynamic parameters of vendor dynamic stability packages.
- Common Distribution Power System Model (IEC 61968-13) (CDPSM). Used to execute DMS applications.

### 61.3.5 XML-Based Message Exchange

Due to the loosely coupled heterogeneous infrastructure of many different power system applications and protocols, the purpose of using CIM is to achieve interoperability and format independency of the communicating subsystems. The proposed middleware architectures based on message technologies like WS and Enterprise Service Buses using common integration technologies. The message structure is defined starting from a generic level 5 down to application-specific definitions for, for example, metering data exchange [46] (Figure 61.5):

- Header: basically required and using a common structure of the service interfaces
- Request: optional with qualifier, for example, *get*, *close*, *cancel*

- Reply: only required for response messages with status indicators
- Payload: only required when transporting message information specified in the header

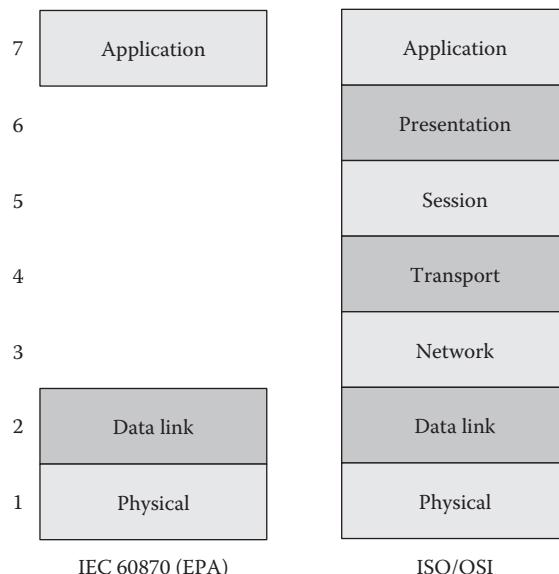

## 61.4 Telecontrol Communication

The IEC 60870-5 standards family describes an open communication approach for industrial automation, which is being applied in (critical) electricity infrastructures such as substations and power grids, but it can generally be also applied to other domains. With IEC 60870-5, it is possible to describe the functions of telecontrol equipment, which is used in geographically widespread processes controlled by SCADA systems. The goal of this specification is to have a standardized approach for transmitting telemetry control and information data in such an automation infrastructure [1,23,36,43].

This protocol specification is based on the enhanced performance architecture (EPA) [21] definition, which describes a three-layer architecture. Originally, IEC 60870-5 was mainly designed for low-bandwidth serial communication, but over the time, the specification has been adopted to be also transmitted over IP networks using TCP. An overview of the IEC 60870-5 protocol specification is provided in Figure 61.6.

IEC 60870-5 has been defined for different purposes, which are described in several parts of this standards family. The following list provides a brief overview of the application areas and the corresponding specifications:

- IEC 60870-5-101: This part of the IEC 60870-5 standards family describes general transmission protocols that have been developed for basic telecontrol tasks. It is mainly used for power system monitoring, control, and the associated communication for control and protection functions in electric power systems and its corresponding components.
- IEC 60870-5-102: It defines a protocol for the transmission of meter data in power systems. This part of the IEC 60870-5 standards family is currently not widely used.

**FIGURE 61.6** IEC 60870-5 three-layer architecture based on EPA specification.

- IEC 60870-5-103: It specifies a protocol for the interoperability of protection equipment/devices and the automation system in substations.
- IEC 60870-5-104: This part of the standard describes the extension of the IEC 60870-5-101 protocol specification for its usage in IP networks. The data transmission is accomplished by encapsulating IEC 60870-5-104 messages in TCP/IP packages.

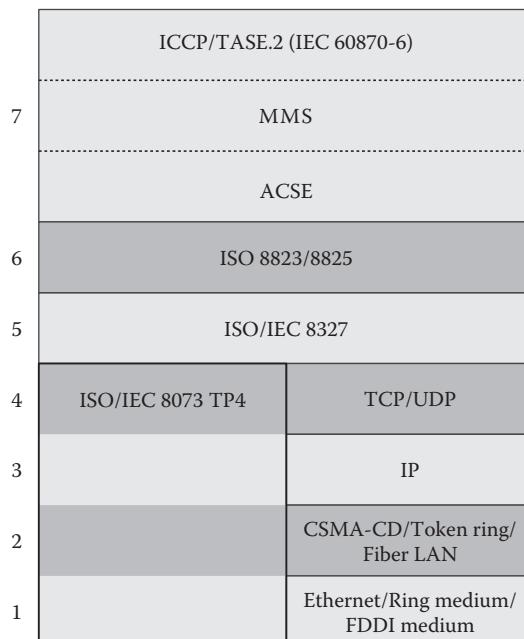

## 61.5 Intercontrol Center Communication

---

Intercontrol Center Protocol (ICCP)—also known as Telecontrol Application Service Element 2 (TASE.2)—is an application-layer protocol specifications, which is used for the data exchange between control centers of electric utilities in WAN and LAN. It was developed by a consortium lead by the Electric Power Research Institute (EPRI) [5]. Today, ICCP/TASE.2 is standardized by IEC in the corresponding IEC 60870-6 series [25].

One very interesting point of this specification is the fact that it is independent of an execution platform/operating systems as well as from the underlying communication layer. In other words, ICCP/TASE.2 is independent of the transport protocol. The protocol specification is based on the ISO 9506 Manufacturing Messaging Specification [2], which is also used by the IEC 61850 interoperability approach for power utility automation [25] and the Association Control Service Element. Originally, ICCP/TASE.2 was developed using only ISO-compliant transport protocol standards, but today, also implementations using packet-oriented approaches like TCP/IP and UDP/IP are very common. An overview of ICCP/TASE.2 in the ISO/OSI model is provided in Figure 61.7.

The ICCP/TASE.2 functions for the intercontrol center data exchange are defined in nine groups called *Conformance Blocks*, whereas the implementation of the first group (i.e., basic services like DataValue, DataSet, and DataSet Transfer objects) is mandatory. The other groups providing more advanced functions and services are related to condition monitoring, messages/alarms, program control, etc.

**FIGURE 61.7** Overview of the ICCP/TASE2 specification using the ISO/OSI model.

## 61.6 Distributed Network Protocol

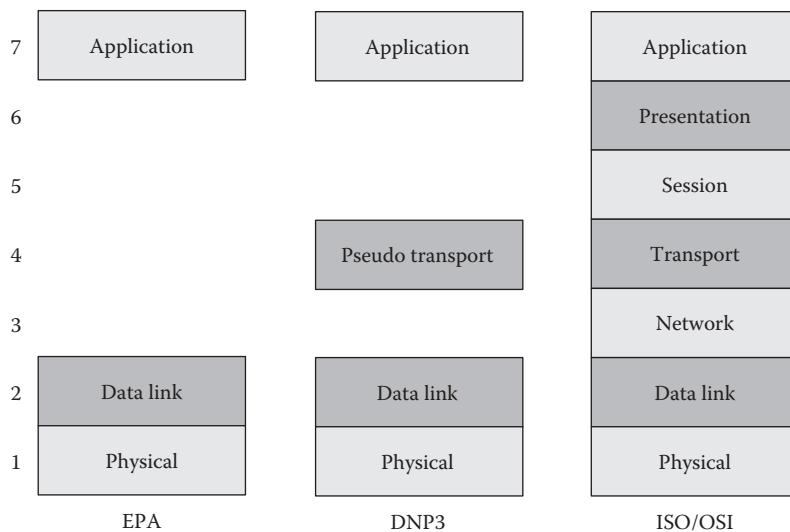

The Distributed Network Protocol Version 3 (DNP3) is a communication approach that has been developed for the information and data exchange in process automation (PA) systems. It is especially being used by electric and water utilities managing their distribution networks. The goal of DNP3 is to connect various devices and equipment used in SCADA systems covering control centers, RTUs, and intelligent electronic devices (IEDs) [14,22].

Originally developed by Westronic (now GE Harris), DNP3 is managed today by the DNP Users Group.\* This SCADA communication approach is based on an early version of the IEC 60870-5 telecontrol specification (details see Section 61.4), but it is not really compatible with it anymore. Since 2012, the DNP3 specification is available as IEEE 1815-2012 standard [6].

Like other SCADA protocols, DNP3 is also based on the EPA specification. Compared with the ISO/OSI model, EPA is a reduced specification covering only the application layer, the data link layer, and the physical layer (normally based on serial communication using RS 232 and RS 485). As a main difference to the EPA and the IEC 60870-5 specification, an additional pseudotransport layer is introduced in DNP3. Figure 61.8 provides an overview of the DNP3 four-layer architecture based on the EPA specification.

The physical layer is not really specified in the DNP3 approach, but general guidelines and rules for networked applications are provided. Moreover, for the avoidance of collisions due to several sending devices, corresponding concepts are defined. Normally, RS 232 or RS 485 serial communication is used by various DNP3 implementations. It is, in principle, also possible to tunnel DNP3 messages over packet-oriented Ethernet networks using TCP/IP or UDP/IP.

Asynchronous and synchronous communication is supported with the DNP3 data link layer. Since RTUs or IEDs support advanced functions and messages that are larger than the maximum data link frame length, a pseudotransport layer has been introduced in the DNP3 specification as mentioned earlier. This additional layer is responsible for message assembly and disassembly and provides corresponding services. With the application layer, various operations on data objects provided by the devices (e.g., RTU and IED) are accomplished. This includes reading and writing values.

**FIGURE 61.8** DNP3 four-layer architecture based on EPA specification.

\* <http://www.dnp.org>.

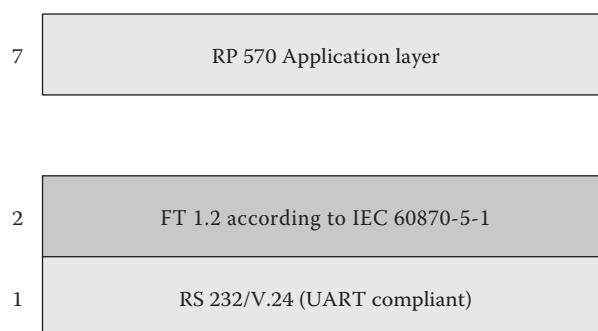

In general, the following three simple communication modes are supported by the DNP3 specification [16]:

1. *Unicast transaction*: A master (e.g., control center) sends out a request message to a specific device (e.g., RTU and IED), whereas this device usually responds with a corresponding message.
2. *Broadcast transaction*: In difference to the unicast transaction, a master sends out a request message to all field devices, whereas the outstation devices are not responding to this request.
3. *Unsolicited responses*: They are sent by the field devices in order to provide periodic updates or alerts (e.g., a measurement value exceeds a threshold).

## 61.7 Other SCADA Communication Protocols

Besides the commonly used and standardized SCADA system communication protocols like IEC 60870-5-101/-104 (for details, see Section 61.4), IEC 60870-6 (details are described in Section 61.5), IEC 61850, and DNP3 (for details, see Section 61.6) also Utility Communications Architecture (UCA) as well as further legacy approaches like Modbus RTU/TCP (for details, see Section 61.9, RP-570), Profibus, and OPC-DA (for details, see Section 61.12) is still applied in industrial systems [12,14,28]. A short summary of those legacy communication protocols is given as follows:

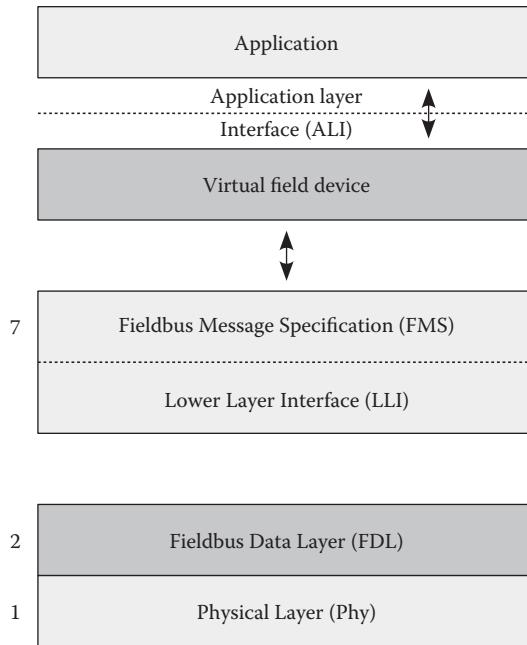

- UCA was an attempt by EPRI and IEEE to define a standardized communication protocol for electric utilities. The development of this approach was started in the beginning of the 1990s. Initially, the focus was on control center communication as well as substation to control center communication (Ed. 1.0). The EPRI/IEEE consortium focuses with version 2.0 on the definition of a common station bus. At the same time, IEC TC 57 started with a similar goal and came out with the well-known IEC 61850 interoperability approach for substation (Ed. 1.0) and power utility automation (Ed. 2.0). In 1997, both groups (i.e., EPRI/IEEE and IEC) joined their forces together resulting in today's IEC 61850 specification. Therefore, UCA 2.0 can be considered as a subset of IEC 61850 [12,15].
- RP-570 (i.e., RTU\*) protocol based on IEC 57 part 5-1† version 0 or 1) was originally developed in the 1990s by ABB as industrial communication protocol for the data exchange between a front-end computer and substations. Therefore, it can be considered as legacy SCADA communication protocol, and it is based on the low-level definition of IEC 60870 using the format class 1.2 [27]. Figure 61.9 shows the RP-570 protocol specification.

**FIGURE 61.9** RP-570 protocol according to the OSI reference model.

\* Remote Terminal Unit.

† Present IEC 60870.

**FIGURE 61.10** PROFIBUS protocol according to the OSI reference model.

- Process Field Bus (PROFIBUS) PA originally developed by Siemens is a communication protocol for the data exchange between measurement and control devices (e.g., RTU, PLC\*) and the SCADA system. It uses the same protocol specification as PROFIBUS decentralized peripherals, which is applied as process field bus for connecting devices on the field layer [19]. An overview of the PROFIBUS protocol specification is provided in Figure 61.10.

In the near future, WS-based communication approaches become widely used [35]. A very promising candidate that is based on this technology is OPC Unified Architecture (OPC-UA) [33]. This upcoming industry standard for machine-to-machine communication uses a service-oriented architecture and is specified in a platform-independent way. This allows implementing it in various embedded devices, RTUs, PLCs, IEDs, as well as in industry PCs. In the IEC 62541 standards family, this important communication approach for the automation industry is defined. Also the mapping of the CIM and IEC 61850 specifications to the OPC-UA object model are currently ongoing (research) activities in the power and energy domain [32,42].

## 61.8 Data and Communication Security

A very important issue in SCADA communication is the protection of the data and information exchange between the power system components, devices, and the control center against cyber attacks [17,24,47]. Therefore, the IEC introduced the IEC 62351 series dealing with information security for power system automation and control applications (e.g., EMS, DMS, distribution automation, smart homes, and automatic meter readings) [3]. It mainly addresses secure communication for the IEC TC 57 developments IEC 60870-5, IEC 60870-6, IEC 61850, IEC 61970, and IEC 61968.

With this important IEC standard, various security mechanisms and objects are introduced. This includes the authentication of data and information transfer using digital signatures. Only authenticated

\* Programmable Logic Controller.

access allows controlling the power system and its connected components. Moreover, the prevention of eavesdropping as well as playback and spoofing is supported. Also mechanisms for intrusion detection are provided by this IEC cyber security specification.

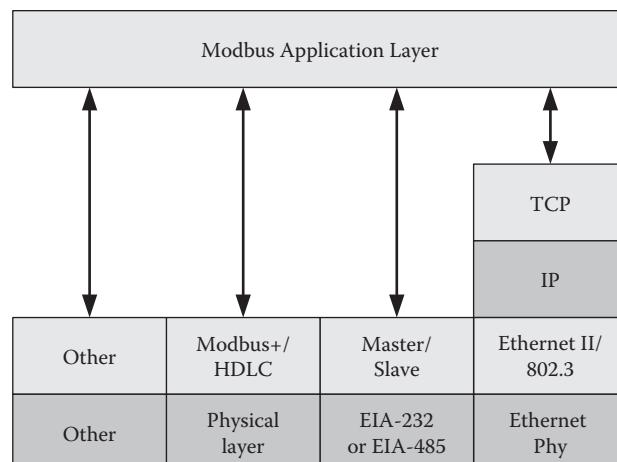

## 61.9 Modbus

Modbus is a flexible and widespread protocol for supervision and control of automation equipment. It is flexible in terms of its data access philosophy, and also in terms of the underlying network technology and topology. In short, Modbus is able to operate over serial lines (EIA 232 and EIA 485) as well as over TCP/IP networks. Modbus communication is client–server–oriented (with multimaster capability) and implements a read/write model of bits or words in a Modbus-specific address space. Modbus/TCP is published in the form of a de-factor industry standard with the Modbus Organization hosting the current specification of the protocol.

Modbus is intended as an application-layer protocol. It supports different types of underlying networks. Most commonly used are the serial variants over EIA 232 and EIA 485, where a Modbus connection can factually be established over a minimum of two (four) twisted wires, as well as the Modbus over TCP/IP version, with Ethernet as underlying physical layer (see Figure 61.11). For high-speed data transfer, the Modbus specification proposes Modbus plus, which is a token-passing network. Since Modbus stays on application level, other physical links can also be used to transmit Modbus data packets.

The Modbus message structure is straightforward; it consists of a function code and an optional data block. The message length can vary. Its maximum is inherited from the first physical layer implementation that was used with Modbus, which was EIA 485 with its limitation to 256 bytes for each protocol data unit (PDU). In Modbus, the pair of function code and data block is referred to as PDU. For communication over a specific network technology, the PDU is extended by a leading protocol-specific addressing block and a trailing error-correction code. The PDU together with these additions is called application data unit.

Modbus has a broad range of applications; these can be found mainly in the field level of power grid automation systems. Modbus is generally used to connect sensors and actuators to a local station's automation bus and thus make them available to the local station SCADA system or even a remote SCADA application. In some cases, the station bus itself is realized as Modbus/TCP bus. In other cases, Modbus is only used for a subset of station equipment.

**FIGURE 61.11** Modbus protocol stack varieties. (From The Modbus Organisation, Modbus application protocol specification v1.1b3, Technical report, The Modbus Organisation, 2012.)

As an application example, the case of an on-load tap changer transformer (transformer with selectable winding ratio) shall be considered. State-of-the-art tap changer controllers often feature Modbus interfaces. The transformer manufacturer defines a number of function-specific Modbus registers. The current tap position as well as the minimum and maximum tap setting can, for example, be held in individual read-only registers. In order to change the tap position, one could choose a solution where just a single register with the destination position is written. For save operation, it is however useful to use two registers, where the first holds the desired position and the second enables the position change. A typical tap changer controller would also feature many more sensor registers, with line currents, nominal values, etc., as well as different mode registers with delay times, etc. By reading and writing the register set via Modbus, all functionalities of the tap changer transformer can easily be accessed.

## 61.10 OpenADR

---

In recent years, one can observe a worldwide trend of utilizing the flexibilities in electrical demand for maintaining the demand-supply balance and management of power grid congestions. Traditionally, it is the task of a few but large bulk generation units to fulfill these functions, but more and more involvement of the demand side in the electric power grid can be observed. These measures are referred to as demand-side management or demand response [30,39]. The drivers for this development are manifold and range from aging infrastructure, restricted generation capacities up to partial loss of controllability on the generation side due to a growing share of renewable energies in the generation mix. While the first demand response schemes were based on telephone calls, where customers were asked in advance to change their load, the first automated demand response (ADR) experiments in the United States were conducted in the 1990s [34].

In order to implement schemes in which electric consumers can offer their flexibility as a service, an appropriate communication system needs to be in place. This is exactly where OpenADR comes into the game. OpenADR is an application-level standard for communication between entities that are required to support demand response, especially utilities, aggregators, and commercial buildings. The standard has been worked out by Demand Response Research Center (DRRC), which itself is managed by US Lawrence Berkeley National Laboratory. It defines a domain-specific data model and different options for message exchange sequences based on this data model. The protocol uses Internet protocols and WS.

In contrast to other ADR protocols, OpenADR's data model does not reference any specific devices. It rather defines a flexible and device-independent set of methods to issue demand response. This can be a concrete request to reduce load by  $x$  kW in 2 h as well as the communication of a time-varying energy tariff. The energy customer does always have the possibility for an opt-out, that is, in critical situations, electrical appliances can remain operative [34]. OpenADR does not specify the way utilities interact with their customers. It rather provides a standardized tool set, from which the utility can choose the elements that support the way the specific demand response scheme is designed.

This philosophy is reflected in the way OpenADR communication is specified. The basic entity for the communication between the demand response automation server and the clients is the *EventState*. An event state contains specific information for a demand response event. Since the design of the demand response program can vary significantly depending on the ideas and requirements of the utility company that defines the program, the data items in an *EventState* are very generic. It usually has a specific time period associated to it in which the event is active. The demand response event itself can be a special energy tariff for the time period or a direct request to reduce load (in categories *moderate*, *high*, and *special* [41], or some other means to specify a demand response event). Using this *EventState*, events can be scheduled as well as activated immediately.

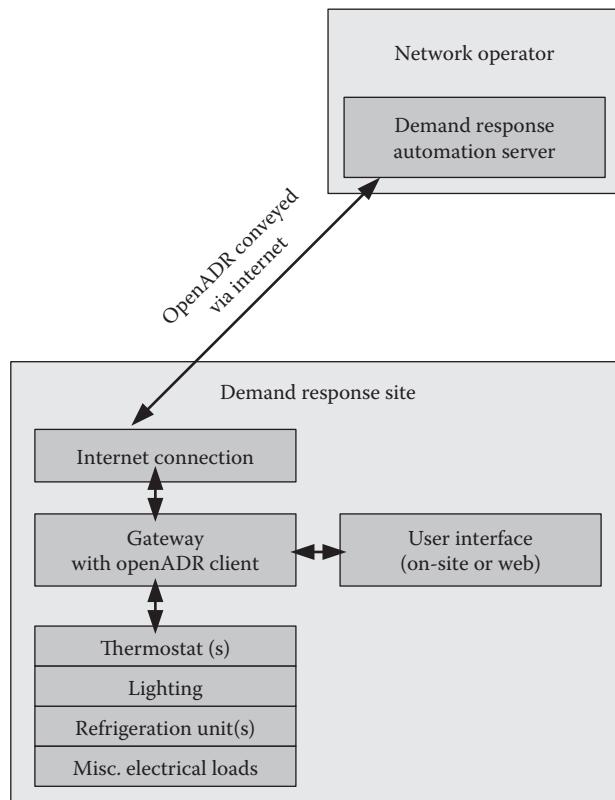

The data fields of an *EventState* are the following [41]:

- *EventState* ID
- Associated demand response program

- Identifier for the event
- Notification time
- Start time
- End time
- Event info instances, etc.

Figure 61.12 depicts a straightforward OpenADR application scenario. The Demand Response Automation Server organizes the EventStates and sends them out to the associated sites, where demand can be remotely managed. The server can use a push or pull model for communication with the sites and therefore is not always a server in the strict sense of the client–server model [41]. The reception of the event state is confirmed by the sites. The on-site OpenADR client can be either an embedded system with simple logic or a PC-based solution with more computation power. The OpenADR specification therefore distinguishes simple and smart clients. The EventState format does differ for the two client types, so that embedded clients do not have to perform extensive parsing and event scheduling [41].

OpenADR does also allow realizing load aggregators. A load aggregator aggregates a number of (flexible) customers and represents them as one large customer to the utility. In this case, the aggregator's OpenADR software is a client toward the utility and a demand response automation server toward the aggregator's contractors.

**FIGURE 61.12** Typical OpenADR application architecture (From Page, J., Kiliccote, S., Dudley, J.H., Piette, M.A., Chiu, A.K., Kellow, B., Koch, E., and Lipkin, P. Automated demand response technology demonstration project for small and medium commercial buildings Ernest Orlando Lawrence Berkeley National Laboratory, Berkeley, CA, 2011.).

## 61.11 EMIX, Energy Interoperability

---

The Organization for the Advancement of Structured Information Standards (OASIS) has formed its Energy Market Information Exchange Technical Committee (EMIX-TC) in order to develop a standard for electricity prices, associated to energy services like power quality or a certain schedule. The outcome is EMIX Version 1.0, available via OASIS. The purpose of this standard is to provide an XML-based language to express [37]:

- Price information
- Bid information
- Time for use or availability
- Units and quantity to be traded
- Characteristics of what is to be traded
- Deal, bid, and acceptance confirmations

If, for instance, a building or a factory participates in a load-shed bidding process, it can use EMIX-based communication to administer the process. EMIX is strongly linked to OASIS WS-Calendar for specifying time aspects.

As EMIX is as generic as possible, it offers extensions to adapt it to particular energy markets like the power market. With this, it is possible to describe electricity-specific terms like reactive power, transport service, or spinning reserve.

One of the profiles defined by EMIX is the Profile for Transactive Power (TeMIX) that defines power delivery in blocks of constant duration (e.g., hourly blocks). Using this, electric vehicles or buildings can express their capabilities and energy market needs on-the-fly. Also power quality and ancillary services are covered by EMIX.

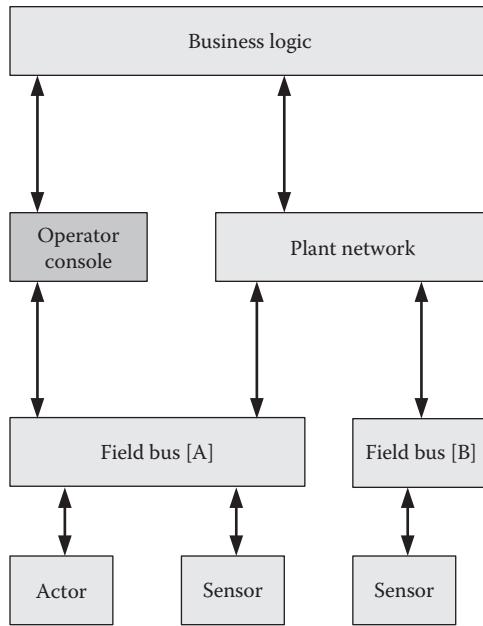

## 61.12 Open Platform Communications

---

The OPC\* standard was originally invented to achieve interoperability between common and also exotic process control system objects and interfaces. Also the integration of data sources in a plant into the plants business logic was a major goal for the OPC Foundation. A normal plant topology consists of a field bus, which interconnects the actor and sensor devices with the control unit and maybe with direct access for the operator console. In a second layer, the plant network interconnects several process management systems and access terminals. In addition, there is a third layer, which interconnects the business logic with the plant network (see Figure 61.13). Each of the field devices and process control system needs its own driver to access the process data. OPC tries to solve this problem by accessing the data sources and databases by an OPC server. The OPC server itself provides a standardized interface for client applications to capture the needed process data. The first standard, OPC-DA (Data Access), is based on Microsoft's COM, DCOM, and OLE and is now at revision 3. Additionally, there are several other specifications to OPC-DA, carried out by the OPC Foundation. The major ones are OPC-A/E, Alarm and Events, and OPC-HDA (Historical Data Access). OPC-DA transports real-time data within the system. The OPC server is not capable of storing historic data. This gap fills OPC-HDA, where capable devices can be accessed to provide historical process data. OPC-A/E is the specification for transporting alarms and events between the devices. It is also based on DCOM and is event driven. Over the years, it has emerged that the relationship of OPC and DCOM is the weak point. DCOM is not capable to communicate between domains and over firewalls, without a loss of flexibility and privacy. The most used way to solve this problem is using specialized programs, which convert the communication from OPC into TCP and vice versa.

## 61.13 Building Automation

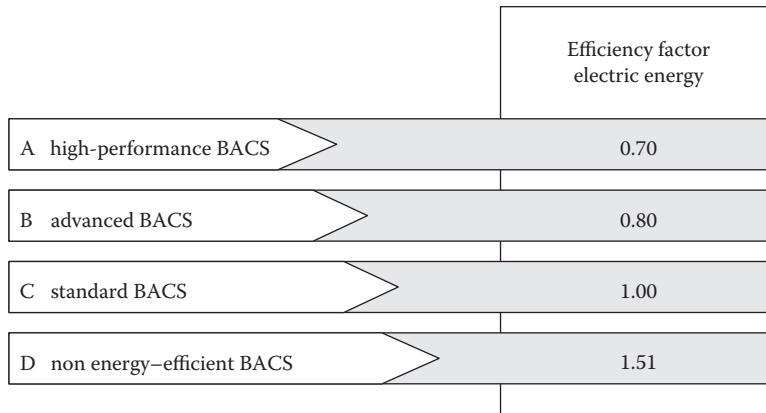

Buildings are responsible for 40% of the energy demand in Western countries. ICT can help to assess, understand, and reduce this demand, both in its dynamics (important for supporting renewable energy sources) and in its total amount (i.e., energy efficiency). One element in implementing the infrastructure for smart buildings is Building Automation and Control Systems (BACSs [11]). BACSs, previously proprietary technologies, dominated by big manufacturers, are now mainly based on public standards and supplied by a large number of small and medium enterprises as well.

Most BACS technologies are application agnostic, but there are still several aspects that expose their relevance for energy-related issues. Applications like demand response [39] and grid-friendly operations [48] are implemented by exploiting the degrees of freedom a BACS offers: shiftable loads, load-shedding, model-based controls [40], smart inverters for local generation, intelligent electric loads [31], etc. The various energy-relevant elements in an automated building are integrated via a BACS network that must fulfill a number of requirements:

- Control cycles/latency of 200 ms (lighting) to 1 min (heating)
- Bandwidth of some kbit/s

These requirements are relaxed and typically easy to achieve with any network technology, wired and wireless. If networks get larger, and if network segments are connected via a backbone, these requirements naturally scale up and might become a challenge. Other requirements that are not so easy to satisfy are as follows:

- Information security: Especially in the case of remote usage and Internet connections.
- Low cost for nodes and communication infrastructure: Some large buildings have more than 100,000 data points.
- Robustness: Self-healing communication channels, reliable transport mechanisms, immunity to electromagnetic interference, etc.
- Interoperability: Multivendor installations in buildings are the standard case, so frictions and errors need to be avoided in a systematic fashion.

**FIGURE 61.14** The impact of BACS onto the energy consumption of an office, based on EN 15232.

Costs are a major factor: Often, energy is simply too cheap to justify expensive investment in ICT [44]. Information security was long neglected, relying on the fact that BACS networks are isolated from hostile public networks and that technologies are proprietary and unknown to the average hacker.

In future, BACS networks will have to incorporate more scalability and flexibility [38], to keep up with the fast pace of IT and Internet business.

Figure 61.14 gives an impression on how BACS can influence the energy balance of buildings. The EN 15232 standard offers evidence-based figures for hotels, schools, and other buildings, depending on how sophisticated their BACS is.

One of the most important aspects of BACS networks in the energy domain is interoperability [29]. The typical two steps to achieve interoperability are to extend the plain protocol specification by standardized data types and standardized functional profiles. They might be called differently in the various BACS technologies (e.g., objects) but are necessary to bring devices of different origin together. Ideally, interoperability is tested and certified [20] in order to allow for clear customer communication.

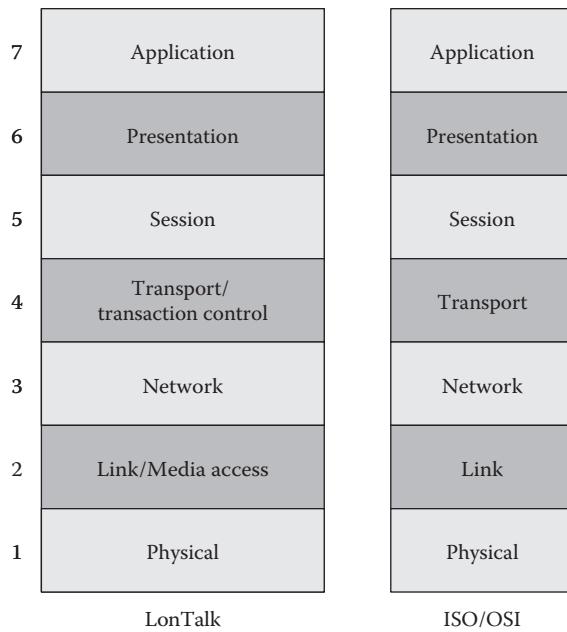

The following sections will cover the most important BACS network technologies and their relevant aspects for energy applications. Three international standards are LonWorks (ISO/IEC 14908), KNX (ISO/IEC 14543-3), and BACnet (ISO/IEC 16484-5).

### 61.13.1 LonWorks

LonWorks [13] is a general-purpose control network that has a high popularity in building automation applications. While LonWorks describes the entire technology family, parts of it are sometimes used in other products and technologies. BACnet (see later) for instance can use a LonTalk (the protocol, defined by LonWorks) channel to communicate. Parts of the LonWorks standard were adopted in the Open Smart Grid Protocol (OSGP) [18], an ETSI standard that covers remote metering, demand control, billing, and other utility-relevant functions. OSGP's networking layer is based on part 1 (protocol stack) of EN14908, enhanced by various IT security features implemented on the application layer. The classical usage is, however, to use all LonTalk layers plus the interoperability rules, developed by LonMark, a nonprofit organization for the promotion and improvement of LonWorks.

LonWorks implements all seven ISO/ISO protocol layers in its LonTalk protocol stack (Figure 61.15). Most remarkable is a sophisticated Layer 2 with collision avoidance and transport channels with configurable retries (if packets are not acknowledged by the recipient). It also offers simple information security via an authentication mechanism.

LonMark offers a number of functional profiles for energy use. Examples are Utility Meter (profile #2201) for meter reading, Automatic Transfer Switch (profile #13120) for selecting a power source

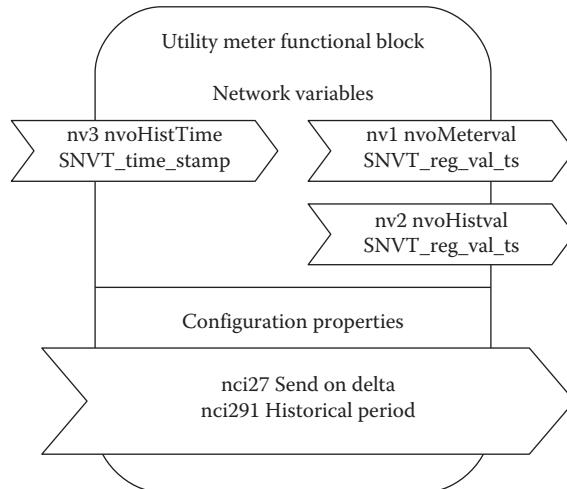

**FIGURE 61.15** The LonWorks Protocol Stack.

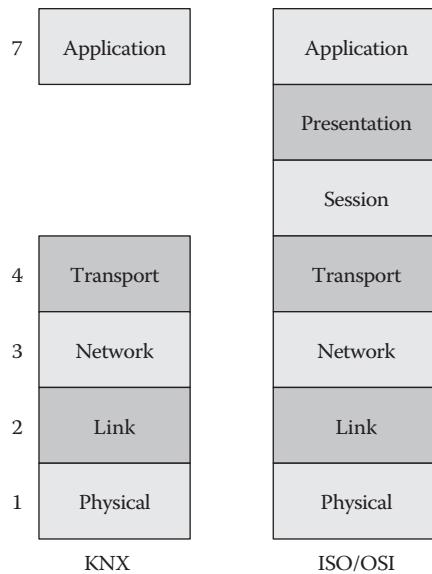

in case of failure, and the Generator Set (profile #13110) for power sources. Other profiles are under development, like Wind Turbine Generator, Demand-Response Load Actuator, and the Photovoltaic Converter profile.

As Figure 61.16 shows, a functional profile consists of a selection of network variables, based on standard network variable types. The given example shows a meter profile where current and historic meter values can be retrieved.

The physical layer of LonWorks systems can be twisted pair, power line, radio frequency, and much more. Large buildings typically have an IP or Ethernet-based backbone for its LonWorks network.

**FIGURE 61.16** The LonMark Utility Meter profile (only the mandatory part).

**FIGURE 61.17** KNX Stack.

## 61.13.2 KNX

KNX, the fusion of three earlier technologies (EIB, EHS, and BatiBUS), is specialized on home and building automation [29]. Its original topology is tree-based, new media like Ethernet, however, allow for other topologies as well. KNX supports several physical media; the most popular are twisted pair and Ethernet. Data types for load management are under development, but there are many other data types that are of relevance for energy applications like *HVAC Operating Mode* or *Boiler Controller Demand Signal*. There are products out for meter reading, M-Bus data collection, and other energy-relevant services.

The biggest benefit of KNX is its reduced cost. It is, however, designed for small to medium buildings. A large complex might bring it to its limits. KNX is specialized for building applications, which is why it only implements the most necessary features. It, as can be seen in Figure 61.17, has, for instance, omitted to offer connection-oriented transport, which is practically never needed in BACS applications.

### 61.13.3 BACnet

BACnet was designed top down, in contrast to its two aforementioned competitors. The applications were the starting point, and transport and wires were done later or not at all: BACnet simply specifies some existing communication standards as selected, one of them even being LonWorks. Building functions were projected into functional blocks, called objects. By doing so, the BACnet designers worked mainly on interoperability questions and (sometimes complex) functions.

One example, relevant for energy automation, is the BACnet load control object (Figure 61.18, Addendum 135-2004e-1). It describes a simple state machine that can represent a device (e.g., a chiller) or an entire building. Its strength is its simplicity: a clear interface that can be incorporated in many energy-relevant processes.

A so-called Protocol Implementation and Conformance Statement (PICS) describes which functions a BACnet device implements. With its PICS, a device can tell that it is a BACnet Building Controller (B-BC), that it supports BACnet/IP as transport, that it contains a schedule object, and many things more, important to compare the device with others. One important part is the BIBBs

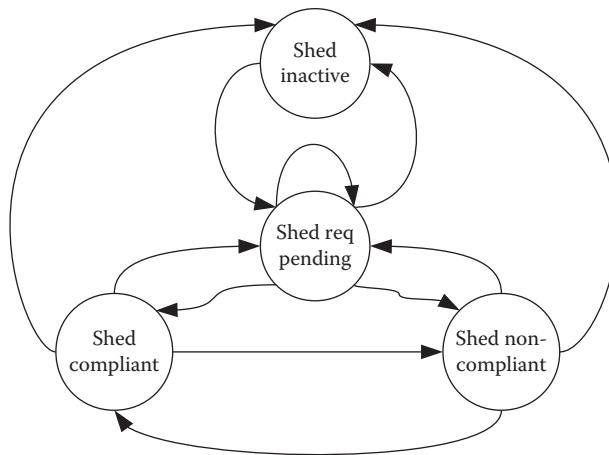

FIGURE 61.18 The BACnet Load Control Object (simplified).

(BACnet Interoperability Building Blocks) that tell which interoperability functions are available. BIBBs are one of six categories (e.g., network management, alarm management, and data sharing), and a device can either act as source of data (client, initiating a function) or as sink of data (server, executing a function).

### 62.1 Introduction

---

Automation, information, and communication systems in power systems are widely used. Usually, they are based on an immense number of proprietary specifications or (de facto) standards. To reduce this variety and to meet future requirements, the standard IEC 61850 (Communication networks and systems for power utility automation) [1] has been developed by users, vendors, and system integrators since 1995.

The standard IEC 61850 provides the basis for many application domains outside of electrical side substations. One of the biggest success stories of IEC 61850 in power delivery systems is the deployment of the standard for wind power systems. Utilities and operators of wind turbines are struggling with the

fast-growing diversity of communication systems for wind turbines. Utilities have initiated the standardization of a communication system in 2001: IEC 61400-25 (Communications for monitoring and control of wind power plants) [2]. IEC 61400-25 is based on IEC 61850.

The standards referenced in IEC 61850, for example, Ethernet, TCP/IP, MMS (ISO 9506), and XML, make use of advanced IT solutions, the reduced bandwidth costs, and increased processor capabilities in the end devices. IEC 61850 focuses on process data and metadata. More than 3000 standardized objects with concrete names and type information have been defined. The standard overcomes the huge point lists to be created for each installation in case traditional communication systems are applied.

The focus of standard series IEC 61850 was on substation operational aspects (mainly protection and control) during the first couple of years. Various groups have identified that IEC 61850 could be used as the basis of further applications, for example, monitoring of functions, processes, primary equipment, and the communication infrastructure in substations and many other power system application domains. The scope and title changed in 2010 from “Communication networks and systems for substations” to “Communication networks and systems for power utility automation.” This reflects the many new application domains that use the standard.

Revised and new parts provide additional definitions for critical measurements like temperatures, oil levels, gas densities, maximum number of connections exceeded, etc. Such extensions cover the monitoring of equipment like switchgear, transformers, on-load tap changers, automatic voltage regulation devices, gas compartments, and lines; generators, gearboxes, and towers in wind turbines; and communication infrastructure like Ethernet switches and routers. Myriads of sensors are needed to monitor the condition of the wind power foundation, tower, rotors, gearboxes, and generators to name just a few.

IEC 61850 is the standard in power and energy delivery systems.

## 62.2 Overview

---

IEC 61850 mainly provides solutions for the following:

- The *information model* of the real world: a circuit breaker model, protection functions, measurement units, nameplate information, condition monitoring information, wave forms, disturbance records, limit violations, etc. Many hundred *signals* are already defined in various standards or draft standards (for substation automation, asset management and monitoring, wind power plants, hydropower plants, and other domain). The models are defined as data object that are contained in logical nodes (LNs)—comprising all typical information that is to be exposed from a real function.
- The *communication services* like get, set, reporting events, logging events, control devices, exchanging GOOSE messages for real-time information, exchanging sampled of current and voltage sensors, recording, transfer of COMTRADE (and other) files, retrieve self-description of the devices *content*, and other services.
- The *mapping* of the information models and communication services to concrete communication protocols like Manufacturing Message Specification (MMS, ISO 9506).
- The *communication networks* (TCP/IP, Ethernet, switches, and routers).
- The *configuration* of the information models and information flow of the whole substation (IEC 61850-6, system configuration language [SCL]) and mainly which devices provide the information to be sent to whom comprising the following:
  - Single-line diagram
  - Binding of the information models to the single-line diagram (lines, current and voltage sensors, circuit breakers, etc.)
  - Binding of the information model to the automation functions and primary equipment
  - Engineering of all communication details: relations between intelligent electronic devices (IEDs) and the message flow (traffic engineering)

The crucial features and characteristics of IEC 61850 are

- Information modeling method (LogicalDevice/LogicalNode.DataObject)
- Information models of real-world objects (LD/LN.DO)
- SCL based on XML
- Information exchange services (abstract definitions that can be mapped to multiple services and protocols)
- Communication services (concrete messages applying Ethernet, TCP/IP, MMS, etc.)
- Applying native standards
- Supporting interoperability of IEDs in small and huge multivendor systems
- Long-term stability of definitions (like AC power system)
- Information models for many application domains (growing quite fast)

The information exchange mechanisms access well-defined information models. IEC 61850 uses the approach of modeling the common information found in real devices as shown in Figure 62.1. All common information made available to be exchanged with other devices is defined. The standard applies an advanced name space concept. The name space allows defining private extensions for the information that is required by an application but not yet standardized.

IEC 61850 defines the information and information exchange independent of a concrete implementation (i.e., it uses abstract models). The standard also uses the concept of virtualization. Virtualization provides a view of those aspects of a real device that are of interest for the information exchange with other devices. Only those details that are required to provide interoperability of devices are defined in IEC 61850.

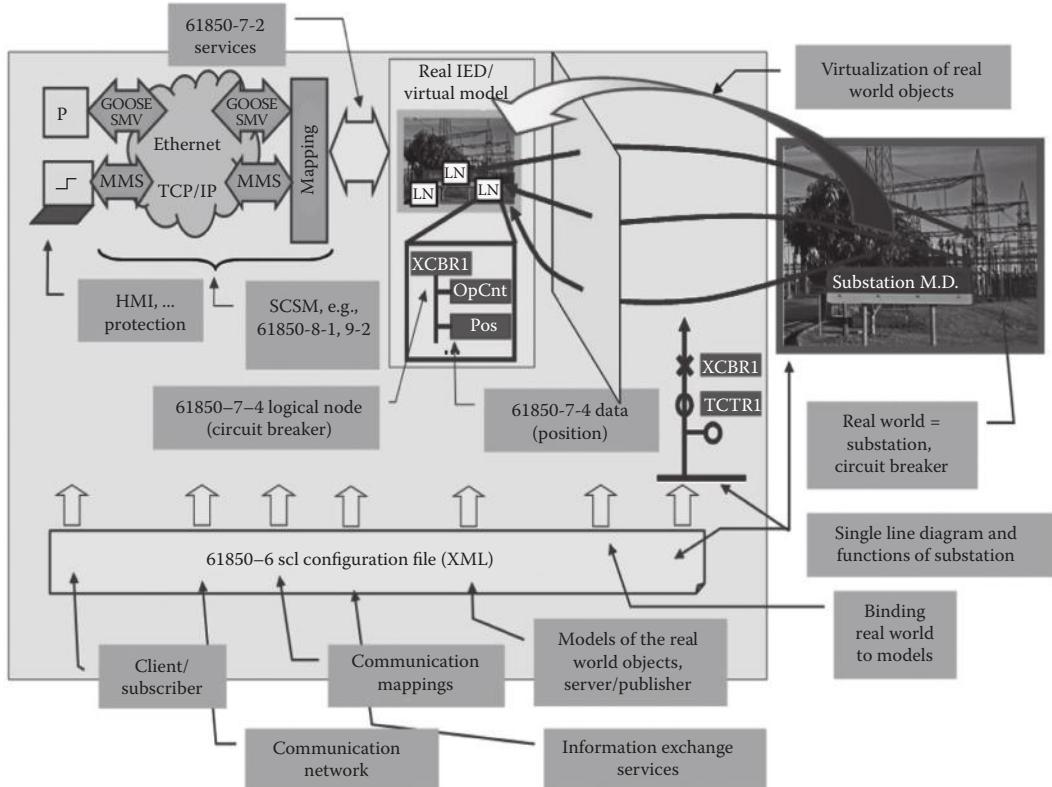

FIGURE 62.1 Topology of IEC 61850.

The approach of the standard is to decompose the application functions into the smallest entities, which are used to exchange information. The granularity is given by a reasonable distributed allocation of these entities to dedicated devices. These entities are called logical nodes (e.g., a virtual representation of a circuit breaker class, with the standardized class name XCBR). Several LNs build a logical device (e.g., a representation of a bay unit). A logical device is always implemented in one IED (intelligent electronic device).

Real devices of an air-insulated substation on the right-hand side of Figure 62.1 are modeled as a virtual model in the middle of the figure. The LNs defined in the logical device (e.g., bay) correspond to well-known functions in the real devices. In this example, the LN XCBR1 represents a specific circuit breaker.

Based on their functionality, an LN contains a list of data object (e.g., Pos for position) with dedicated data attributes. The data objects have a structure and a well-defined semantic (meaning in the context of substation automation systems [SASs]). The semantic is partly very common (status or measurement). Other information is substation specific (directional mode information of a distance protection function). The information represented by the data and their attributes is accessed by various services. The services are implemented by specific and concrete communication means (e.g., using MMS, TCP/IP, and Ethernet among others). The LNs and the data contained in the LNs are crucial for the description and information exchange of SAS to reach interoperability (Table 62.1).

**TABLE 62.1** Logical Node Groups

Id	Logical Node Groups
A	Automatic control
B	Reserved
C	Supervisory control
D	Distributed energy resources
E	Enthalpy (steam and gas power plants)
F	Functional blocks
G	Generic function references
H	Hydropower
I	Interfacing and archiving
J	Reserved
K	Mechanical and nonelectrical primary equipment
L	System logical nodes
M	Metering and measurement
N	Reserved
O	Reserved
P	Protection functions
Q	Power quality events detection related
R	Protection-related functions
S	Supervision and monitoring
T	Instrument transformer and sensors
U	Reserved
V	Reserved
W	Wind power
X	Switchgear
Y	Power transformer and related functions
Z	Further (power system) equipment

The logical devices, the LNs, and the data they contain need to be configured. The main reason for the configuration is to select the appropriate LNs and data from the standard and to assign the instance-specific values, for example, concrete references between instances of the LNs (their data) and the exchange mechanisms, and initial values for process data.

Another task of the configuration language is the binding between the model and the real world. It must be known which real circuit breaker in the switch yard is opened or closed when a control command is sent to the model instance XCBR1. The binding is contained in an SCL file for a whole substation.

An example of a change of the circuit breaker position and how this change can be communicated is shown in Figure 62.2. The real circuit breaker that is represented by the XCBR1 model opens at time  $t_n$ . This change of the status represented by the model XCBR1.Pos.stVal is an event that could cause sending a spontaneous report message over TCP/IP to a supervision device. Report messages are understood to be non-time-critical messages; the timeliness is in the range of 1 s.

The supervision device may also just read (poll) the current status of the circuit breaker. Another option is to store (log) the change in a local log of the device that implements the object model (e.g., a bay controller). The log (historical storage) could be queried at any time.

The fourth possibility is to distribute the state change in real time to all devices in the substation that need to know continuously what the status of the switchgears are at any time. GOOSE messages (using Ethertype and multicast) are carrying this kind of information within a few milliseconds to all devices that need this information. All devices that have information to be shared with other devices are configured by an SCL file. In case of GOOSE messages, it is required that a device that wants to receive the status change of XCBR1.Pos.stVal is configured to listen to that specific GOOSE messages. The GOOSE messages are just sent to the network not knowing which devices are interested in receiving the values carried; the system SCL document specifies the publisher and which subscriber listens to which publisher.

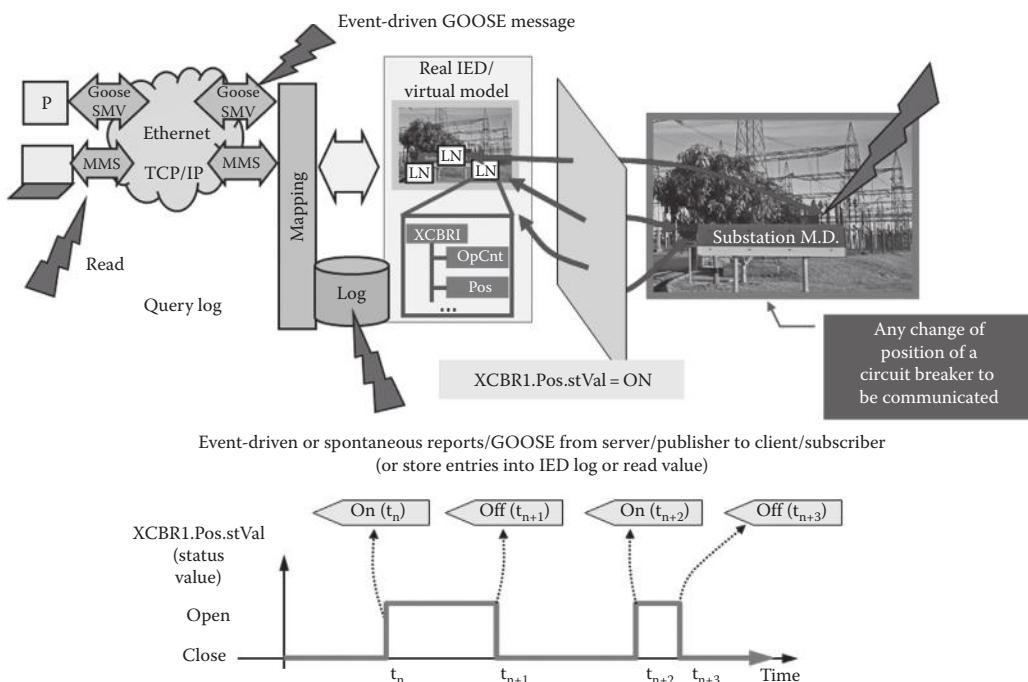

FIGURE 62.2 Communication example.

The four main building blocks of IEC 61850 for substations are (see Figure 62.1) as follows:

#### Information models

IEC 61850-7-4 defines substation-specific and common information models for substation automation functions (e.g., breaker with the status of breaker position, settings for a protection function, etc.)—what is modeled and could be accessed for information exchange. The models could be used to derive an electronic data sheet embedded in the IED for self-identification and self-description.

IEC 61850-7-3 defines a list of commonly used information templates (e.g., double-point control, three-phase electrical measured value, etc.); these are the most common information building blocks.

#### Information exchange methods

IEC 61850-7-2 provides the services to exchange information for the different kinds of functions (e.g., control, report, log, and get and set); it defines how to exchange information. The information to be accessed comprises also the IED's self-identification and self-description.

#### Mapping to concrete communication protocols

IEC 61850-8-1 defines the concrete means to communicate the information between IEDs (e.g., the application layer and the encoding)—how to serialize the information in corresponding messages.

#### Configuration of a substation (system configuration language [SCL])

IEC 61850-6 offers the formal configuration description of a substation and all devices including the description of the relations with other devices and with the power process (single-line diagram)—how to describe the configuration. This offline data sheet completely describes the devices information provided by all devices and how it could be exchanged. The SCL file (XML document) eliminates the need to manually input these data when configuring a device. This not only reduces system configuration time, but also increases the general integrity and reliability of systems by reducing human error. And it can be used as comprehensive system documentation.

These four building blocks are independent of each other to a high degree. The information models can easily be extended by definition of new LNs and new data according to specific and flexible rules—as required by other application domains (e.g., wind power plants). In the same way, additional communication stacks may be used following the advancement in communication technology.

The information is separated from the presentation and from the information exchange services. The information exchange services are separated from the concrete communication profiles.

The standard series has an impact on many phases during the life of an SAS. The most crucial aspects are as follows:

- Design and development of devices and systems
- Procurement process
- Engineering and configuration of devices and systems
- System simulation
- Commissioning and testing of systems
- Network engineering and management
- Operation
- Error diagnostics
- Maintenance
- Asset management

- Condition monitoring
- Organization
- Remote control and monitoring of SS from control centers
- Integration in company networks
- Integration of control and monitoring of renewable and decentralized Energy

The standard series IEC 61850 is not just another communication protocol; it is a series of documents that cover many aspects to get interoperable multivendor systems for the protection, control, supervision, and automation of the power delivery system.

For that reason, it is recommended for users and vendors to create teams that have members with different background, like power system protection and power engineering, network infrastructure, communication protocols, applications, SCADA, security issues, and other people.

For IEC 61850, it is really true what has been said: Teamwork makes the Dream work.

Most important is still the fact that the main task still is to keep the power flowing and the meter running. The business case of utilities is power—not only communication.

## 62.3 Information Modeling and Information Models

Information models represent measurements and status information taken at the process level and other kinds of processed information like rms measurements and metering information and settings. The information models are independent of any communication protocol and network solution. They are intended to have a *long life*—a Phase C Voltage in a 50 Hz system is a Phase C Voltage today, tomorrow, in 20 years, in Karlsruhe and in Reykjavik.

Figure 62.3 shows the different levels of standard definitions: from *long life* at the top to *short life* at the bottom.

The models are organized in LNs containing data objects. An LN is, for example, the MMXU: the measurements and calculated values of a three-phase electrical system. Figure 62.4 depicts the application of the standard LN MMXU for different voltage levels.

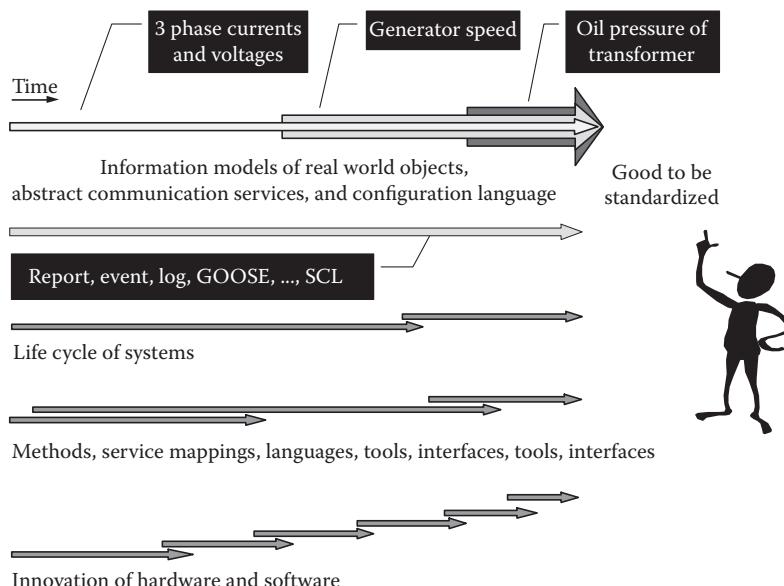

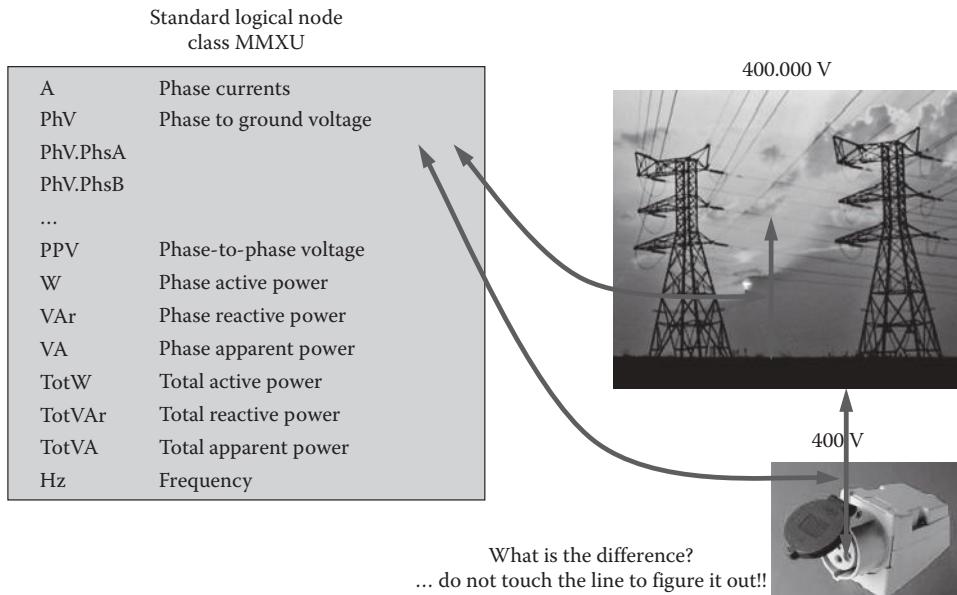

FIGURE 62.3 Information models and implementation issues.

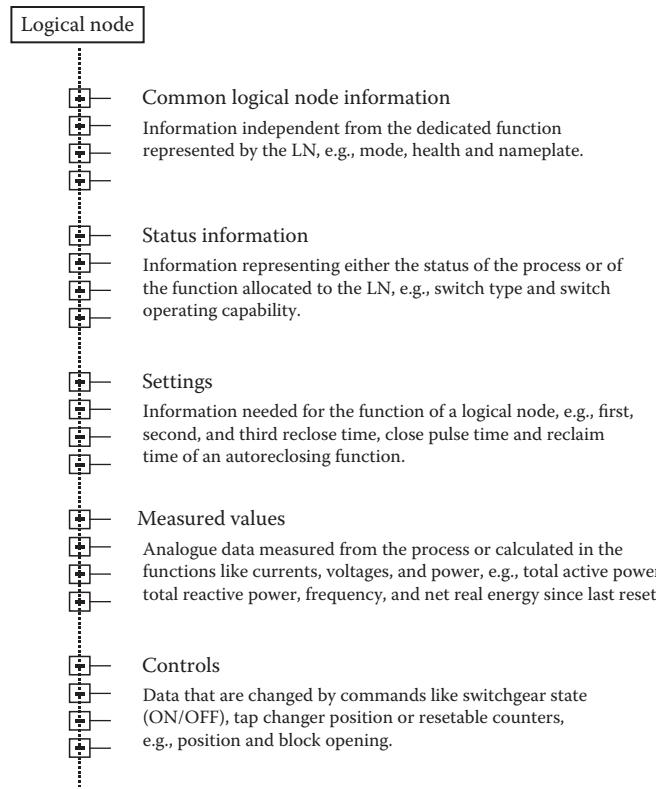

**FIGURE 62.4** Information model of electrical values.

IEC 61850 and related standards define thousands of *signals* in data objects organized in LN; more than 280 standardized LNs are already defined.

Information models are one of the key elements of the standard series IEC 61850 and related standards. Several LNs covering the most common applications in electric power delivery systems are defined. The applications inside and beyond substations are

- System information
- Protection functions
- Protection-related functions
- Supervisory control
- Generic references
- Interfacing and archiving
- Automatic control
- Metering and measurement
- Sensors and monitoring
- Switchgear
- Instrument transformer
- Power transformer
- Further power system equipment
- Decentralized energy resources (DER)
- Hydropower plants
- Wind power turbines
- Distribution automation
- Power quality
- Electric vehicle charging station and others

Most LNs provide information that can be categorized as depicted in Figure 62.5. The semantic of an LN is represented by data and data attributes. LNs may provide a few or up to 30 or more data objects.

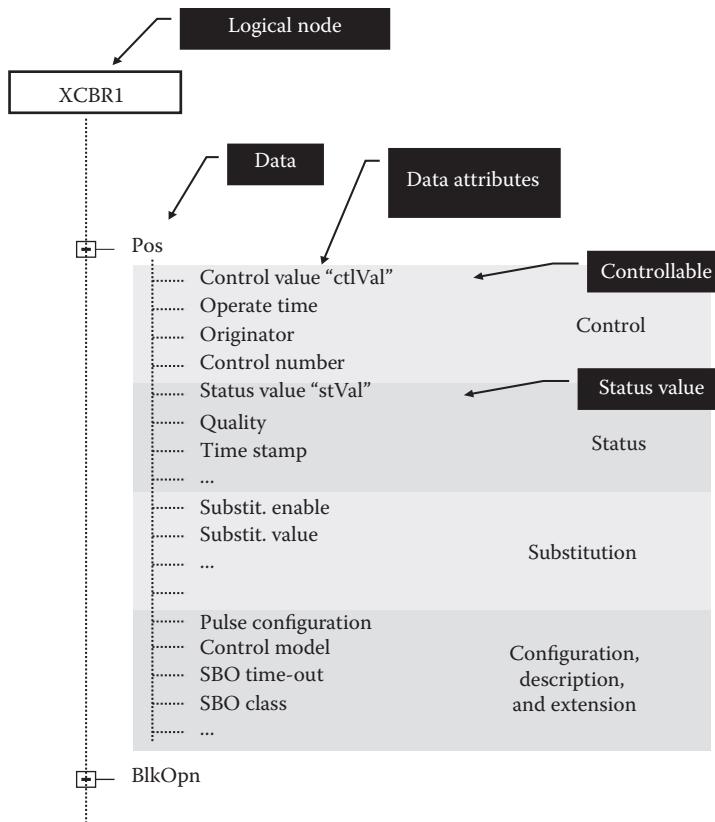

**FIGURE 62.5** Logical node information categories.

Data objects may contain a few or even more than 20 data attributes. LNs may contain more than 100 individual information (points) organized in a hierarchical structure.

The first letter in the name of the LN class indicates the application domain. The following list contains the assigned first letters (2012):

Some examples of LNs of the group measurements and metering information are provided in the following text:

Environmental information	MENV
Flicker measurement name	MFLK
Flow measurements	MFLW
Fuel characteristics	MFUL
Harmonics or interharmonics	MHAI
Heat measured values	MHET
Hydrological information	MHYD
DC measurement	MMDC
Measurement (electrical three-phase system)	MMXU
Meteorological information	MMET
Metering (three phase)	MMTR
Metering (single phase)	MMTN
Metering statistics	MSTA
Non-phase-related harmonics or interharmonics	MHAN
Non-phase-related measurement	MMXN
Pressure measurements	MPRS
Sequence and imbalance	MSQI

**FIGURE 62.6** Position information depicted as a tree (conceptual).

The length of the LN class name is always four characters. The mean number of data objects provided by LNs defined in IEC 61850-7-4 is approximately 20. Each of the data (e.g., position of a circuit breaker) comprises several details (the data attributes). The position (named *Pos*) of a circuit breaker is defined in the LN XCBR (see Figure 62.6). The position is defined as data object.

The position *Pos* is more than just a simple *point* in the sense of traditional RTU protocols. It contains several data attributes. The data attributes are categorized as follows:

- Information to control a circuit breaker
- Status or measured/metered value
- Substitution
- Configuration, description, and extension

The example data object *Pos* has approximately 20 data attributes; some are mandatory while others are optional. The data attribute “*Pos.ctlVal*” represents the controllable information (can be used to operate a switch to open or close). The data attribute “*Pos.stVal*” represents the position of the real breaker (could be in intermediate state, off, on, or bad state).

The position also has optional information about when to process the control command (Operate time), the originator that issued the command, and the control number (given by the originator in the request). The quality and time stamp information indicates the current validity of the status value and the time of the last change of the status value.

The current values for “*stVal*,” “*q*” (quality), and “*t*” (time stamp) can be read, reported, or logged in a buffer of the IED or exchanged by GOOSE.

The values for “stVal” and “q” can be remotely substituted. The substituted values take effect immediately after enabling substitution.

Common data classes (CDCs, templates) are used to define data attributes of data. The crucial CDCs defined in IEC 61850-7-3 are as follows:

#### CDCs for status information

- Single-point status (SPS)
- Double-point status (DPS)
- Integer status
- Binary counter reading

#### CDCs for measurand information

- Measured value (MV)
- Complex measured value
- Sampled value (SAV)
- Phase-to-ground-related measured values of a three-phase system (WYE)
- Phase-to-phase-related measured values of a three-phase system (DEL)
- Harmonic value
- Harmonic value for WYE
- Harmonic value for DEL

#### CDCs for controllable status information

- Controllable single point
- Controllable double point (DPC)
- Controllable integer status
- Binary controlled step position information
- Integer controlled step position information

#### CDCs for description information

- Device nameplate
- LN nameplate

The minimum subset of data attributes of the CDC MV is as follows:

“mag” Deadbanded value. Value based on a deadband calculation. The value of mag is updated when the value has changed according to the configuration parameter db specifying a percentage change of the value (deadband—online changeable)

“q” Quality of the attribute(s) representing the value of the data

“t” Time stamp of the last change in one of the attribute(s) representing the value of the data or in the q attribute (UTC-based)

These three data attributes can be used for immediate reading, reporting, or logging. Almost all RTU protocols like IEC 60870-5 or DNP3 communicate usually these three data attributes. These protocols have been developed to exchange status information, measurements, metered values, and control commands.

The XCBR LN Model in IEC 61850-7-4 comprises a list of generic information of the circuit breaker as shown in Table 62.2. This LN class contains some 20 data objects that expose specific information of a real circuit breaker. Most of the data objects are optional (O). The most common data attributes are mandatory (M). The data object Pos (Position) of the circuit breaker is used to control (open or close) it or to provide the status of the position.

**TABLE 62.2** Circuit Breaker Model

XCBR Class				
Data Object Name	Common Data Class	Explanation	T	M/O/C
LNNName	The name shall be composed of the class name, the LN-Prefix and LN-Instance ID according to IEC 61850-7-2, Clause 22.			
Data objects				
<i>Descriptions</i>				
EEName	DPL	External equipment nameplate	O	
<i>Status Information</i>				
EEHealth	ENS	External equipment health	O	
LocKey	SPS	Local or remote key (local means without substation automation communication, hardwired direct control)	O	
Loc	SPS	Local control behavior	M	
OpCnt	INS	Operation counter	M	
CBOpCap	ENS	Circuit breaker operating capability	O	
POWCap	ENS	Point on wave switching capability	O	
MaxOpCap	INS	Circuit breaker operating capability when fully charged	O	
Dsc	SPS	Discrepancy	O	
<i>Measured and metered values</i>				
SumSwARs	BCR	Sum of switched amperes, resettable	O	
<i>Controls</i>				
LocSta	SPC	Switching authority at station level	O	
Pos	DPC	Switch position	M	
BlkOpen	SPC	Block opening	M	
BlkCls	SPC	Block closing	M	
ChaMotEna	SPC	Charger motor enabled	O	
<i>Settings</i>				
CBTmms	ING	Closing time of breaker	O	

The Pos is of type DPC (CDC DPC). This type defines the details of the object (see Table 62.3). It contains several switchgear-specific attributes.

The currently published documents use a simple table notation as shown in Table 62.2. Due to the fact that the number of LNs is growing very fast, it was decided to convert the models into UML models using the tool Enterprise Architect. This UML notation is used for maintenance and extensions of the various object models. The circuit breaker model in UML notation is shown in Figure 62.7 as an example.

The content is the same in both diagrams. The benefit of using UML is this: It requires specifying the detail more precisely. The consistency is easier to check. This model allows also to automatically generating Word-, PDF-, and html-formatted documents. The models can be exported also in an XML format.

For people that are used to read models in the form of UML notation, it is now easier to study the models.

The data object Pos of the circuit breaker position has the CDC DPC. Just six data attributes of the DPC CDC are mandatory; the others are optional or conditional (indicated by the term “constraints”). The abstract class Substitution CDC (the right box in Table 62.3) has four attributes that are dependent on the constraints {PICS\_SUBST}—if substitution is supported, then all four substitution-specific attributes are mandatory.

**TABLE 62.3** Double-Point Common Data Class (DPC) in Table Notation

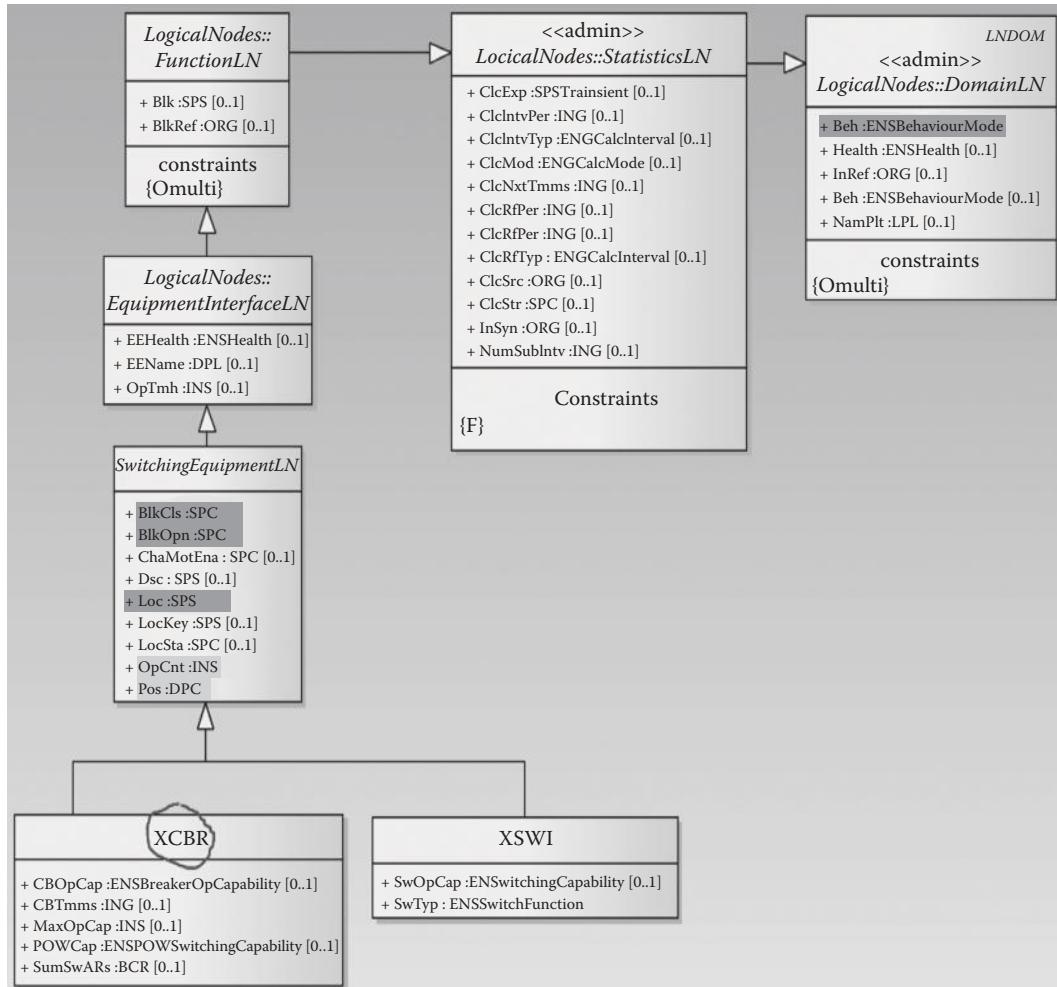

DPC class					
Data Attribute Name	Type	FC	TrgOp	Value/Value Range	M/O/C
DataName	Inherited from GenDataObject Class or from GenSubDataObject Class (see IEC 61850-7-2)				
<i>DataAttribute</i>					
<i>Status and control mirror</i>					
origin	Originator	ST			AC_CO_O
ctlNum	INT8U	ST		0.255	AC_CO_O
stVal	CODED ENUM	ST	dchg	intermediate-state   off   on   bad-state	M
q	Quality	ST	qchg		M
t	TimeStamp	ST			M
stSeld	BOOLEAN	ST	dchg		O
opRcvd	BOOLEAN	OR	dchg		O
opOk	BOOLEAN	OR	dchg		O
tOpOk	TimeStamp	OR			O
<i>Substitution and blocked</i>					
subEna	BOOLEAN	SV			PICS_SUBST
subVal	CODED ENUM	SV		intermediate-state   off   on   bad-state	PICS_SUBST
subQ	Quality	SV			PICS_SUBST
subID	VISIBLE STRING64	SV			PICS_SUBST
blkEna	BOOLEAN	BL			O
<i>Configuration, description, and extension</i>					
pulseConfig	PulseConfig	CF	dchg		AC_CO_O
ctlModel	CtlModels	CF	dchg		M
sboTimeout	INT32U	CF	dchg		AC_CO_O
sboClass	SboClasses	CF	dchg		AC_CO_O
operTimeout	INT32U	CF	dchg		AC_CO_O
d	VISIBLE STRING255	DC		Text	O
dU	UNICODE STRING255	DC			O
cdcNs	VISIBLE STRING255	EX			AC_DLINDA_M
cdcName	VISIBLE STRING255	EX			AC_DLINDA_M
dataNs	VISIBLE STRING255	EX			AC_DL_N_M

The most crucial data attributes are shown in the lower box DPC that indicates that the five gray marked data attributes are mandatory:

- ctlVal (open or close)
- ctlModel (selects different control features: direct control, select before operate, etc.)
- q (quality of status signal)
- t (time of last change)
- stVal (DPS)
- The ctlVal is represented by a control service parameter and then mapped to the data attribute ctlVal in the mapping IEC 61850-8-1

The CDC for DPC is depicted in Table 62.3.

These are the minimum data attributes that are required to implement a simple control function to open or close a circuit breaker or other switchgear.

**FIGURE 62.7** Circuit breaker model in UML notation.

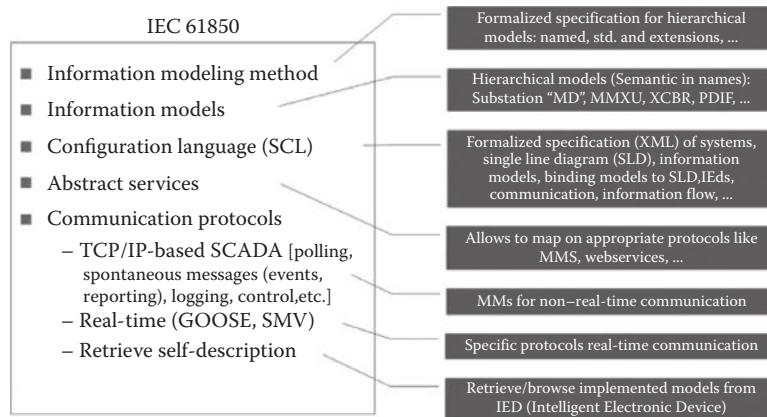

The various parts of IEC 61850 define some 300 LNs. The number of information models is growing quite fast.

<sup>1</sup> The UML models are working group internal tools. The main objective is to keep the information models consistent and at a high quality level.

## 62.4 Parts and Application Domains of the Standard

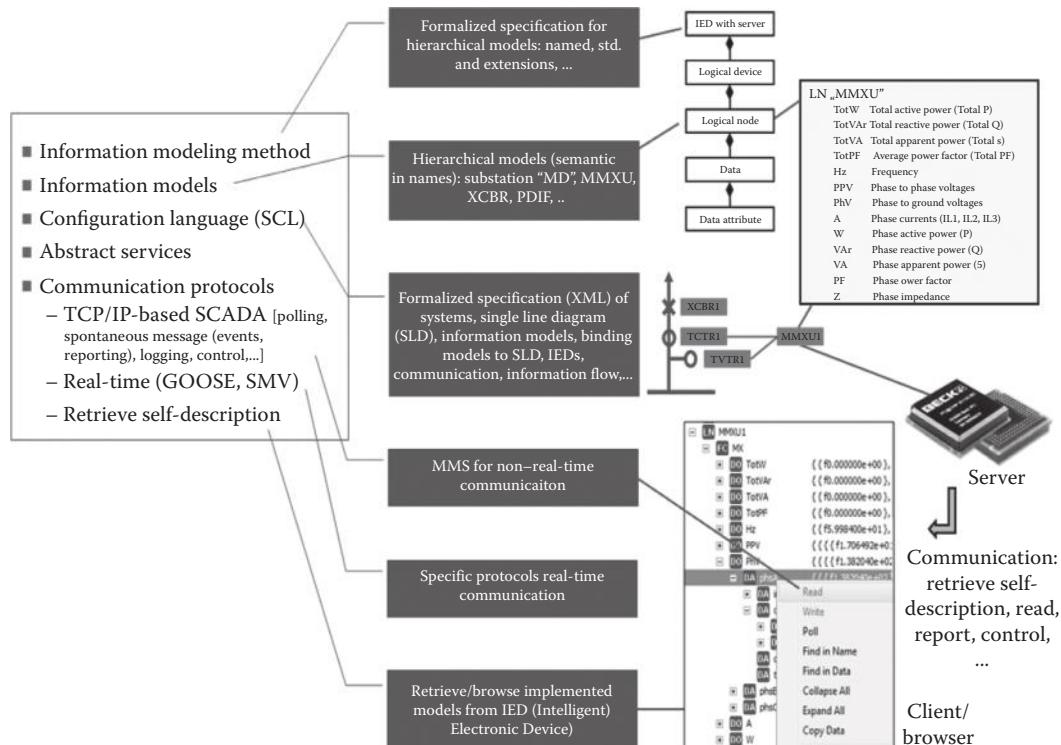

A summary of the coverage of the many parts of the IEC 61850 standard series is sketched in Figure 62.8. There are five main areas:

1. Information modeling method
  2. Information models
  3. Configuration language (SCL)
  4. Abstract services
  5. Communication protocols
    - TCP/IP-based SCADA (polling, spontaneous messages (events, reporting), logging, control, etc.)

**FIGURE 62.8** Summary of modeling.

- Real time (GOOSE, SMV)
- Retrieve self-description

Figure 62.9 shows simple examples for the five areas. The single-line diagram shows a bay with a bus bar (line at bottom), a circuit breaker (cross), current and voltage sensors (circles), and four LNs: XCBR1 (circuit breaker), TCTR1 (current sensor), TVTR1 (voltage sensor), and MMXU1 (electrical measurements in rms). The line between the sensors and the MMXU1 specifies that the voltage and

**FIGURE 62.9** Modeling example.

current samples from the two sensors are communicated to the MMXU1. The MMXU1 represents the calculated rms values of voltages, currents, frequency, active power, reactive power, and other data that are bound to the exact position in the electrical drawing (single line). The line between the MMXU and the embedded controller to the right means that the MMXU1 is implemented on that platform.

The non-real-time communication that retrieves, for example, the information model from the server device is used to get all information directly from the device and allows immediate access to the model of the device without any further configuration at the client side. The self-description leads to a self-configuration of simple client (monitoring and control) applications.

The various aspects of IEC 61850 go far beyond the definitions in fieldbus standards, telecontrol standards like IEC 60870-5, or DNP.

The scope of the standard was in the early days focusing on high-voltage substations. The market for high-voltage substation automation and protection is quite small compared to the industrial automation for factories and petrochemical plants. This niche market was one of the crucial reasons why the utilities and vendors decided to start the standardization project IEC 61850 in order to prevent proliferation of solutions compared to the fieldbus standardization project with the many solution defined in one standard.

The experience with the MAP project, fieldbus standardization, and the telecontrol applications was taken into account when the IEC TC 57 Working Groups 10, 11, and 12 started to work on a single standard covering all aspects of information modeling, information models, communication, and configuration of the whole system as well as the devices that implement protection, control, and monitoring of power delivery systems.

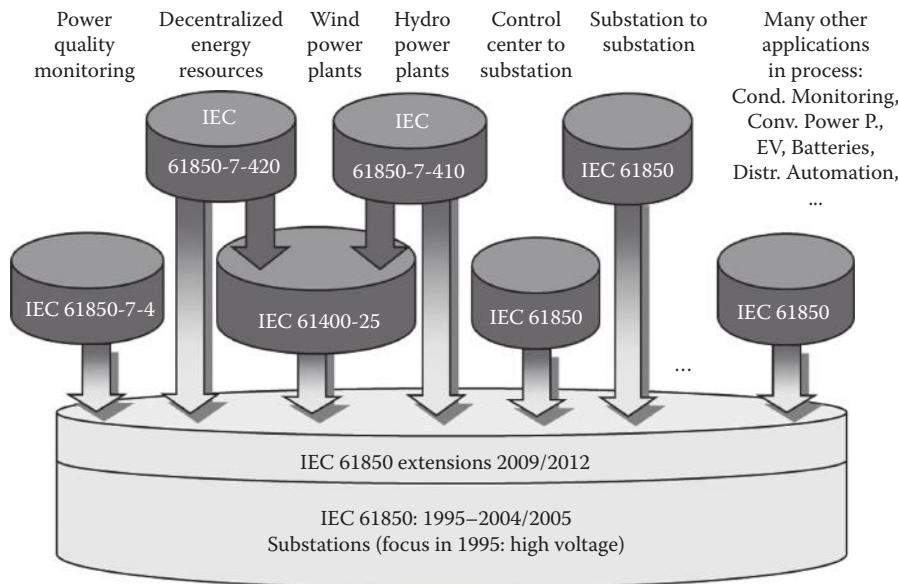

Due to the fact that the power automation in high-voltage systems was a very special application domain, there was little interest for the vendors of industrial automation systems to enter into that market niche. The work on IEC 61850 was done by protection engineers, power engineers, SCADA engineers, and communication specialists. Several communication experts had long-term experience in the many power- and non-power-specific application domains.

Since the first projects with IEC 61850 were commissioned and in operation, there was an ever-increasing interest using existing information model and defining further domain-specific models. Figure 62.10 lists the most interesting extensions. All extensions except those listed over the right cylinder are already published as official IEC documents. The interest in industrial applications is growing these days.

The published documents of the series “Communication networks and systems for power utility automation” are as follows:

#### Already published documents (2012-07)

1. Part 1: Introduction and overview
2. Part 2: Glossary
3. Part 3: General requirements
4. Part 4: System and project management
5. Part 5: Communication requirements for functions and device models
6. Part 6: Configuration description language for communication in electrical substations related to IEDs
7. Part 7-1: Basic communication structure—Principles and models
8. Part 7-2: Basic information and communication structure—Abstract communication service interface (ACSI)
9. Part 7-3: Basic communication structure—Common data classes
10. Part 7-4: Basic communication structure—Compatible logical node classes and data object classes
11. Part 7-410: Hydroelectric power plants—Communication for monitoring and control

**FIGURE 62.10** Application domains of IEC 61850.

12. Part 7-420: Basic communication structure—Distributed energy resources logical nodes
13. Part 7-510: Basic communication structure—Hydroelectric power plants—Modelling concepts and guidelines
14. Part 8-1: Specific communication service mapping (SCSM)—Mappings to MMS (ISO 9506-1 and -2) and to ISO/IEC 8802-3
15. Part 9-2: Specific communication service mapping (SCSM)—Sampled values over ISO/IEC 8802-3
16. Part 10: Conformance testing
17. Part 80-1: Guideline to exchanging information from a CDC-based data model using IEC 60870-5-101 or IEC 60870-5-104
18. Part 90-1: Use of IEC 61850 for the communication between substations
19. Part 90-5: Use of IEC 61850 to transmit synchrophasor information according to IEEE C37.118
20. Part 90-7: Object Models for PV, Storage ... inverters

Documents in **bold** are often called the IEC 61850 Core Parts. These documents contain basic definitions for the modeling approach and for the models in other domains. A CDC DPC or MV can be used in any other domain. The reusability of the models is very high—the term “common” in CDC is truly very generic and can be applied not only in the electrical world but also in any other application domain. A temperature LN STMP (see details further down in this clause) could expose temperature measurements in building automation, computer farms, and power plants.

The following documents are in preparation (2012-07):

21. Part 7-5: Usage of information models SAS (substation automation system)
22. Part 7-500: Use of LN to model functions (SAS)
23. Part 7-520: Use of LN (DER)
24. Part 8-2: Web service mapping
25. Part 10-2: Interoperability test for hydro equipment
26. Part 90-2: Using IEC 61850 for SS-CC communication
27. Part 90-3: Using IEC 61850 for Condition Monitoring
28. Part 90-4: Network Engineering Guidelines

29. Part 90-6: Use of IEC 61850 for Distribution Automation
30. Part 90-8: Object Models for Electrical Transportation
31. Part 90-9: Object Models for Batteries
32. Part 90-410: Communication network structures in hydro power plants
33. Part 90-9: Object Models for Batteries
34. Part 90-10: Object models for schedules
35. Part 90-11: Methodologies for modelling of logics for IEC 61850 based applications
36. Part 90-12: Wide area network engineering guidelines
37. Part 90-13: Extension of IEC 61850 information models to include logical nodes and data models for steam and gas turbines
38. Part 90-14: Using IEC 61850 for FACTS data modelling
39. Part 90-15: Hierarchical DER system model
40. Part 100-1: Functional testing of IEC 61850 based systems

The published documents are mainly independent of each other (except the core documents). For specific application domains, it is helpful to give some guidance on which documents are relevant for a particular application domain.

The security requirements are defined in a separate series: IEC 62351

- IEC 62351-1: Security for TC57 standards and end-to-end security
- IEC 62351-2: Glossary
- IEC 62351-3: Security using transport layer security (TLS)
- IEC 62351-4: Security for manufacturing messaging specification (MMS)
- IEC 62351-5: Security for IEC 60870-5 and DNP3
- IEC 62351-6: Security for IEC 61850
- IEC 62351-7: Network and system management objects
- IEC 62351-8: Role-based access control (RBAC)
- IEC 62351-9: Cyber security key management for power system equipment
- IEC 62351-10: Security architecture guidelines for TC 57 systems
- IEC 62351-11: Security for XML files

From a model point of view, a device can comprise any LN model from any of the 11 parts that define object models (LNs, data, and CDCs). Applications that need models that are not (yet) standardized can be defined as extended models. The extensions are marked as “Functional Constraint” FC = “EX” (extended) in the corresponding name space attribute (for LNs, data, and CDCs).

The name space concept is appreciated very well, because very often devices and applications have more data to be communicated than what the standards provide currently. From the communication software viewpoint, the handling of the models in the communication software is the same if the model is extended or not.

The comprehensive information models are of interest by several other groups. Note that the IEC 61850 information models are independent of the communication system that carries the data values. The following groups use subsets of the IEC 61850 models and put them into their own context:

- IETF EMAN (Energy Management Group) that used many models and translated them into the Management Information Base. This would allow accessing the models by Simple Network Management Protocol [3].
- ISO/TC 205/WG 3 (Building Automation and Control System Design) has published recently a new work proposal on power system information models [4].
- SunSpec Alliance uses many information models and maps them to Modbus [5].

## 62.5 Functional Description of Applications

Most of the models defined in the standards listed are static in the sense that they mainly provide input and output signals and settings for well-known functions in the different application domains (see Figure 62.11). The functions are expected to be known by the domain experts. The meaning of the setting “MinOpTmms = Minimum operate time” of several protection LNs (e.g., PTOV = Time over current protection) is understood by protection engineers (only). This setting can have a value that is set by the application (thus not configurable or online writable); the setting may also be configured in the configuration file for that device, or it may be additionally writable remotely. These possibilities could be specified in the SCL file.

The standardization work was mainly done by protection engineers at the beginning. These engineers have not defined the details of the protection functions in IEC 61850, because they understood the details anyway. Other groups define the protection functions, for example, IEC TC 95 (Measuring relays and protection equipment). There are also general LNs that define data objects that are self-explanatory, that is, their names indicate uniquely what the function behind the data object is all about. Example: The temperature measurement model STMP (Supervision temperature) has a data object Tmp; this is of course the object that exposes the measured temperature. The data object TmpAlmSpt (Set point) represents the value of the Alarm level or limit. The data object Alm exposes the case that the Tmp value reached the alarm level.

How and by whom the inputs and output are used is also outside the standard. In the real world, there is often a need to specify and to know how LNs interoperate—which signals (data attributes) are needed when and from which other LN(s). This is usually the task of the system engineering. The engineering of the signal flow and how these signals are used internally to implement specific functions are outside the standard. The need for functional specifications is known by various standardization groups. One crucial reason why the functional specification is very important is the need of standardized definitions for implementing functional tests of devices and the whole system.

Examples of LNs that define functions can be found in IEC 61850-90-7 “IEC 61850 object models for photovoltaic, storage, and other DER inverters.” The need for a precise definition on how hundreds of photovoltaic inverter could connect to the electrical grid and how to monitor and control them is a very crucial issue in electrical networks with high penetration of PV into the grid. Figure 62.12 shows the PV performance on 2013-07-27 of 20.7 GW—with an average total consumption of some 60 GW [6].

The installation of PV systems and connecting them to the grid is still growing. This situation requires that (at least larger) PV systems have to be monitored and controlled by grid operators by means of remote access. IEC 61850-90-7 is more often the reference solution. The Italian power industry has

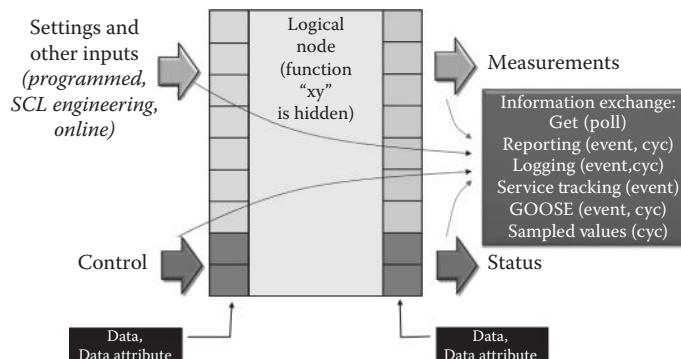

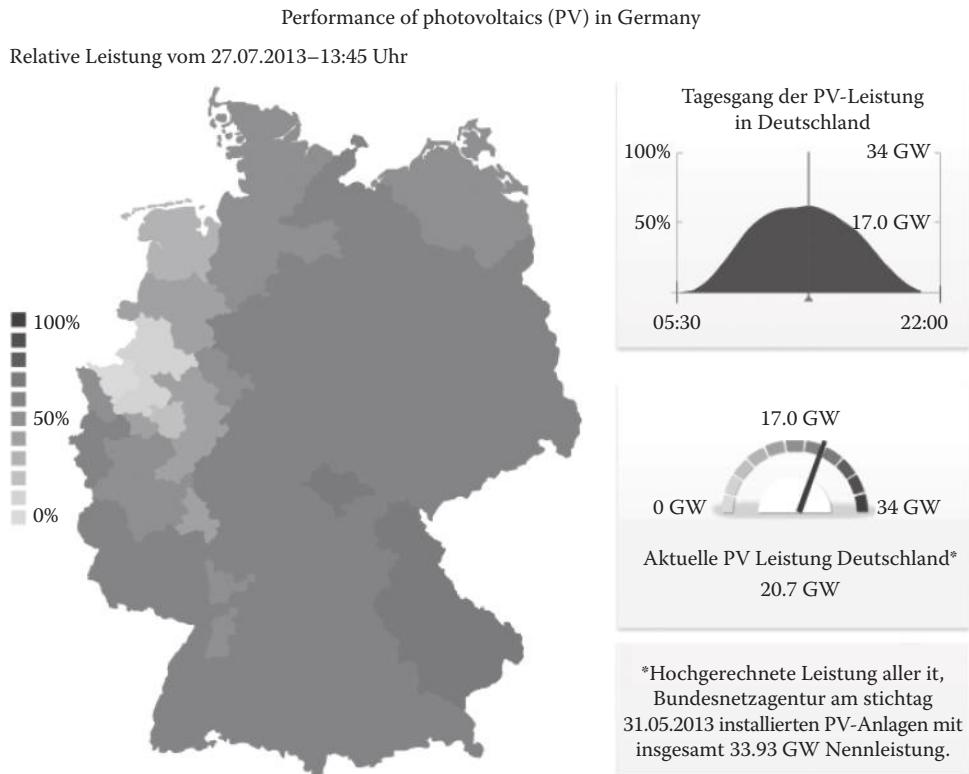

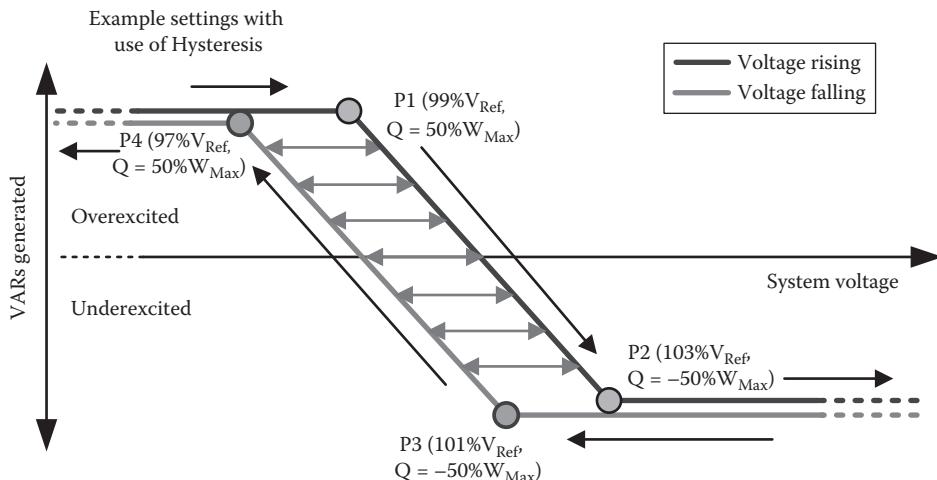

FIGURE 62.11 Function block view of IEC 61850 models.

**FIGURE 62.12** PV performance into German grids.

published two norms (CEI 0-16 and CEI 0-21) to use IEC 61850 for connecting control centers with PV systems at high- and low-voltage levels. First pilot systems are in operation since summer 2013.

IEC 61850-90-7 defines exactly how various control functions are defined and how they can be configured and used. Figure 62.13 shows the diagram for one of the many different electrical behaviors of the PV inverter at the electrical connection point. The reactive power production

**FIGURE 62.13** Example of hysteresis in volt-var curves.

(over- or underexcited) has to follow a defined curve that is configured based on the data objects in the LN models defined in IEC 61850-90-7.

These models allow grid operators to manage and manipulate the electrical grid with a single international standard. Applying IEC 61850-90-7 reduces the proliferation of grid codes for connecting PV and other inverters to the electric power grid. The benefit for grid operators is this: There is only one specification and requirement documentation needed per utility. The vendors of inverters do not need to implement a variety of grid codes—one per utility of region.

The standard could also be used to build closed loop control mechanisms that could be implemented by horizontal communication between an energy manager next to the power transformer and the loads and generation units along the feeder line.

The definition of functions is also crucial for testing an inverter. The function and the communication with the inverter can now be tested together. The electrical output of the inverter can be tested against the settings of the LN model. The behavior of the electrical output must be the same as defined by the configured curve as shown in Figure 62.13. The certification of the communication and the inverter function by one test lab would build confidence that the inverter does what it is intended for: managing the electrical connecting point with an open information and information exchange solution.

The inverter functions modeled in IEC 61850-90-7 range from simple to complex control operations. Most inverter functions are based on settings or curves that allow inverters to respond autonomously to local electrical conditions, while some require direct control commands. The following list describes briefly some crucial functions that are defined in IEC 61850-90-7:

#### Immediate control functions for inverters

- Function INV1: Connect/disconnect from grid
- Function INV2: Adjust maximum generation level up/down
- Function INV3: Adjust power factor
- Function INV4: Request active power (charge or discharge storage)
- Function INV5: Request action through a pricing signal

#### Volt-var management modes

- Volt-var mode VV11: Available var mode with no impact on watts
- Volt-var mode VV12: Maximum var support mode based on maximum watts
- Volt-var mode VV13: Static inverter mode based on settings
- Volt-var mode VV14: Passive mode with no var support

#### Frequency-watt management modes

- Frequency-watt mode FW21: High frequency reduces active power or low frequency reduces charging
- Frequency-watt mode FW22: Constraining generating/charging by frequency
- Frequency-watt mode FW23: Watt generation/absorption counteractions to frequency deviations

#### Dynamic reactive current support during abnormally high- or low-voltage levels

- Dynamic reactive current support TV31: Volt-var support during abnormally high- or low-voltage levels

## 62.6 Information Exchange Models

---

Information exchange models in IEC 61850 are first defined in an abstract way: the ACSI (IEC 61850-7-2). The service models comprise

- Association
- Information model
  - Directory services to retrieve the information (logical device, LN, data object, and data attributes) and communication models (data sets and control blocks)

- Read and write data or data sets (polling)
- Create/delete data sets
- Substitute data (freeze)
- Setting groups for device settings contained in LNs
  - Edit setting groups
  - Activate setting groups
- Service tracking (useful for security solutions)
  - Specialized reporting and logging
  - Track service parameters of message exchange with a device
- Spontaneous or event-driven data transmission (reporting)
  - Configuring reports
  - Transmit buffered or unbuffered reports (very efficient communication)
- Storing sequence of events (SOE; logging)
  - Configuring logs
  - Read logged information
- Real-time transmission of events and other signals
  - Multicasting of events (Generic Object-Oriented Event [GOOSE])
- Transmission of SVs
  - Multicasting of samples (current, voltage, vibration, etc.)
- Control model
  - Select and operate
  - Time-activated operation
- Time synchronization
  - SNTP (for SCADA)
  - IEEE 1588 or extra fiber for SVs
- File transfer
  - Read and write files
  - Delete files

Most service models defined in IEC 61850-7-2 are based on a client/server model. The client and the server are roles that can be implemented by real devices. The server exposes information (models) that can be accessed through TC/IP connections by one or several clients (see Figure 62.14). This client/server concept maps directly to the MMS approach. Real devices may implement both roles independently.

The second concept is the multicast-based communication for GOOSE and SV exchange. The publisher (role) sends Ethernet (Ethertype) multicast messages on the network. All devices that need to receive multicast messages take the messages they want to receive from the network. The publisher role usually is implemented in a device that also implements a server. The server model is needed in case the information objects, data sets, and control blocks are required to be exposed by client/server services.

All models (application information models and communication models) have to be configured. Especially this comprises the LNs, data objects, data sets, and control blocks. An SCL document can contain all these details of the sending devices (server and publisher). In addition, the SCL document can also contain clients and subscriber information. The subscriber, for example, can be configured to listen to a specific GOOSE message and to use a specific subset of the payload for a specific function. The function has inputs and outputs. These are modeled as LNs as well (see Figure 62.15).

At configuration level, there is another feature defined in IEC 61850-6: the reference to the physical or logical input and outputs (sAddr—short address for inputs; and intAdr—internal address). This internal configuration is not visible to the online communication. The concept of SCL comprises the complete signal from a source to the model, through online exchange (client/server or publisher/subscriber), to an application or output at the receiving device. The IEC 61850-6 allows specifying the complete traffic in a system with a few or hundreds of devices.

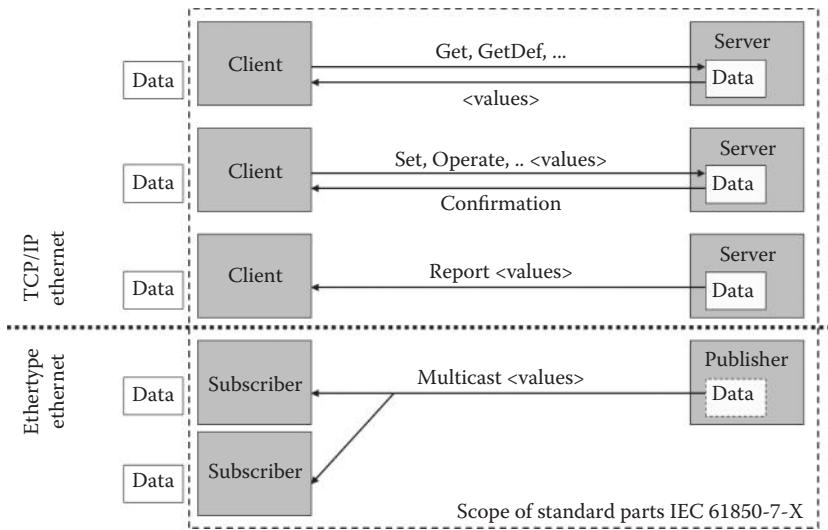

FIGURE 62.14 Service concepts in IEC 61850-7-2.

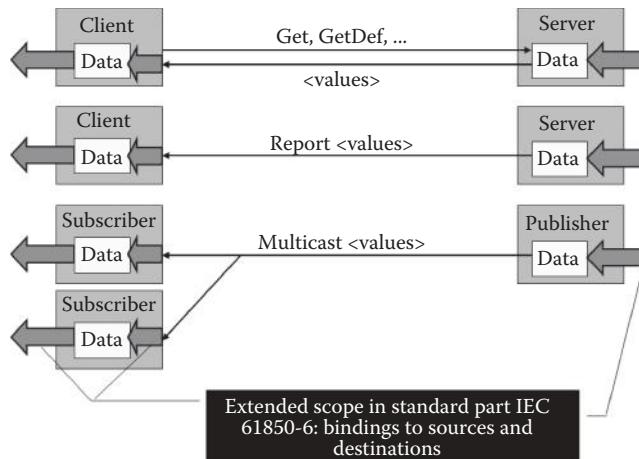

FIGURE 62.15 Services used and extended in the configuration.

An excerpt of the information exchange services for accessing information models in a device (implementing a server and subscriber role) is displayed in Figure 62.16. The circles with the numbers refer to the bulleted list provided later.

The operate service manipulates the control-specific data attributes of a circuit breaker position (open or close the circuit breaker). The report services spontaneously inform another device that the position of the circuit breaker has been changed. The substitute service forces a specific data attribute to be set to a specific value; this may be required for test purposes or when the position sensors are defective.

The categories of services (defined in IEC 61850-7-2) are as follows:

- Control devices (operate service or by multicast trip signals) [1]
- Fast and reliable peer-to-peer exchange of status information (tripping or blocking of functions or devices) [2]
- Reporting of any set of data (data attributes), SOE—cyclic and event triggered [7]
- Logging and retrieving of any set of data (data attributes)—cyclic and event-triggered [8]

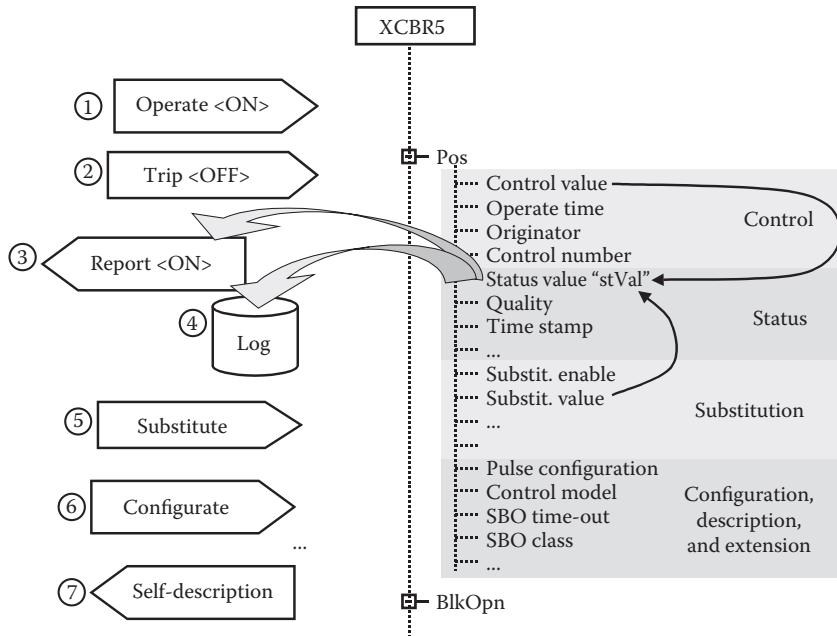

FIGURE 62.16 Service excerpt.

- Substitution [9]
- Handling and setting of parameter setting groups
- Transmission of SVs from sensors
- Time synchronization
- File transfer
- Online configuration [10]
- Retrieving the self-description of a device [3]

The information exchange models defined in IEC 61850-7-2 are listed in Table 62.4.

The information exchange supports various methods to access process data. The polling is the most common method. The use is restricted to applications that do not rely on real-time information and SOE. Data values may be lost because the value may have been overwritten by the application between two GetDataValue requests.

The buffered and unbuffered reporting starts with the configuration of the report control blocks. The basic buffered reporting mechanism is shown in Figure 62.17. The reporting starts with setting the enable buffer attribute to TRUE; setting to FALSE stops the reporting.

The specific characteristic of the buffered report control block is that it continues buffering the event data as they occur according to the enabled trigger options in case of, for example, a communication loss. The reporting process continues as soon as the communication is available again. The buffered report control block guarantees the SOE up to some practical limits (e.g., buffer size and maximum interruption time).

The basic architecture of reporting, logging, GOOSE, and SVs is the existence of an information model, data sets (that refers to data attributes), and control blocks that refer to a data set (see Figure 62.18). A specific data set can be used by any of the four control block types (reporting, logging, GOOSE, and SVs). And a specific data set can be used by multiple control blocks at the same time. This makes the information model and how the values are exchanged independent of each other.

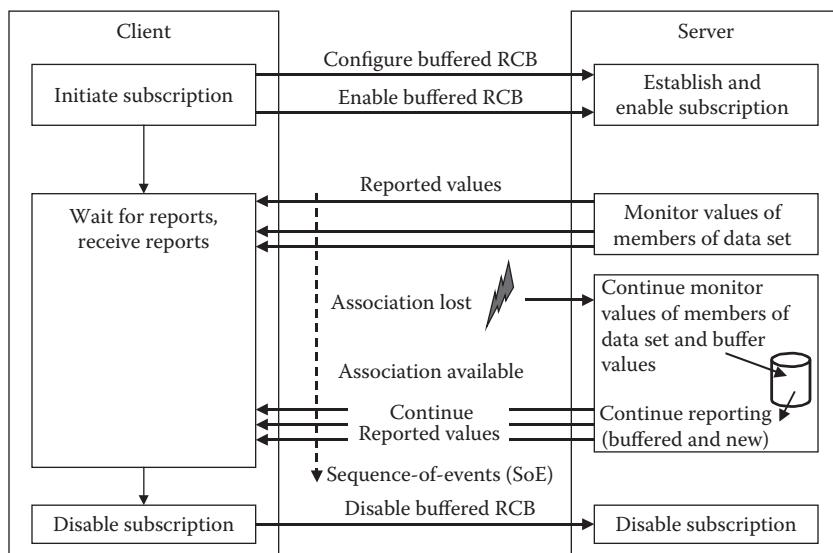

**TABLE 62.4** Information Exchange Models

Information Exchange Model	Description	Services
Server	Represents the external visible behavior of a device. All other ACSI models are part of the server.	ServerDirectory
Application association	Provision of how two or more devices can be connected. Provides different views to a device: restricted access to the server's information and functions.	Associate Abort Release
Logical device	Represents a group of functions; each function is defined as a logical node.	LogicalDeviceDirectory GetAllDataValues
Logical node	Represents a specific function of the substation system, for example, overvoltage protection.	LogicalNodeDirectory
Data	Provides a means to specify typed information, for example, position of a switch with quality information, and time stamp.	GetDataValues SetDataValues GetDataDefinition GetDataDirectory
Data set	Allow to group various data together.	GetDataSetValue SetDataSetValue CreateDataSet DeleteDataSet GetDataSetDirectory
Service tracking	Specialized reporting and logging services that allow to report and log (track) the service parameters of received service indications and service responses. Special common data classes for service tracking are defined in IEC 61850-7-2.	Services of reporting and logging are applied.
Substitution	The client can request the server to replace a process value by a value set by the client, for example, in the case of an invalid measurement value.	SetDataValues
Setting group control	Defines how to switch from one set of setting values to another one and how to edit setting groups.	SelectActiveSG SelectEditSG SetSGValues ConfirmEditSGValues GetSGValues GetSGCBValues
Reporting and logging	Describes the conditions for generating reports and logs based on parameters set by the client. Reports may be triggered by changes of process data values (e.g., state change or deadband) or by quality changes. Logs can be queried for later retrieval. Reports may be sent immediately or deferred (buffered). Reports provide change-of-state and sequence-of-events information exchange.	<b>Buffered RCB:</b> Report GetBRCBValues SetBRCBValues <b>Unbuffered RCB:</b> Report GetURCBValues SetURCBValues <b>Log CB:</b> GetLCBValues SetLCBValues <b>Log:</b> QueryLogByTime QueryLogAfter GetLogStatusValues <b>GOOSE CB:</b> SendGOOSEMessage GetGoReference GetGOOSEElementNumber GetGoCBValues SetGoCBValues
Generic substation events (GSE)	Provides fast and reliable system-wide distribution of data; peer-to-peer exchange of IED binary status information. GOOSE means Generic Object-Oriented Substation Event and supports the exchange of a wide range of possible common data organized by a data set.	

(continued)

**TABLE 62.4 (continued)** Information Exchange Models

Information Exchange Model	Description	Services
Transmission of sampled values	Fast and cyclic transfer of samples, for example, of instrument transformers.	<b>Multicast SVC:</b> SendMSVMessage GetMSVCBValues SetMSVCBValues <b>Unicast SVC:</b> SendUSVMessage GetUSVCBValues SetUSVCBValues
Control	Describes the services to control, for example, devices or parameter setting groups.	Select SelectWithValue Cancel Operate CommandTermination TimeActivatedOperate
Time and time synchronization	Provides the time base for the device and system.	services in SCSM
File transfer	Defines the exchange of huge data blocks such as programs.	GetFile SetFile DeleteFile GetFileAttributeValues

**FIGURE 62.17** Buffered reporting (conceptual).

The reporting model supports two kinds: unbuffered and buffered (see Figures 62.19 and 62.20). In the case of unbuffered reporting, the events that issue a report are communicated only when communication is available. In case of a communication interrupt, the buffered reporting will store (buffer) the events during the interrupt and send the reports when communication is available again.

The buffered reporting is used to get an SOE. The SOE is crucial to a user for providing all changes that happened in order to react on changes.

The data attributes (like the position of a switchgear, XSWI.Pos) of several LNs and data objects are listed in a data set as shown in Figure 62.21. The members of the data set are references to the models

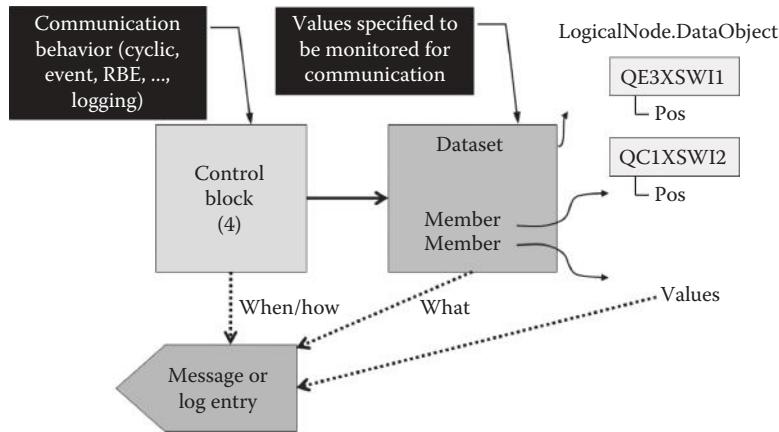

FIGURE 62.18 Control blocks and data set.

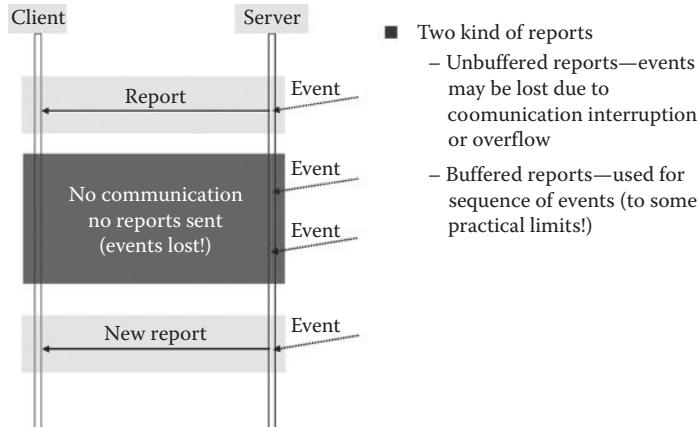

FIGURE 62.19 Unbuffered event reporting mechanism.

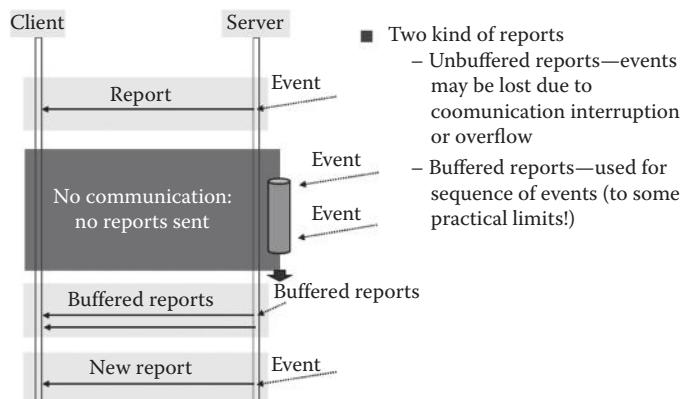

FIGURE 62.20 Buffered event reporting mechanism.

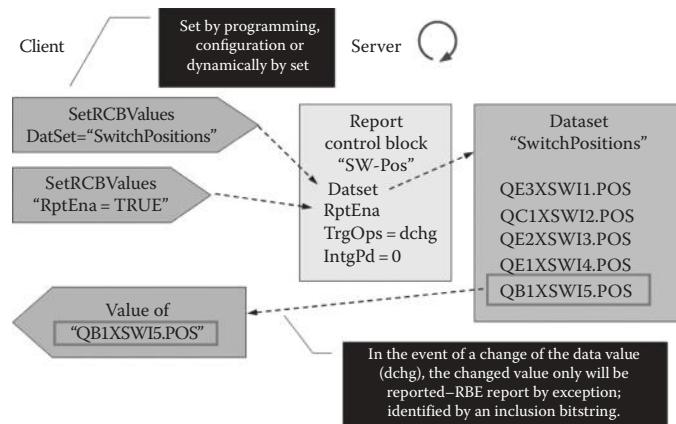

FIGURE 62.21 Report by exception.

that expose the real status values of the switch yard. If a position of one of the members of the data set changes, then only the value of that object will be reported according to the configuration of the report control block, for example, the value of QB1XSWI5.Pos. This behavior is called report by exception (RBE). This reduces the number of octets to be communicated to the minimum.

In our example, the report message just communicates one value—the fifth member of the data set. The report message included a so-called inclusion bitstring that indicates to the receiving side which object has issued the report—in this case number 5. The structure of the data set is quite important and should not be changed once the device is running.

Note that the report control block model is more comprehensive than shown in the earlier example.

Figure 62.22 shows an example of a log and three log control blocks. The first step is to configure and enable log control blocks. After enabling, the association with that server may be closed. The log entries are stored into the log as they arrive for inclusion into the log. The logs are stored in time sequence order. This allows the retrieval of an SOE list.

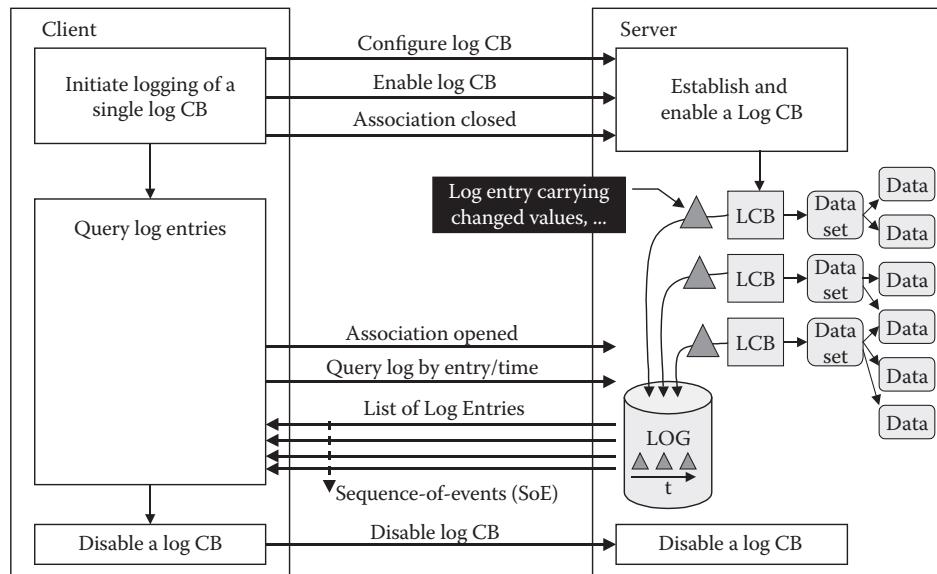

FIGURE 62.22 Log control block (conceptual).

The different log control blocks allow storage of information from different data sets into a log instance. Each log control block is independent of the other control blocks.

Two models are dedicated to the transmission of information with high priority in real time:

*GOOSE Event* is used to model the transmission of high-priority information like trip commands or interlocking information. The model is based on cyclic and high-priority transmission of status information. Information like a trip command is transmitted spontaneously and then cyclically at increasing intervals.

*SV* is used to model the exchange of the sampled MVs from current and voltage transducers to any IED that need the samples. The model is based on an unconfirmed transmission of a set of SVs. A counter is added to time-correlate samples from different sources and to detect the loss of a set of samples.

*GOOSE* and *SV* service models are defined in IEC 61850-7-2. The mapping of the SMV model to a concrete communication system is specified in IEC 61850-9-1.

A summary of all services that allow exchanging information between two devices could be found in Table 62.5. The application of one of the various possibilities depends on the needs of an application.

The two main approaches (TCP/IP-based reporting and Ethernet-based communication) are compared in Table 62.6. The main differences is the maximum length of the messages: The use of TCP/IP for the message routing respective using Ethernet directly without routing capabilities.

The resulting timeliness is quite different in both solutions. With TCP/IP, reaction times in the range of 1 s could be expected. This seems to be sufficient for most SCADA applications. The multicast messaging could be applied for real-time applications in the power transmission and distribution domain. Reaction times in the range of a few milliseconds could be implemented.

**TABLE 62.5** Information Exchange Mechanisms

Get a value of single data object ( <u>GetDataValues</u> – Client initiated)
Get a list of values of data objects ( <u>GetDataValues</u> with list sent in each request – Client initiated)
Get the complete list values of data objects using a dataset object ( <u>GetDataSetValues</u> – Client initiated)
Get the complete list of values of data objects (of a dataset) using reporting ( <u>reporting</u> , <u>General Interrogation</u> – Client initiated)
Get the complete list of values of data objects (of a dataset) using reporting ( <u>reporting</u> , <u>Integrity period</u> – Server initiated)
Get one (ButTm=0) or more (ButTm>0) value(s) of data objects (of a dataset) using <u>reporting</u> on data and quality change and data update – Server initiated
GOOSE and Sampled Values ... exchanges complete list of values of data objects of a dataset (events: application specific – Server initiated)
Get sequence of value(s) of data objects (of a dataset) using <u>logging</u> (on data and quality change and data update – Client initiate)

**TABLE 62.6** Comparison of Event Reporting Mechanism

	Reporting	GOOSE/SMV
Max. message size	... 64.000 ... octets	< 1.500 octets
Segmentation	Yes (option in report)	No
Flow control	Yes (TCP)	No
Detection of loss	Yes (TCP)	Yes (var. counters)
Reliable transmission	Yes (TCP)	Yes (re-transm./cyc.)
Network routing	Yes (IP)	No (yes: 90-5 UDP/IP)
Relation – 1:1	Yes	No/yes
Relation – 1:n	Yes (multiple CBs)	Yes (layer 2 multicast)
Timeliness	... 1 sec ...	... few msec ...
General interrogation	Yes	No
Layers	1 ... 7, application	1,2,7, application
Documents	IEC 61850-7-2, 8-1	IEC 61850-7-2, 8-1/9-2

The multicast messages are according to IEC 61850-8-1 (GOOSE) and IEC 61850-9-2 (SVs) not routable through a network. The requirement for wide-area awareness of the situation of the electrical network has led to a new part IEC 61850-90-5 applied for wide-area phasor measurement exchange. IEC 61850-90-5 defines that GOOSE and SVs can also be exchanged using UDP/IP. The timeliness is less stringent; it is typically for crucial applications in the range of several seconds.

The timeliness of the communication according to the IEC 61850 standard series depends mainly on the implementation at the senders and receivers of messages. The communication system comprised of Ethernet switches and routers is usually less critical.

## 62.7 System Configuration Language

The use of IEC 61850 requires to be very precise on how and when to communicate which information to whom. All this configuration information is formally defined by applying a huge XML schema according to IEC 61850-6. Vendors have to use these templates to configure their devices. Users can use the same template independent of the devices' manufacturer.

IEC 61850-6 also describes the electrical single-line drawing in the form of an XML document derived from the part 6 XML schemas (Figure 62.23). The textual description is on the left. The single-line diagram depicts also a couple of LNs that indicate that there will be a distance protection function (PDIF) at the top and a differential protection at the transformer. The current sensor (TCTR) is below the transformer. Next to the circuit breaker, there are three LNs that describe the circuit breaker information (XCBR) and how it can be controlled (CSWI and CILO). The CSWI is exposing the information for the control function, while CILO represents the interlocking information, that is, closing or opening of the circuit breaker allowed at the moment or not.

The formal representation of this diagram (only the topology and not the graphical representation) is contained in an XML document (see Figure 62.24).

This document is the result of a system design process. The document will be used as input for the system engineering process to map the information and communication needed to real devices. The protection function may be implemented in a single protection device and the control functions in another. The current sensor may be implemented in a third device (usually called merging unit).

FIGURE 62.24 Single-line diagram according to SCL schema.

The merging unit typically may send 80 samples per nominal period or 4.000 per second at 50 Hz systems. This means that for protection functions, the merging unit sends 4.000 messages per second over the network—continuously.

The substation specification description as partly shown in Figure 62.24 contains the complete topology of the substation from an electrical and information point of view. The information represents all information needed and provided by the underlying function like CILO for interlocking.

There are various tools available that support the design of the single-line diagram.

The next step in substation description is to map the information indicated by the shown LNs to real devices like merging units for the current and voltage sampling and SV exchange.

The third step in the engineering process is the configuration of the needed devices:

- Instantiate devices
- Define unique names for devices and logical devices
- Map logical in the single-line diagram to LNs in the instantiated devices
- Design communication network
- Design data flow

The design of the data flow (traffic engineering) is one of the most crucial steps to reach a stable communication system at the end of the day. The reason is quite simple: The traffic in systems like substation protection and automation will be characterized by cyclical and spontaneous information exchange. The transmission of SVs generates a constant flow, for example, 4.000 messages with samples of voltages and currents for protection devices. There is a lot of traffic that is issued by events (state changes, limit violations, quality changes, etc.) and alarms. The number of messages is increased when the monitoring process is checking for rather small changes (change of measurement by 1%) instead of changes in the range of 10%. IEC 61850 can also send messages cyclically—configured by a setting.

The settings for monitoring values and cyclical reports could end up in a situation that the many interworking devices exchange many more messages than required by the application. There could be showers or even avalanches of messages occur that congest the communication system to some degree, causing unacceptable delays.

```

**FIGURE 62.25** SCL document for a simple device.

For that reason, a good understanding of the needs is very crucial during the traffic engineering. Based on the needs, the following steps have to be processed:

- Configure reports and required data sets
- Preconfigure a client for the report
- Configure data flow for publish/subscriber services
- Configure GOOSE and SMV controls and required data sets
- Optionally configure subscribing IEDs
- Configure inputs to LNs
- Data required as inputs can be transmitted by GOOSE/SMV or as reports

An example of an SCL document of a simple device is shown in Figure 62.25.

The figure shows a device (IED) with a logical device LDevice1 and logical nodes LN0, LPHD, and WEBPLC\_GGIO1. The logical node LN0 comprises a data set and a report control block.

SCL documents of real devices are usually quite comprehensive exposing hundreds or thousands of signals modeled in umpteen LNs. The document usually is used to be imported by a device-specific configuration to generate a device-specific file that is loaded onto the device to configure the device. There are also devices that can interpret SCL files and configure the information and communication models during the start-up of the device. An example will be introduced further down in the clause.

## 62.8 Overview of Implementation Layering

One of the challenges with IEC 61850 is that there are multiple layers involved from models all the way down to messages exchanged over the network. The standard IEC 61850 is more than just a protocol. Therefore, the various levels have to be mapped to the next underlying layer and provide in the end messages that carry meaningful information—information that can be encoded and decoded in a multivendor environment to create interoperable systems.

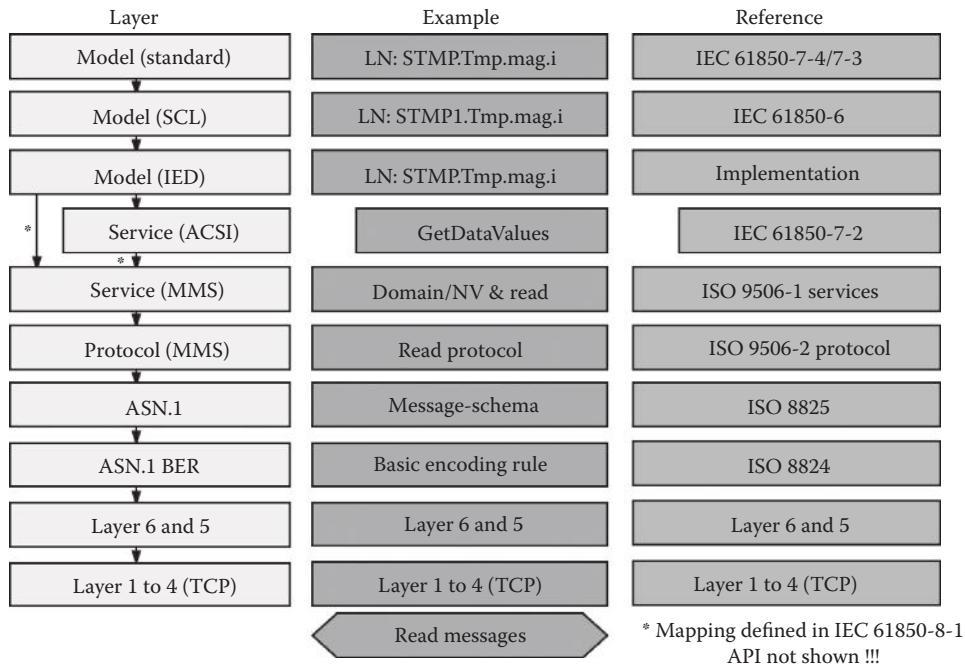

FIGURE 62.26 Layers from models to messages.

Figure 62.26 shows how the 10 layers involved from models down to messages. The left column defines the layer, the middle column shows an example, and the right contains the documents that define the corresponding layer.

The top layer shows the model of a temperature supervision LN STMP (see Figure 62.27). The model comprises data objects that represent information of specific monitoring functions. The attribute

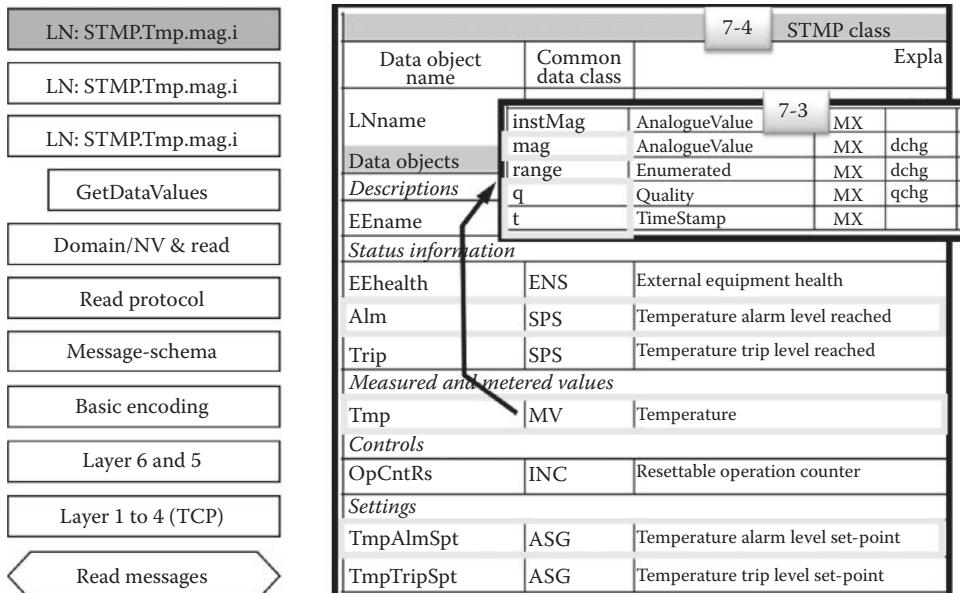

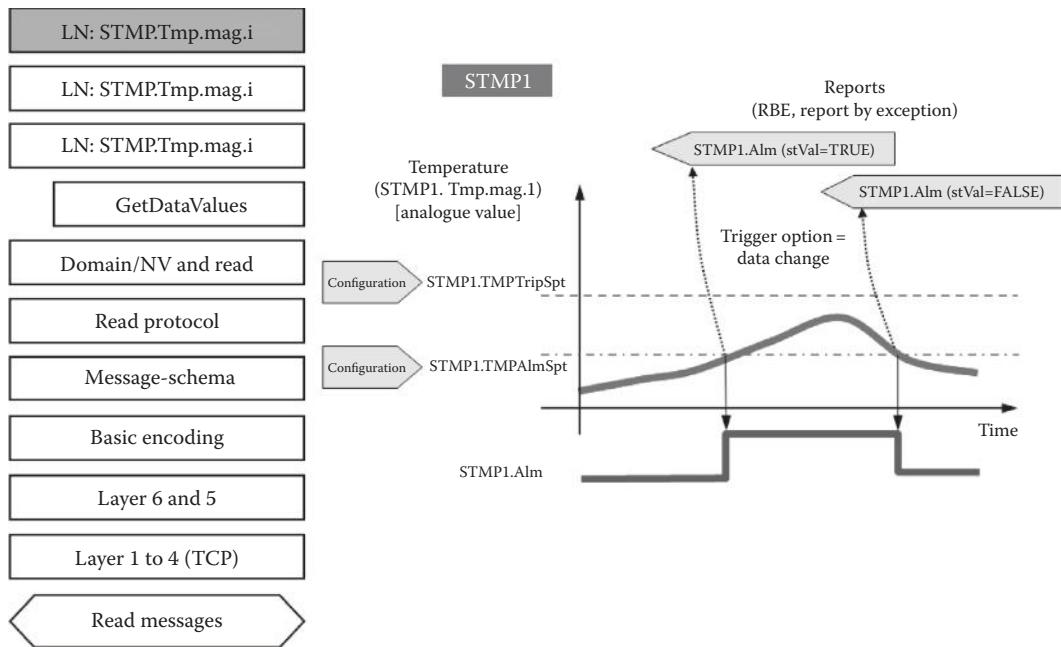

FIGURE 62.27 Model standard.

**FIGURE 62.28** STMP supervision function.

STMP.Tmp.mag.i exposes the temperature value of a temperature sensor. The sensor itself is modeled with the LN TTMP.

The STMP LN is composed of a list of data objects that are used to define input and output values for the function. The main data object is the object Tmp. The temperature is an instance of the CDC MV. An MV has several data attributes like instMag (the current rms value), mag (a deadband filtered value), q (quality), and t (time stamp of the last change of the mag attribute). These attributes are all characterized as measurement (FC = MX). The last column in the MV CDC is defining the trigger option (dchg = data value change, qchg = quality change). The trigger option is used to control the reporting and logging procedures. If the value of mag changes (based on a percentage value change, e.g., value changes by 5%), then a report message with the new value, q and t, could be issued automatically.

Further data objects are TmpAlmSpt (alarm set point) and Alm (alarm). The diagram in Figure 62.28 shows the overview of the supervision function.

In this case, the supervision function is more or less trivial. The monitoring of temperatures is quite straightforward. Further monitoring features like supervising the change rate of the temperature and others are not (yet) standardized. The standard IEC 61850 is open to add more supervision functions in these basic supervision functions.

The second layer (see Figure 62.29) is the description of the model as an instance of the SCL schema. The example shown here is the LN element that has attributes InClass (= STMP), an instance number 1, no prefix, and InType (= STMP\_0). The InClass is the definition of the standard model; the InType is a subset of the standard model and possibly including some preconfigured values like scaling factor or offset of an integer typed analog value. The underlying elements like DOI contain the data object instances—here the Alm, Tmp, and TmpAlmSpt.

The next level (see Figure 62.30) describes an example of the implementation of the model in a real IEC 61850-8-1 communication stack (using MMS) and API. The stack and application software use the private binding element (five values in five fields) to bind the application memory to the IEC 61850 information model (signal) and vice versa. These five fields are exchanged between the application and stack. This API is vendor specific.

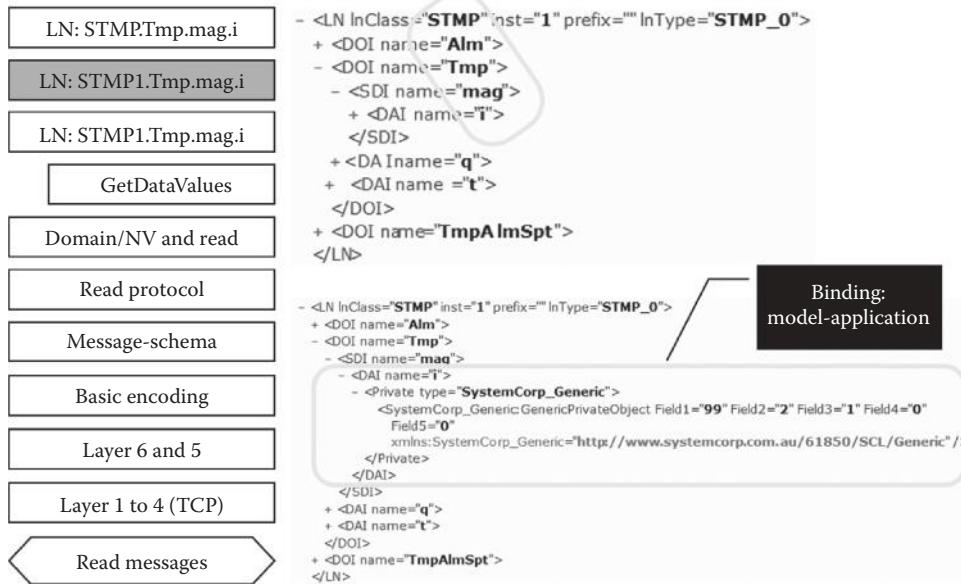

FIGURE 62.29 SCL document of example.

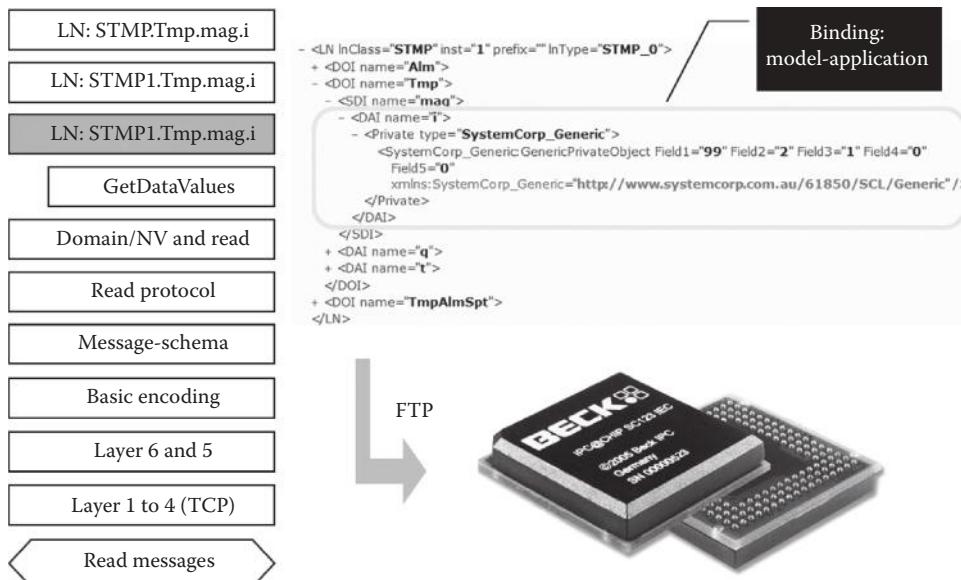

FIGURE 62.30 Model implementation with real stack and API.

The SCL document with that LN and binding is transferred to the embedded controller. This controller runs the stack, API, and application. When the application starts, it reads the SCL file, interprets, and implements the model. The stack instantiates all data sets and control blocks for reporting, logging, GOOSE, and SVs. There is no further configuration for IEC 61850 functions required. Note that the LNs are just interfaces to the functions. The real values of the data objects of the STMP LN are calculated and processed by the application program; it is outside of IEC 61850.

The application that figured out a new value of the STMP.Tmp.mag informs the stack through the API of a new value (API update function call). The stack autonomously issues a report message, or the client can read the new value by issuing a Read service request that will be answered with a Read response by the server device.

The model and services must be mapped to the MMS standard. The logical device in IEC 61850 maps to a Domain object in MMS. The LN is mapped to an MMS NamedVariable that is contained in a Domain. The ACSI service GetDataObjectValue maps to an MMS Read service.

The layers of the detailed mapping (IEC 61850-8-1), the MMS Read service (ISO 9506-1) and Read protocol (ISO 9506-2), the used abstract syntax notation (ASN.1) as well as the concrete basic message encoding (ASN.1 BER), and the other layers (Presentation, Session, Transport, Network, Data Link, and Physical) are defined in the documents shown in Figure 62.26.

As a result of applying all definitions of the different layers, the message that carries the Read service request can be encoded as shown in Figure 62.31. The various layers are indicated in the figure (using the Wireshark to analyze the message). The top indicates the complete frame of size 123 octets. Then the details like Ethernet, IP, TCP, TPKT (RFC 1006 for the mapping of ISO Transport Layer class 0 to TCP), session, presentation, and MMS. The application layer protocol encoding of messages is not important; the overhead of the TCP/IP routing takes most of the time.

The MMS Read request comes with the tags to interpret this message as a MMS Read request, the invokeID (message number), and the path name for the object to read: STMP1.Tmp.mag.i. The message in the mapping to MMS adds the functional constraint FC = MX into the name and replaces the “.” with “\$” due to restrictions in MMS.

It is important to note that all layers and the mapping to the corresponding underlying layer are defined in a suite of standards.

The message encoding of MMS has been criticized since the very beginning in the late 1980s. The encoding rules of ASN.1 BER (ISO 8825) generate some overhead. This could be neglected when using event-driven or spontaneous reporting and applying RBE mechanism. The amount of bits and messages to be transmitted with high-efficient encoding and applying polling is much higher than less efficient encoding and just a few crucial messages to be transmitted.

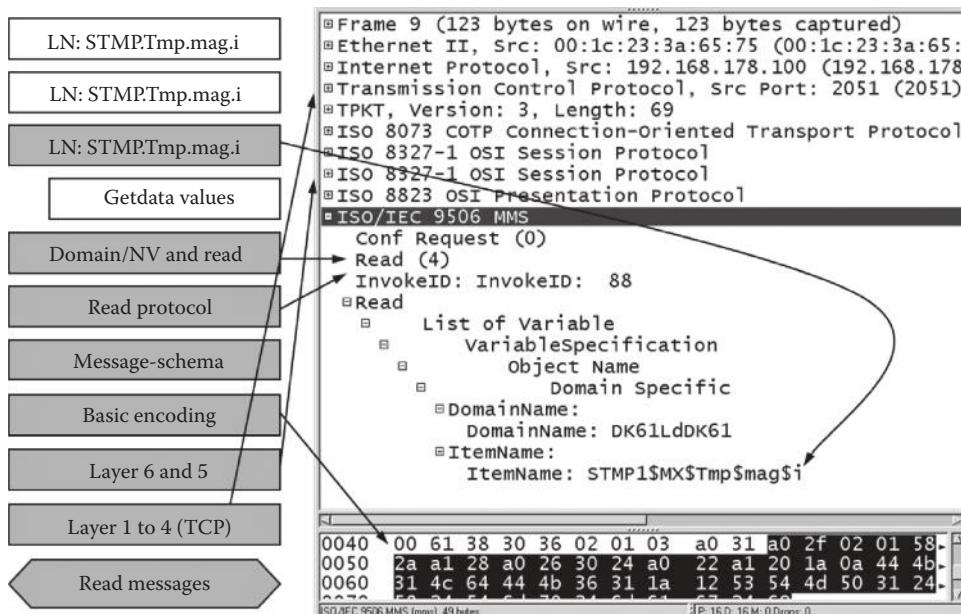

FIGURE 62.31 MMS Read request message example.

In addition to event-driven messages, it is also important to understand the process requirements and configure a system such that only the severe signals are transmitted. The overhead of a single message is one issue; another is the optimization of event and alarm generation and how these are packed into one or several messages. In case there is a data set comprising a lot of status signals to be monitored for changes, it is crucial to configure the system in a way that a minimum of messages are issued and transmitted.

IEC 61850 can collect several status changes that occur in a short time, for example, 1 s. All status changes that happen within 1 s after the first change of a signal in that data set will be sent together in one message after 1 s expired. If five changes happened in that second, there is a tremendous saving of bits and messages on the wire.

The optimum is mainly dependent on the configuration of the signal flow (traffic engineering). The configuration language of IEC 61850-6 carries the configuration values set by human beings that should know the applications needs very well. Garbage in–garbage out! IEC 61850 is just a tool that can be used by humans.

It is highly recommended to spend appropriate time in analyzing the application needs before any device is configured for flow control. This is true for any other communication system as well—even for communication that is based on cyclic polling. Polling does not scale if there are many signals that need to be communicated with short reaction time, especially in the case of very few events and alarms over time. Spontaneous messages require powerful receivers. In case of event showers these devices have to handle the amount of messages that arrive in a short time. The number of messages is more critical than the length of messages.

For real-time information exchange like GOOSE messages (repetitions in the range of milliseconds) and SV exchange (cyclic transmissions up to several thousand messages per second), the encoding is critical. IEC 61850 encodes the payload for these messages as an octet string with fixed-length values. The encoding and decoding are very efficient; the flexibility is of course reduced, and a change in the structure is not easy to figure out.

## 62.9 Related International Projects and Application Example

---

The requirement for secure and reliable information exchange is one of the most crucial requirements in the future of the power delivery systems. It is no surprise that many activities refer to the list of standards published by IEC and especially by the Technical Committee 57.

The following list shows some of the international projects that recommend applying international standard for information exchange and communication; most documents refer especially to IEC 61850:

- OGEMA—Open Energy Management Gateway
- <http://ogema.org/>

One of the key questions in the years to come is this: How can gateways for smart grid applications implemented that allow using the common RTU protocols and giving a migration path to IEC 61850? The following example is used to demonstrate that IEC 61850 could be implemented in small embedded devices.

### 62.9.1 Gateway for Smart Grid Applications

First implementations of IEC 61850 were focused on high-voltage substations. The devices and software for IEC 61850 were quite expensive, complex, and with restricted services. There were more or less just two vendors of stack software; that was acceptable for the beginning of the new approach. Many R&D projects all over interested in IEC 61850 lab or pilot projects failed to purchase or port the source code on their platforms.

The OGEMA project purchased a source code—which was at the end of the day not ported due to restricted resources. The need for simple stack and API for small devices in power generation, distribution automation, and smart grids was more than due.

In order to focus on the many challenges of the automation and management of the power system, it was quite important to hide details of MMS, IEC 61850 software, and their configuration—and to expose only those features that are very crucial. This would have allowed a fast start with low cost and low risk.

Due to the many challenges with the IEC 61850 implementation, many projects implemented appropriate LNs and data objects and used proprietary web services to exchange values with IEC 61850 models. One of the involved institutes (ISE—Fraunhofer Institute for Solar Systems in Freiburg, Germany) implemented MMS in Java and C as open-source projects. The open-source code implements a small subset of IEC 61850 models and services.

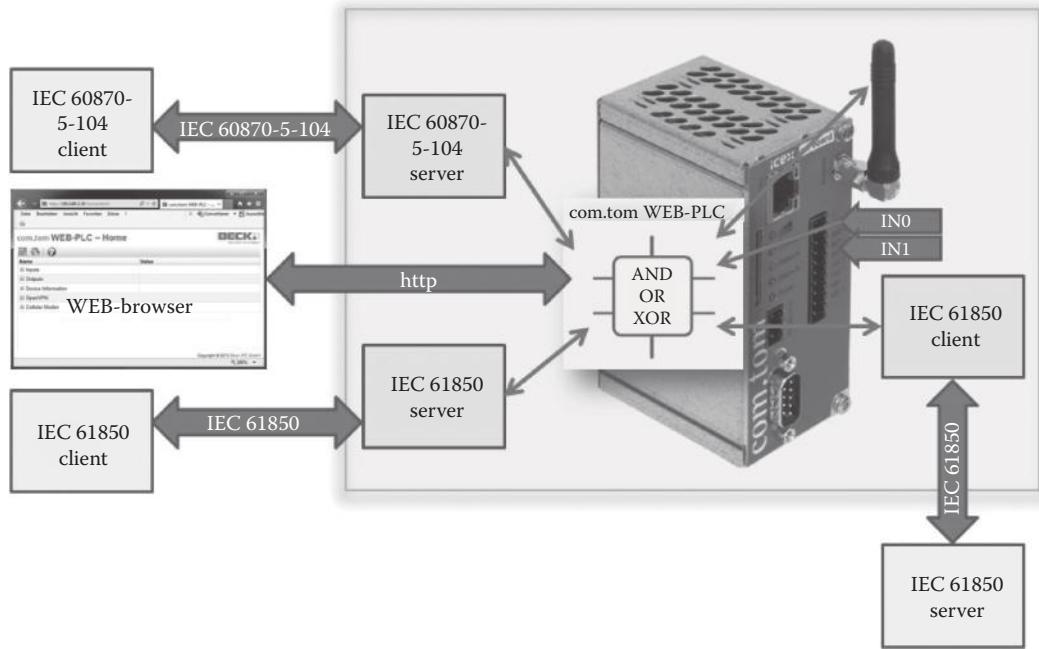

FIGURE 62.32 WEB-PLC and multiprotocol gateway.

Finally, for the OGEMA gateway, the IEC 61850 stack and API from SystemCorp was integrated into the OGEMA framework. This allows applying almost all services of IEC 61850-7-2 and IEC 61850-8-1 including reporting and GOOSE.

IEC 61850 has been successfully integrated as well into the embedded controller **com.tom** provided by Beck IPC (see Figure 62.32). This small platform uses a real-time operating system that has a lot of components like serial links, I/Os, wireless, GPRS, and openVPN already integrated in the platform. It supports all crucial protocols like IEC 61850, IEC 60870-5-104, DNP3, Modbus, CAN bus, and Profibus. The programming languages C/C#, IEC 61158-3 (PLC Programming languages), and a very simple web-based logic programming (WEB-PLC) are implemented.

The WEB-PLC could be used as core component to map signals from one communication system to another. All major protocols used in the energy world are implemented and could be used without a need for a vendor-specific tool—it requires just a standard web browser once connected to the server (see Figure 62.33).

Once the application (logic) diagram is drawn, the diagram can be loaded to the platform (**com.tom**) and started by pushing a button on the web browser. No vendor-specific engineering tool is required.

The WEB-PLC objects “IEC 61850 Indication1-from-DK61” and “IEC 61850 Indication2-from-DK61” are representing two binary signals from an underlying device with an IEC 61850 server. The two signals are reported from the server device at any time when they change. The two signals are used as input to the AND gate. The output of the AND gate is then communicated internally to the WEB-PLC output object IEC 60870-5-104 server Indication0-from-61850-Client. In case the two signals from the IEC 61850 server are both becoming true, then the AND output will change to true as well, and the change to true will be communicated to a master station via an IEC 60870-5-104 message.

Any control center, HMI or SCADA system, that could receive messages according to IEC 60870-5-104 would be able to receive the AND output signal. The signals from the IEC 61850 server could of course directly map 1:1 to an IEC 60870-5-104 or DNP3 message.

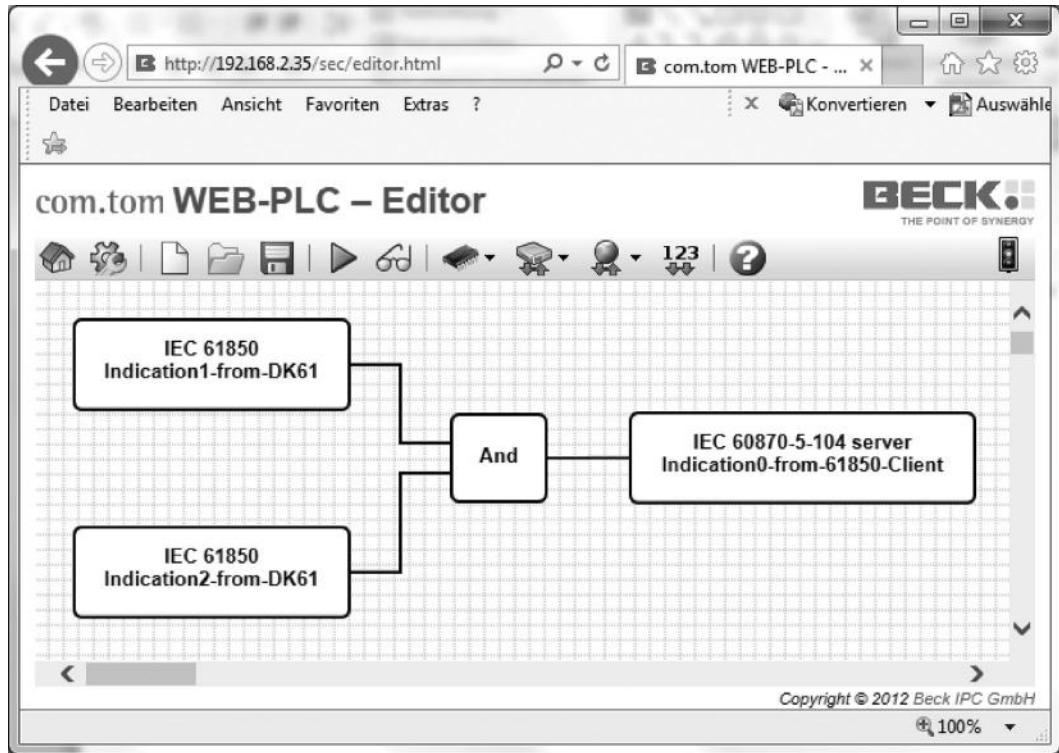

FIGURE 62.33 WEB-PLC to bind inputs to outputs.

In order to program a function all input and output objects (shown as rectangle icons of the WEB-PLC) on both sides (uplink with IEC 60870-5-104 and downlink with IEC 61850) need to be bound to the incoming respective the outgoing signals.

## 62.10 UCA International Users Group (UCA IUG) and Quality Assurance

The UCA International Users Group [11] is a not-for-profit corporation focused on assisting users and vendors in the deployment of standards for real-time applications for several industries with related requirements. The Users Group does not write standards; however, it works closely with those bodies that have primary responsibility for the completion of standards (notably IEC TC 57: Power Systems Management and Associated Information Exchange).

The UCAIug as well as its member groups (CIMug, Open Smart Grid, and IEC61850) draws its membership from utility user and supplier companies. The mission of the UCA International Users Group is to enable integration through the deployment of open standards by providing a forum in which the various stakeholders in the energy and utility industry can work cooperatively together as members of a common organization to do the following:

- Influence, select, and/or endorse open and public standards appropriate to the energy and utility market based upon the needs of the membership.
- Specify, develop, and/or accredit product/system-testing programs that facilitate the field interoperability of products and systems based upon these standards.

- Implement educational and promotional activities that increase awareness and deployment of these standards in the energy and utility industry.
- Influence and promote the adoption of standards and technologies specific to the ever-increasing smart grid initiatives worldwide.

The USAIUG is responsible for the definition of requirements and procedures for IEC 61850 conformance tests and accrediting and auditing test laboratories globally. The test procedures cover server tests, client tests, and tests of merging units.

Five third-party test labs and five company internal test labs are accredited. As of May 2013, the UCAIUG has certified 24 client devices, 344 server devices, and 9 merging units.

To collect and discuss technical errors and document the resulting correction, the standardization experts of the various groups that are defining, maintaining, and extending the standard definitions maintain the so-called tissue data base (technical issues) [12].

The tissue data base is a very helpful tool to keep track of the known and reported issues like errors, missing text, inconsistencies.

TÜV SÜD (Munich Germany) is one of the five third-party testers [13]. They are also deeply involved and support interoperability tests. It is understood that interoperability tests are very crucial for the acceptance and widespread use of the standard. TÜV SÜD acts also as a competence center for IEC 61850.

## 62.11 Third-Party Solutions for IEC 61850

---

The standard series IEC 61850 and IEC 61400-25 are quite comprehensive and abstract. One lesson learned since the mid-1980 (when MMS was defined and published) is this: Talking about benefits of a standard is needed, *but* it is most crucial that vendors are developing standard complaint devices. The implementation of MMS and the underlying layer services and protocols—as a core component in the message exchange between all devices in a system—was understood as calling for an unparalleled and huge effort and amount of resources.

Until 2010, there were mainly two source code solutions available. These two had been developed in the late 1980 and early 1990. Most of the early supporters and vendors of IEC 61850-compliant devices used one or the other of the two. Very few vendors implemented the complete stack and API on their own. If they did, it took years before they finished. Even with the source code, very often it took a year or two before the software was ported and integrated into the applications.

Stack and API especially for embedded systems

### 63.1 Introduction

---

Building, managing, and monitoring systems for renewable energy plants are challenging tasks since they require the integration of big amount of data of diverse nature produced by different equipment from several vendors. Commonly, manufacturers provide proprietary software packages for specific data access. This introduces a higher level of complexity to the operators, administrators, and system integrators as they must deal with equipment from different vendors offering specific data access and formats.

In this scenario, the International Electrotechnical Commission (IEC) (Technical Committee TC88/PT25) proposed a new communications standard for the wind power industry aiming at providing a common communication approach for wind power plant (WPP) monitoring and control. This standard makes the integration of heterogeneous devices in large and complex WPPs easy, and at present, it is the only available standard for wind turbine (WT) communications.

The IEC 61400-25 standard may be regarded as an extension of the IEC 61850 standard [1,13], which deals with communication networks and systems in substations. More specifically, the IEC 61850 series cover the integration of the so-called intelligent electronic devices (IEDs), that is, any device incorporating one or more processors with communication capabilities within substation automated systems (SASs). IEC 61400-25 reuses the information and exchange models defined in IEC 61850 for electric power systems but adapted to WPPs. Thus, it defines the relevant information specific to WPPs as well as manufacturer-independent mechanisms for information exchange.

The communication approach is based on three different areas: (1) the *information model* (IM), which defines the hierarchy of relevant information in WPPs using standardized names and semantics; (2) the *information exchange model* (IEM), which defines the access to the content and structure of the WPP IMs; and (3) the *mapping* of these two models to *standard protocol stacks*, such as OPC [2], MMS [3], or DNP3 [4]. It is important to remark that feeders and substation equipment are not covered in IEC 61400-25 as they are included in IEC 61850.

As a result, the IEC 61400-25 series allows applications such as SCADA (Supervisory Control and Data Acquisition) systems, local real-time build-in control systems, or energy dispatch centers, to access WPP information data from different vendor equipment while providing scalability, connectivity, and interoperability.

In 2008, the USE 61400-25 (IEC 61400-25 users group) [5] was created to facilitate the adoption of the standard in the wind power generation industry. Major WT vendors, system integrators, and users are actively involved in this initiative.

## 63.2 Overall Description of the IEC 61400-25 Series

---

The main objective of the IEC 61400-25 series is to define a standard basis for manufacturer-independent communications for monitoring and control of WPPs. They define what vendors (manufacturer and suppliers) of WPP's components should implement in their systems and devices to be compliant to the standard and consequently to achieve vendor-independent interoperability between the WPP and external actors (applications).

The IEC 61400-25 standard is divided into six different parts:

1. IEC 61400-25-1 Overall description of principles and models: Part 1 gives a general overview of the standard, analyzing the major communication requirements, establishing the terminology used through all the parts, and giving a brief description of the information and exchange models.
2. IEC 61400-25-2 Information models: Part 2 defines the elements of the models representing the WPP's components from the communication point of view (data objects) and the naming convention for both the elements and the data (communication content).
3. IEC 61400-25-3 Information exchange models: Part 3 is dedicated to the description of the data exchange mechanisms, such as authentication, control commands, subscription to data publication, or device description.
4. IEC 61400-25-4 Mapping to communication profiles: Part 4 proposes several communication profiles for mapping the models described in previous sections to standard communication protocols.
5. IEC 61400-25-5 Conformance testing: Part 5 defines methods and abstract test cases for conformance testing of devices used in WPPs.
6. IEC 61400-25-6 Logical node (LN) classes and data classes (DCs) for condition monitoring: Finally, part 6 defines additional IMs to be used in condition monitoring systems.

The IEC 61400-25 series defines models, but recommendations for implementing the communication interface and the application program interface are not included.

### 63.2.1 Wind Power Plants

According to the IEC 61400-25 series, WPPs may be regarded as a particular case of SAS of the IEC 61850 series. WPPs are complex systems composed of the following components:

- *WT* is the main component of a WPP, and it is responsible for generating energy by converting kinetic wind energy into electric energy. The main subcomponents within a WT are the rotor, the transmission system, the generator, the converter nacelle, the yaw system, the tower, and the alarm system.
- *Meteorological system* is in charge of monitoring the ambient conditions. Ambient variables such as the wind speed and direction, the pressure, or the temperature are measured and provided for different purposes such as correlating the meteorological data to the electrical energy output.
- *WPP management system* is responsible for ensuring that the complete system adapts itself to the static and dynamic conditions as well as to the requirements of the electrical power connection (i.e., interoperation of the WTs with substations and other power network-related devices).
- *Electrical system* is responsible for collecting and transmitting the energy produced in the WTs.

### 63.2.2 Requirements on Communications

Monitoring and control operations over WPPs are typically executed by SCADA systems, local real-time build-in control systems, or energy dispatch centers. In this scenario, communication technologies play an important role since they enable the communication between these systems and the whole WPP or any of its components, that is, the individual devices. WTs include local controllers, which are primarily responsible for the monitoring and control of the internal processes within the WT. Besides, these local controllers must provide the mechanisms to interact with external systems or applications performing monitoring and control operations of the whole plant.

The communication requirements referred to both the content (type and formats) and the functions to get or set such content, that is, the communication functions. The following sections briefly summarize the requirements on communication defined in the IEC 61400-25 series.

#### 63.2.2.1 Communication Content

The IEC 61400-25 series differentiates five types of information: (1) *process information* that contains information about the behavior and the current state of systems and components; (2) *statistical information* that allows evaluating the operation of WPPs; (3) *historical information* in the style of logs and reports, useful to track operational trends; (4) *control information* intended to perform control operations over the WPP, such as access profiles, set points, parameters setting, and commands; and (5) *descriptive information* that is related to the type and accuracy of the information.

#### 63.2.2.2 Communication Functions

External systems and applications that perform the control and monitoring of WPPs need to be provided with specific functions to operate and manage WPPs. They are divided into two categories:

1. *Operational functions*: They are used by the external systems to get information from/send control commands to WPPs, as Table 63.1 illustrates.
2. *Management functions*: They are used by the external system to manage users and access to WPP data. Management functions are illustrated in Table 63.2.

**TABLE 63.1** Operational Functions

Operational Functions	Range of Use
Monitoring	Local or remote observation of a system or process in order to track any changes that may happen over time. It may include single data values or groups of data values
Control	Changing, modifying, intervening, switching, controlling, parameterizing, and optimizing WPPs
Data retrieval	Collecting of WPP data
Logging	Recording of data and events in chronological order
Reporting	Data transfer initiated from a server triggered by event or condition

**TABLE 63.2** Management Functions

Management Functions	Range of Use
User/access management	Setting up, modifying and deleting users, managing access rights, monitoring access
Time synchronization	Synchronization of devices within a communication system
Diagnostics (self-monitoring)	Self-monitoring of the communication system
System setup functions	Definition of the way the information exchange takes place: setting, changing, and retrieval of system setup data

### 63.2.3 Communication Model

The IEC 61400-25 series defines an abstract communication model for monitoring and controlling the operation of WPPs. As in the IEC 61850 series, the communication model follows the client–server paradigm. The approach is based on the definition of *abstract classes* and *services* independent of specific implementations of the protocol stack as well as of the underlying operating system.

The communication model, depicted in Figure 63.1, uses three different views:

1. The *IM* standardizes object-oriented abstract models that represent the components of a WPP (devices) and the information to be exchanged between the devices within WPPs and the external world. The modeling approach represents the physical devices of the WPP as a set of reusable DCs associated to devices through logical entities. DCs can be instanced in objects that contain information such as analog values, binary status, commands, or set points. The IM is described in IEC 61400-25-2.
2. The *IEM* describes an abstract representation of the services available at the servers through which the clients can access and modify the IM data. This model is described in IEC 61400-25-3.
3. *Mapping to standard communication profiles*: The information exchange between a client and a server requires a uniform communication protocol stack at both ends in order to transport the data and implement the services defined by the IM and IEM, respectively. The mapping is structured in layers according to the OSI reference model [14], and it specifies the communication protocol stacks used in the IEC 61400-25 series. It is described in IEC 61400-25-4.

Although the IEC 61400-25 standard defines the model of information data, the model of exchange services, and the mapping to standard communication protocols, it does not give any recommendation on implementation issues. The distribution of objects among the servers available or the implementation of the modeling approach on the servers is completely open.

As commented earlier, the IEC 61400-25 series can be considered as an extension of the IEC 61850 series, and thus, it uses the communication structure described in IEC 61850-7 [1]. In particular, IEC 61400-25-3 describes the communication services described in IEC 61850-7-2 (Abstract Communication

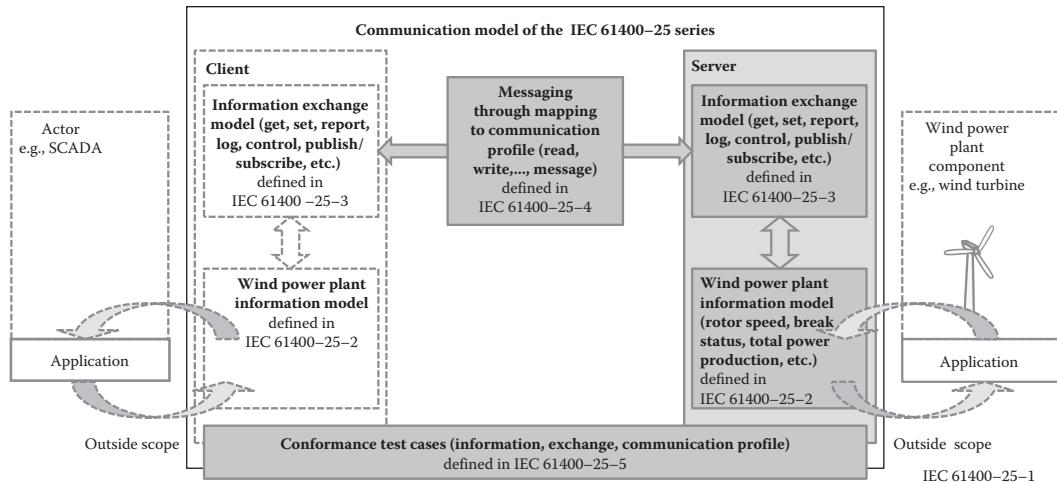

FIGURE 63.1 Conceptual communication model of the IEC 61400-25 series.

Service Interface [ACSI]) [6]. The IM proposed in IEC 61400-25-2 conforms to IEC 61850-7-3 (common data classes [CDC]) [7] and IEC 61850-7-4 (compatible logical node classes and data classes) [8]. Neither IEC 61850 nor IEC 61400-25 standards define new process data, but they assign data and data types to physical entities. The mapping described in IEC 61400-25-4 follows the same methodology as the one described in IEC 61850-8 (specific communication service mapping [SCSM]) [9], and it uses the device description approach specified in IEC 61850-6 (configuration description language for communication) [10]. As a consequence, the WPP models can be accessed from tools and communication protocols conforming to the IEC 61850 standard.

### 63.3 Wind Power Plant Information Model

The IM of WPPs defines the relevant aspects of the real system from the point of view of monitoring and control, abstracting the nonessential details. All the information to be exchanged between devices of the WPP or between a device and the external world is defined in the model. The target is to have a standard frame of interpretation via which the server may process all data into relevant and semantically standardized information and may grant the client access to these data in a component-oriented view.

The conceptual modeling approach is depicted in Figure 63.2. It abstracts the physical devices of the real world in logical devices (LDs) to which relevant and semantically standardized information is associated. The server processes this information and makes it available to clients.

The central part of Figure 63.2 illustrates the hierarchy of the WPP IM. It is a model of the real world consisting of physical devices. In the context of the IEC 61400-25 modeling approach, a physical device is a device connected to the network (a server). They are typically defined by their network address. A physical device may have associated one or more LD. An example of LD is a WT. LDs are decomposed into LNs representing the physical device's components with given functionality, for example, an LD representing a WT can be composed of a rotor (with a standardized name WROT), a transmission (WRTM), a generator (WGEN), a nacelle (WNAC), and a tower (WTOW) among others. LNs are the basic objects containing a collection of data objects, instances of predefined DCs, depending on its functionality. Each data class inherits a collection of properties, as defined by the corresponding CDC. A CDC consists of a collection of data records (*attributes*). DCs are standard templates for representing the exchangeable information through the services defined by the IEM. An example of a DC instance is represented in Figure 63.2, corresponding to an instance of the DC RotSpd that contains the speed of the rotor of the WT.

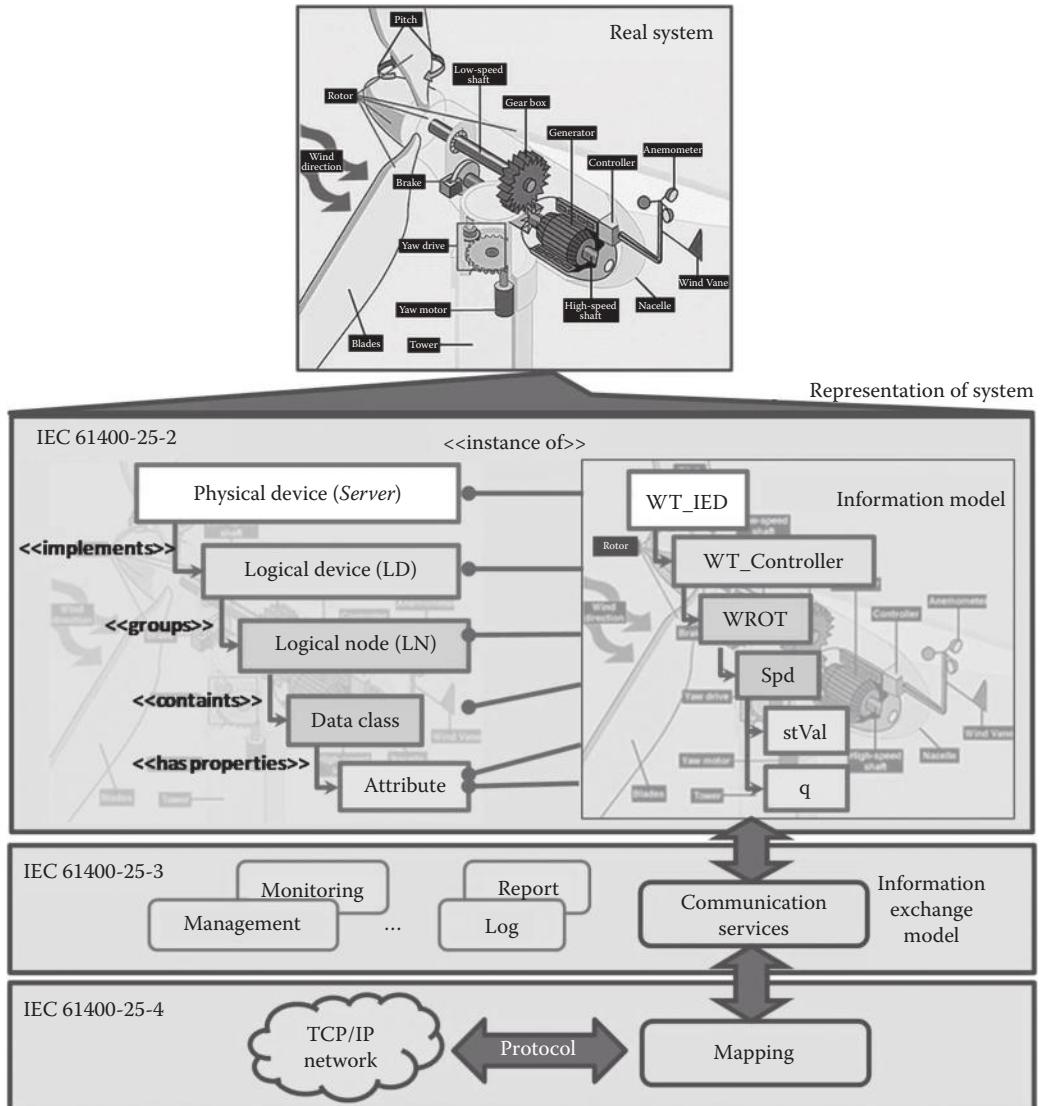

FIGURE 63.2 Modeling approach of the IEC 61400-25 standard.

The IM of a concrete WPP is then an instance of the metamodel depicted in Figure 63.3. The following sections detail the basic concepts of the metamodel, that is, the concept of LD, LN, and DC.

### 63.3.1 Logical Device

As commented earlier, an LD encapsulates all the needed LNs that contain the data corresponding to a WPP device. An LD residing on a server is composed of a collection of specific LNs that will further contain data instances reflecting the actual physical state of the real WPP device.

Besides the specific LNs within a WPP device, an LD also contains mandatory data related to the physical device (IED or server) that hosts it and WPP-independent information. This common information is contained in specific LNs serving only for this purpose: the logical node physical device (LPHD)

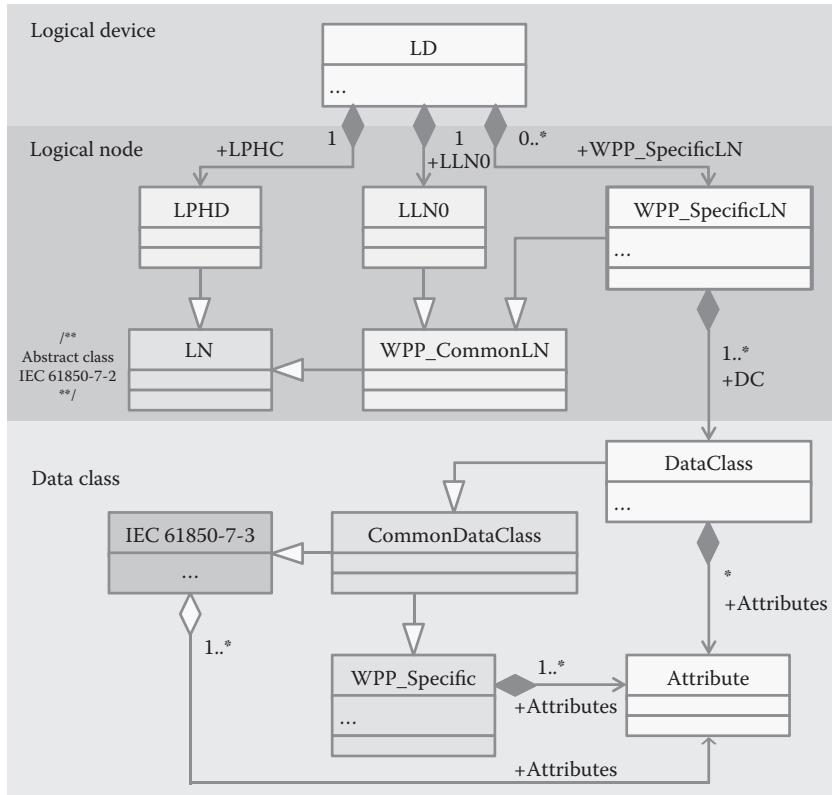

FIGURE 63.3 Metamodel of the WPP information model.

represents common data of the physical device hosting the LD. The logical node zero (LLN0) represents information specific to the LD, such as the LD name space. They are called *system-specific* LNs.

As any other LN, LPHD and LLN0 must belong to an LD. If the WPP only has one LD associated, then it will also contain LPHD and LLN0. However, if there is more than one LD, LPHD can be associated to the specially named LD0, together with an LLN0 and the common data for all LNs (communication-related data sets and control blocks). This allows dedicating the rest of LDs exclusively for functional modeling. These *system-specific* LNs are described in Clause 8 of IEC 61850-7-1.

### 63.3.2 Logical Node

All functions performed in WPPs have been split into the smallest entities that communicate with each other and with the external world. These entities or objects are called *WPP\_Specific Logical Nodes* (*WPP\_SpecificLN* in Figure 63.3). They contain all exchangeable function-related data and their attributes.

All LN classes defined in IEC 61400-25-2 series inherit their structure from the LN abstract class (see Figure 63.3) defined in 9.1.1 of IEC 61850-7-2. Apart from the LPHD LN class, LLN0 and WPP-specific LNs inherit at least the mandatory information of the WPP common LN (*WPP\_CommonLN* in Figure 63.3). The features of LNs are detailed in 9.1.1 of IEC 61850 standard.

The standard defines a set of LNs specific to WPPs (*WPP\_SpecificLN* in Figure 63.3). They have a standardized mnemonic name of four letters, beginning with “W” followed by three capitals representing the content. Instances of these LNs may be implemented single or multiple in any server, but their name must be unique. Commonly, LNs for common applications are grouped into the same LD. As commented earlier, the common device properties are described in the LPHD.

**TABLE 63.3** WPP-Specific Logical Nodes

LN Classes	Description	M/O
WTUR	Wind turbine general information	M
WALM	Wind power plant alarm information	O
WMET	Wind power plant meteorological information	O
WAPC	Wind power plant active power control information	O
WRPC	Wind power plant reactive power control information	O

**TABLE 63.4** Wind Turbine-Specific Logical Nodes

LN Classes	Description	M/O
WTUR	Wind turbine general information	M
WROT	Wind turbine rotor information	M
WTRM	Wind turbine transmission information	O
WGEN	Wind turbine generator information	M
WCNV	Wind turbine converter information	O
WTRF	Wind turbine transformer information	O
WNAC	Wind turbine nacelle information	M
WYAW	Wind turbine yawing information	M
WTOW	Wind turbine tower information	O
WALM	Wind power plant alarm information	O
WSLG	Wind turbine state log information	O
WALG	Wind turbine analog log information	O
WREP	Wind turbine report information	O

The LN classes can be instantiated several times on the device, implementing its functionality. If not mentioned especially, this document always means instances when talking about LNs in the context of modeling.

LNs consist of a collection of related data, defined by means of the corresponding DCs. All the information in an LN is contained in instances of DCs. The structure of all LNs is similar, and it is possible to build different types of LNs by combining different optional DCs.

Clause 5 of IEC 61400-25-2 defines five categories of WPP-Specific LNs, as Table 63.3 illustrates, being the WT general information (WTUR) the only mandatory LN.

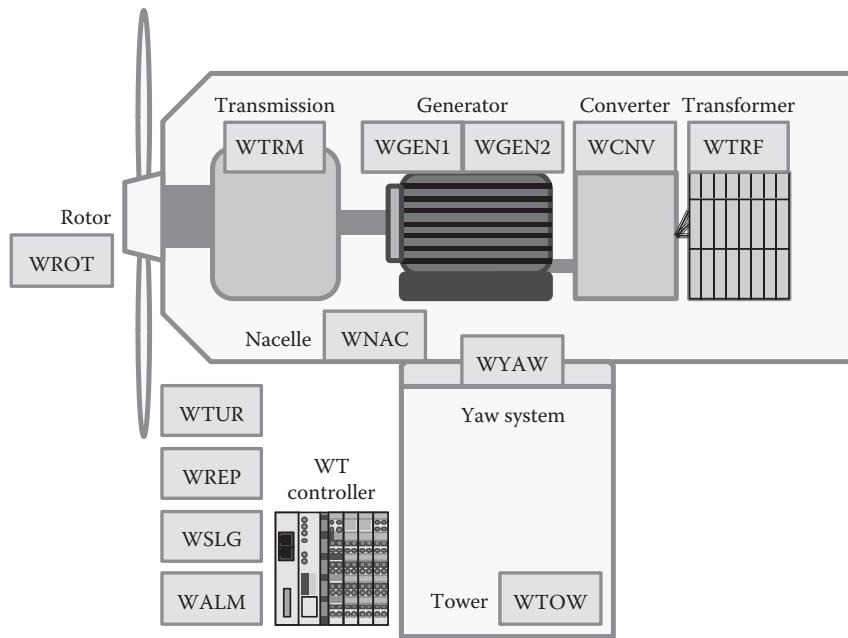

A WT model is composed of a set of turbine-specific LNs. Table 63.4 lists the WT-specific LNs highlighting the mandatory ones.

As shown in Tables 63.3 and 63.4, the information is mainly modeled by a set of LN classes that correspond to the physical turbine physical components. The only exception is the information related to alarms that are represented in a separate LN. There are also specific LNs for logged events (status, alarms, commands, event counters, and state timers) and logged analog time series (long period, demands, and transient recording).

Figure 63.4 illustrates an example of real WT that instances different LNs.

### 63.3.3 Data Class

As commented in Section 63.2.2.1, the information related to WPPs is organized into three main categories: (1) *process information* that stands for manufacturer-independent features, state status, and analog behavior information; (2) *control information* that is related to commands, set points, and configuration parameters; and (3) *derived information* that consists of statistical, logging, and report information.

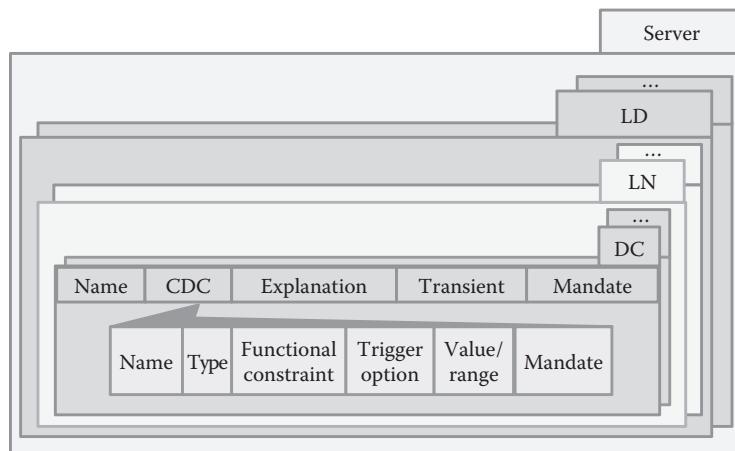

**FIGURE 63.4** LN instances in a real WT.

Clause 6.2 of the IEC 61400-25-2 series defines the DCs corresponding to LNs of a WPP. Figure 63.5 illustrates the general format of DCs.

Based on WPP information requirements, a set of specific CDC have been specified. The name of all of them is unique and is formed by three capital letters. They can be grouped into two main groups (see Data Class elements in the metamodel in Figure 63.3):

A. WPP-specific CDCs (WPP\_Specific)

1. WPP\_Specific DC for Process Information: Set Point Value (SPV) and STatus Value (STV)
2. WPP\_Specific DC for Control Information: ALarM (ALM) and CoMmand (CMD)
3. WPP\_Specific DC for Derived Information CDCs: Event counting (CTE), State TiMing (TMS), and Alarm Set Status (ASS)

**FIGURE 63.5** Identification of DC attributes.

## B. CDCs inherited from IEC 61850-7-3

1. DCs for process information: single point status (SPS), INteger status (INS), binary counter reading (BCR), phase-to-ground-related measured values of a three-phase system (WYE), and phase-to-phase-related measured values of a three-phase system (DEL)
2. DCs for control information: controllable single point (SPC), controllable integer status (INC), and controllable analog process value (APC)
3. DCs for derived information: Logical name plate (LPL) and device name plate (DPL)

As commented earlier, all of them collect a set of information attributes. The fields required for a complete characterization of the attributes are as follows:

1. *Name*: Mnemonic abbreviation of the attribute (e.g., clockFailure).
2. *Type*: It can be BASIC (e.g., BOOLEAN, INT8 ..., INT32U, FLOAT32, CODED ENUM, ENUMERATED, ...) or composed (e.g. PACKAGE LIST).
3. *Functional Constraint*: This is used in order to build group for efficient information exchange. The possible list of values is defined in clause 2 of IEC 61850-7. Examples are: status (ST), Measurand (MX), Control (CO), Set Point (SP), Configuration (CF), or Description (DC).
4. *Trigger Option*: It is used as conditional notification when a value or state has changed. Data change (dchg), quality change (qchg), and data update (dupd).
5. *Explanation/Range*: Description and range of an attribute record.
6. *Mandate*: It indicates if the attribute is mandatory (M), optional (O), or conditional (C).

As an illustrative example of CDCs, Table 63.5 presents the attributes that Characterize Quality and Analog CDCs. Quality CDC is defined by five attributes. Validity and source are *enumerated*; detail-Qual is a complex attribute constituted by other eight basic *Boolean* fields. Finally, test and operator-Blocked attributes are *Boolean*. Among those attributes, only the former is mandatory and the rest are

**TABLE 63.5** Examples of Characterization of Common Data Class Attributes

Quality			
Attribute Name	Attribute Type	Value/Range/Explanation	M/O
	PACKED LIST		
validity	CODED ENUM	good invalid reserved questionable	M
detailQual	PACKED LIST		O
overflow	BOOLEAN		O
outOfRange	BOOLEAN		O
badReference	BOOLEAN		O
oscillatory	BOOLEAN		O
Failure	BOOLEAN		O
oldData	BOOLEAN		O
inconsistent	BOOLEAN		O
Inaccurate	BOOLEAN		O
source	CODED ENUM	process substituted, DEFAULT process	O
test	BOOLEAN	DEFAULT FALSE	O
operatorBlocked	BOOLEAN	DEFAULT FALSE	O
Analogue Value			
Attribute Name	Attribute Type	Value/Range/Explanation	M/O
i	INT32	Integer value	(*)
f	FOAT32	Floating point value	(*)

<sup>\*</sup>, At least one of the attributes must appear in the instance.

**TABLE 63.6** CDC: Status Value (STV)

STV—Status Value					
Attribute Name	Attribute Type	FC	TrgOp	Explanation and Value/Range	M/O
Data Name	Inherited from DC (see IEC 61850-7-2)				
Data					
Status information					
actSt	INS			Actual status	M
stVal	CtxInt	ST	dchg		M
q	Quality	ST	qchg		M
t	TimeStamp	ST			M
oldSt	INS			Previous status	O
stVal	CtxInt	ST	dchg		M
q	Quality	ST	qchg		M
t	TimeStamp	ST			M
Statistical information					
stTm	TMS			Time duration of active status	O
stCt	CTE			Number of changes to active status	O

*Note:* Configurations, Description, and Extension Information Services (detailed in Section 63.4).

optional. The analog CDC is composed of two attributes: one for integer values (*i*) and the other for float values, being mandatory to have one of them in an instance.

Following the same philosophy, Table 63.6 illustrates the characterization of the Status Value WPP-specific CDC. STV data class contains attributes that represent the status information of a status data. In this case, a complex attribute for actual status (actSt) is mandatory. Optionally, it could be information about the previous status using the same complex attribute (oldSt).

## 63.4 Wind Power Plant Information Exchange Model

The IEC 61400-25 standard provides a platform-independent interface between a client and a server through the WPP IM and the IEM. In Section 63.3, the IM, which provides a uniform, component-oriented view of the WPP data, has been described. This section focuses on the IEM, which defines an ACSI with a complete collection of services that represent the whole functionality of the server. More specifically, these services include the following operations: (1) data access and retrieval; (2) device control; (3) event reporting and logging; (4) publish/subscribe of data; (5) self-description of devices; and (6) retrieving the WPP IM.

It is important to remark that the IEC 61400-25 standard defines a hierarchical model for representing real devices (see Figure 63.2). Following the object orientation paradigm, the data associated to real devices are contained in LNs, and the server grants access to authorized clients through a set of specified services. However, the access to real physical devices is the responsibility of the device that hosts the server. The standard only defines the information exchange through the model.

The IEC 61400-25 series excludes a definition of how and where to implement the communication interface, the application program interface, and implementation recommendations. However, the objective is that the information associated with a single WPP component (such as a WT) be accessible through a corresponding LD. Clause 6 of IEC 61400-25-3 gives an overview of the IEM for operational functions and management functions. Clause 7 introduces the IEMs for operational functions: authorization, control, monitoring, reporting and logging. Clause 8 gives an overview of the IEMs for management functions. Clause 9 provides the details of the services for the service model classes. Annex A provides examples of the reporting and logging services required. Annex B provides relationship

between ACSI services and functional constraints, and Annex C provides relationship between ACSIs defined in IEC 61850-7-2 and IEC 61400-25-3.

The following sections summarize the most important concepts of the IEM.

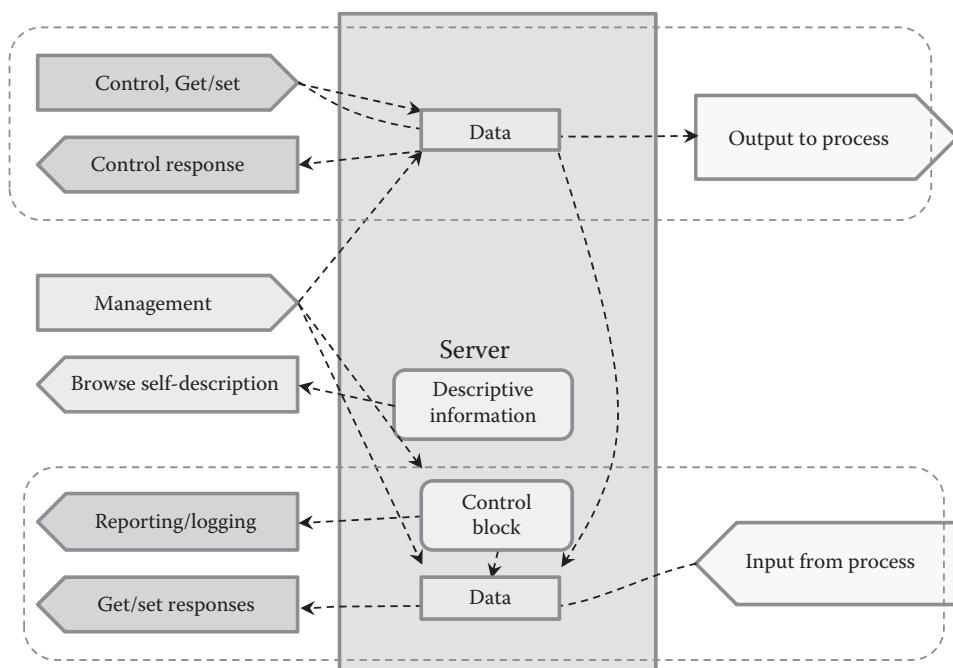

### 63.4.1 Communication Functions

The IEM defines services for accessing the IM data. The services may be classified in two major categories: those that provide *operational functions* and those that are dedicated to *management functions*. All these functions generate data traffic of different nature, for example, periodic/aperiodic and synchronous/asynchronous. As a consequence, the IEM must support different transfer principles and provide the required abstract communication services. Every instance of the WPP IM defined in the previous section, such as LD, LN, data (DC), data attributes (ATTR), and control block (CB) objects, will be accessed by instances of the IEM described later. Figure 63.6 summarizes the communication as well as the management functions required from the clients.

#### 63.4.1.1 Operational Functions

Operational functions may be classified in the following categories:

1. *Authorization and association*: Aiming at providing a secure information exchange via an association between a client and a server. These functions provide client authentication and control the access to server functions. They provide authentication, authorization and access control, integrity against unauthorized modification or destruction, confidentiality, nonrepudiation, and prevention of denial of service.
2. *Control*: Aiming at defining the IEM for sending commands and controlling groups of set points in an operational device. The operate commands set the values of controllable data, which are derived from controllable CDCs.

IEC 61400-25-1

**FIGURE 63.6** IEM services and interactions.

3. *Monitoring, reporting, and logging*: Aiming at retrieving information from one server. Three independent information retrieval methods are included: (1) *Retrieval on demand*: It includes operations such as Get or Read in which the response must be transmitted immediately. (2) *Publish/Subscribe*: Servers can be configured to transmit values periodically or triggered by changes or events. They may buffer values if necessary. Clients will initiate and finalize subscriptions. Finally, (3) *Logging*: Allow delivering values logged at the server. These values may be grouped by means of Data Sets. The client can query for all logged entries or for the entries between two time stamps.

#### 63.4.1.2 Management Functions

These functions are used to configure or maintain a system. More specifically, they allow setting and changing configuration data and retrieving configuration information from the system. They also include services for the management of users and access security, configuration, time synchronization, and diagnosis operations.

#### 63.4.2 Abstract Communication Service Interface

The set of basic services used to accomplish the information exchange between the clients and the virtual components that represent real-world devices are referred to as the Abstract Communication Service Interface. Since WPP automation requirements are similar, but not exactly equal, to those required by Substation Automation Systems, ACSI models defined in IEC 61400-25-3 are similar to those defined in IEC 61850-7-2 [6]. However, some entities defined in IEC 61850-7-2 are not used in WPP, whereas the IEC 61400-25-3 solves some restrictions for WPPs and adds new operations to some entities.

Figure 63.7 depicts the basic IEMs, illustrating the various components of the ACSI services.

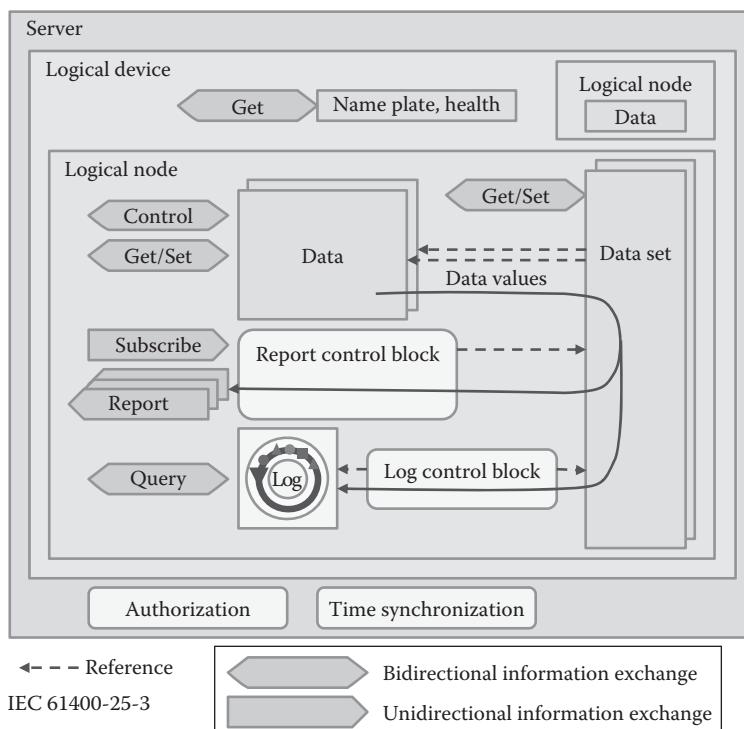

FIGURE 63.7 Conceptual information exchange model for a WPP.

LNs contain data that can be written or read individually or in groups (Data Sets), they respond to control inputs, provide solicited and unsolicited reports, and contain logs that can be queried. Get/Set and Control services are provided to read (get) and write (set) the data in LNs. The rules for logging and reporting are defined in the Log Control Block (LCB) and Report Control Block (RCB), respectively. Table 63.7 represents the IEC 61400-25 ACSI services associated to the corresponding IM entity.

**TABLE 63.7** IEC 61400-25 ACSI Services

IEC 61400-25 ACSI Services			
IM Entity	Service	Explanation	M/O
Server	Associate	Used for two-party application association	M
	Abort		O
	Release		O
	GetServerDirectory	Retrieve the list of names of all LDs	O
Logical Device	GetLogicalDeviceDirectory	Retrieve the list of names of all LNs	O
Logical Node	GetLogicalNodeDirectory	Retrieve the list of names of all Data	O
Data	GetDataValues	Apply to CF, DC, ST, MX, SP, EX <sup>a</sup>	M
	SetDataValues	Apply to CF, SP <sup>a</sup>	M
	GetDataDirectory	Apply to CF, DC, ST, MX, SP, CO, EX <sup>a</sup>	O
	GetDataDefinition	Apply to CF, DC, ST, MX, SP, CO, EX <sup>a</sup>	O
DataSet <sup>b</sup>	GetDataSetValue		M
	SetDataSetValues		O
	CreateDataSet		O
	DeleteDataSet		O
	GetDataSetDirectory		O
ReportControl <sup>c</sup>	Report	A report can include any elements of any	O
	GetBRCBValues	Only applies to Buffered Report Control Blocks	O
	SetBRCBValues		O
	GetURCBValues	Only applies to Unbuffered Report Control Blocks	O
	SetURCBValues		O
	AddSubscription	Applies to Buffered/Unbuffered Report Control Blocks	O
	RemoveSubscription		O
LogControlBlock <sup>d</sup>	GetLCBValues		O
	SetLCBValues		O
Log <sup>e</sup>	GetLogStatusValues		O
	QueryLogByTime		O
	QueryLogAfter		O
Control <sup>f</sup>	Select		O
	SelectWithValue		O
	Cancel		O
	Operate		M
	CommandTermination		O
	TimeActivatedOperate		O

<sup>a</sup> Functional constraints: CF, Configuration; DC, Description; ST, Status; MX, Measure; SP, Set Point; CO, Control; EX, Extended Definition.

<sup>b</sup> DataSets are groups of references to Data. They can be used for Report Control Blocks or Log Control Blocks.

<sup>c</sup> Report Control Blocks provide the mechanism to report data values on specific criteria. There are two types: Buffered Report Control Block (BRCB) and Unbuffered Report Control Block (URCB).

<sup>d</sup> Log Control Blocks provide the mechanism to log data values on specific criteria.

<sup>e</sup> Log provides the query service to receive data values stored between two time stamps.

<sup>f</sup> Control provides the mechanism to control functions and real devices represented by a server.

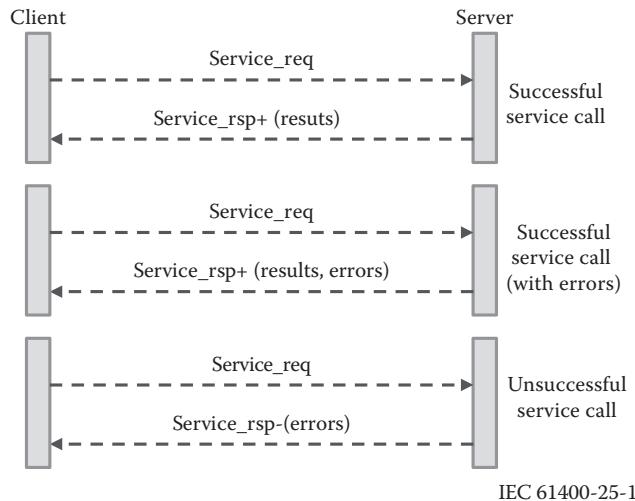

FIGURE 63.8 Sequence diagram.

### 63.4.3 Service Modeling Convention

ACSI services are generally defined by the following:

1. A set of rules for the definition of messages so that receivers can unambiguously understand messages sent from a peer
2. The service request parameters as well as results and errors that may be returned to the service caller
3. An agreed-on action to be executed by the service

All services are based on three message primitives: request, positive response, and negative response, as illustrated in Figure 63.8 by means of a sequence diagram. A message primitive may have a number of parameters, called results and errors in case of response primitives.

## 63.5 Mapping to Communication Protocols

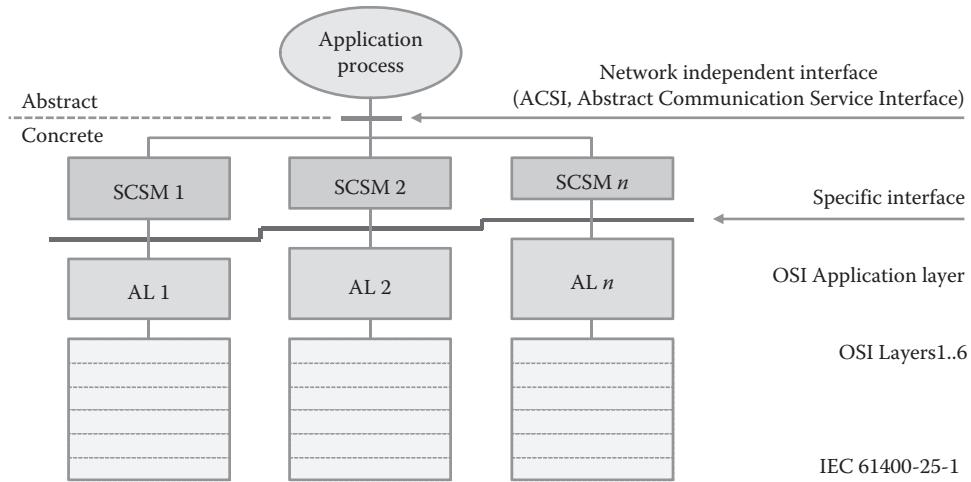

---

Both IMs and IEMs need to be mapped to appropriate protocols. Even though the IEC 61400-25 series follow a more independent format, they are still based on IEC 61850. Consequently, IEC 61400-25 inherits and references many of the IEC 61850 rules and definitions keeping the compatibility between the two standards.

IEC 61400-25-4 focuses on the mapping of services, objects, and parameters defined in the standard to specific communication protocols. Independent mappings may be implemented using the IEC 61850 SCSM, aimed to provide independence from a specific communication stack, as illustrated in Figure 63.9.

The SCSM defines how the services and the server objects (LD, LN, data, data sets, report controls, log controls, or setting group objects) are mapped to the application layer by means of specific communication stacks compatible with the OSI reference model. These mappings and the application layer define the syntax for the data exchanged over the network.

The mappings may have different complexities depending on the communication network technology used. Thus, some of the ACSI services defined in the previous section may not be supported in all mappings. However, when a service is provided in a mapping, that service is equivalent to the same service in the benchmark mapping. It is also possible that the application layer combine one or more stacks simultaneously.

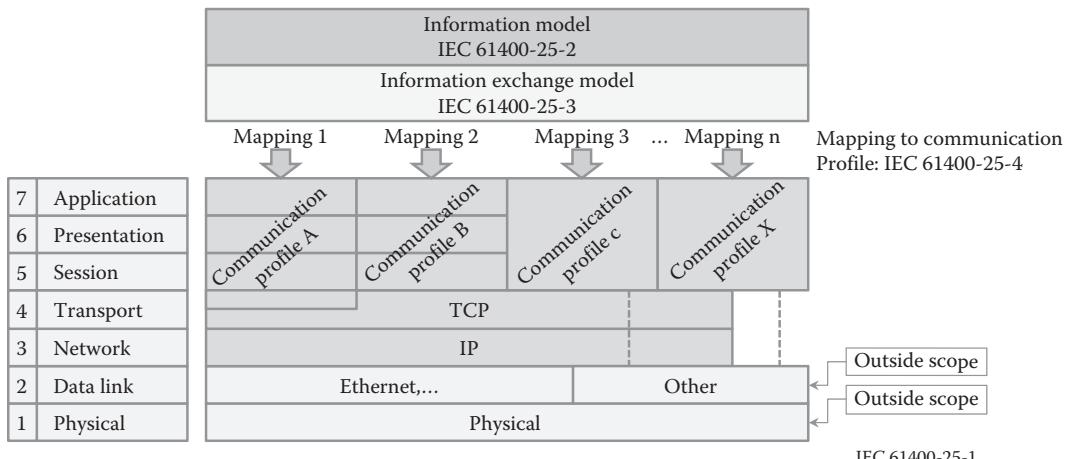

**FIGURE 63.9** ACSI mapping to communication stacks/profiles.

IEC 61400-25-4 maps both, the IM and the IEM, within a client–server relation application using different, optional, communication profiles. The general mapping architecture consists of three parts:

1. Mapping of the IM, including the mapping of the DCs
2. Mapping of the information exchange services
3. Definition of the communication stacks

The IM and the IEM define the interface specification between a client and a server. The IM provides a logical view of the WPP data that are used by the server to offer a uniform and component-oriented view of the WPP data to the client.

Typically, TCP/IP protocols are used at the transport/network layers in most communication profiles (see Figure 63.10). Specifications for the data link and the physical layers are implementation specific and beyond the scope of the IEC 61400-25 series.

**FIGURE 63.10** Communication profiles.

According to the market relevance, the IEC 61400-25-4 standard specifies mappings to five communication protocol stacks:

1. Mapping to SOAP-based web services (WSs)
2. Mapping to OPC/XML-DA
3. Mapping to IEC 61850-8-1 MMS
4. Mapping to IEC 60870-5-104
5. Mapping to DNP3

Due to the proximity between the IEC 61400-25 and IEC 61850 standards, the IEC 61850-8-1 MMS [9] mapping is a natural choice. IEC 60870-5-104 [11] and DNP3 [4] mappings are included due to their current use in power system automation applications. Also, market trends back the use of WSs and OPC [2] in electrical and automation applications.

All mappings are optional, but at least one mapping must be implemented in order to be compliant with IEC 61400-25-4. These mappings must provide the abstract services defined in IEC 61400-25-3 fully or in part. However, some services are only implemented in some mappings, for example, the IEM services aiming at retrieving the WPP IM of a device (self-description) are only defined in the MMS and in the WS mappings.

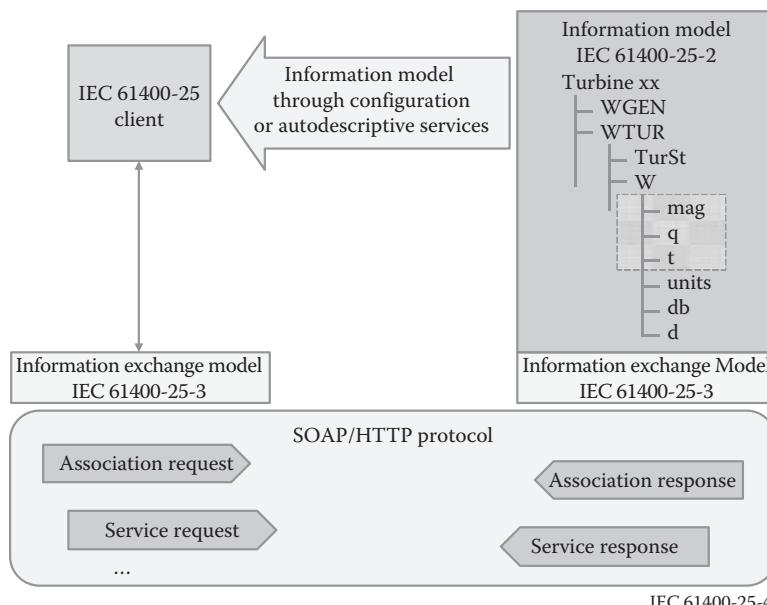

The use of a specific mapping may influence the overall performance of the applications. For example, the IEC 61850-8-1 mapping, which uses binary encoded messages, provides a higher performance than the WS mapping, based on ASCII characters.

### 63.5.1 Mapping to SOAP-Based WSs

The mapping to WSs is based on using XML to represent the IM defined in IEC 61400-25-2 for the WPP components and SOAP to implement the IEM services according to IEC 61400-25-3 (see Figure 63.11).

The WPP IM defined in IEC 61400-25-2 is mapped to a hierarchical structure that is preserved when mapped to WSs. This means the following:

- The server represents its internal data according to a hierarchical structure that follows the IEC 61400-25-2 standard. These data can be retrieved by a full set of services.

**FIGURE 63.11** Conceptual Web Services mapping architecture.

**TABLE 63.8** Web Services Protocol Stack for IEC 61400-25 Communication Profile

OSI Layer	Specification		
	Name	Service/Protocol Specification	M/O
Application	Web Services	Web Services Architecture, <a href="http://www.w3.org/TR/2002/WD-wsarch-20021114/">http://www.w3.org/TR/2002/WD-wsarch-20021114/</a>	M
	SOAP	SOAP ver. 1.1	M
	HTTP ver. 1.1	RFC 2616, RFC 2817	M
	SSL/TLS ver. 1.0	RFC 2246	O
Presentation	—	—	—
Session	—	—	—
Transport	TCP	RFC 793	M
Network	ICMP	RFC 792	M
	IP	RFC 791	M
	ARP	RFC 826	M
	Broadcasting Internet Datagrams	RFC 922  RFC 922 RFC 919	M
Data Link Layer	Host Extensions for IP Multicasting	RFC 1112	M
	Implementation specific and beyond the scope of IEC 61400-25		
Physical Layer	Implementation specific and beyond the scope of IEC 61400-25		

- The client is configured with the hierarchical structure representing the server's IM or may retrieve it from the server by means of self-description services.
- The client is capable of accessing the server's hierarchy through the services provided by WSs according to the IEC 61400-25-3.

As in other SCSMs, the TCP/IP protocol stack is the basic communication stack provided for the WS mapping. Table 63.8 describes in detail which are the protocols used in this mapping.

The WSDL (Web Services Description Language (WSDL) specification for the mapping to WSs is defined in the standard and is given as a WSDL text file that includes all definitions and mappings.

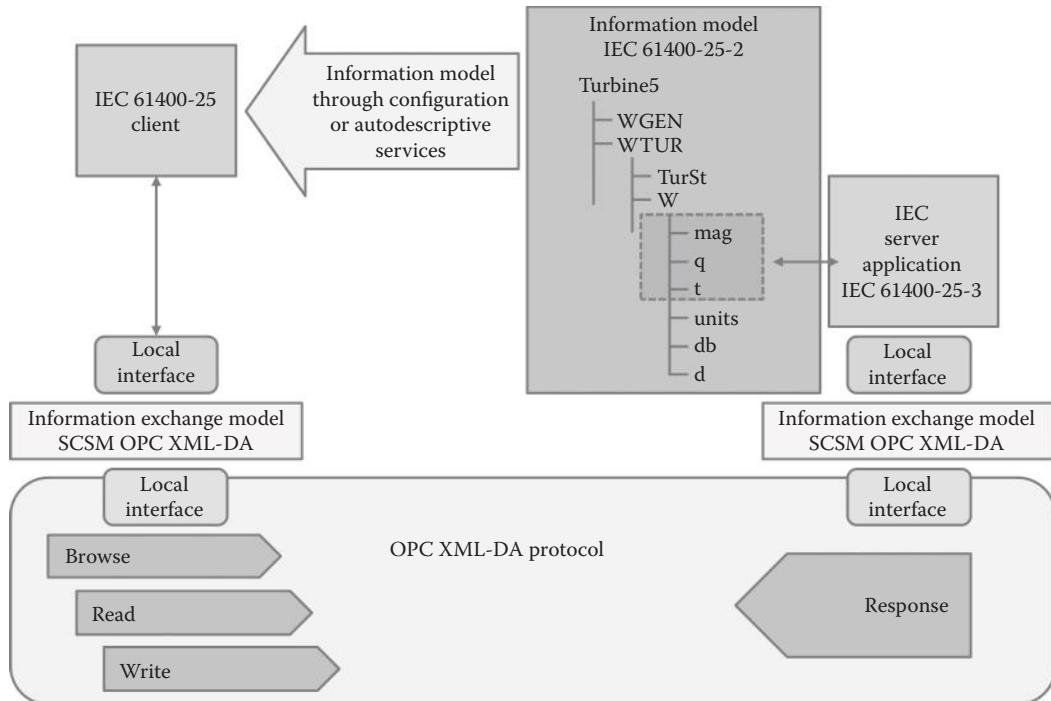

This mapping provides a complete communication solution for all data objects and services for implementing the IEM of a WPP as defined in the standard. However, since this mapping requires the translation of the IM to XML format and the IEM as SOAP messages, and consequently into ASCII text, the need of bandwidth increases, and problems may arise when big amounts of information have to be exchanged.

### 63.5.2 Mapping to OPC XML DA

OPC XML DA [2] is a technology specified by OPC Foundation to provide a hardware and software independent platform to exchange real-time process information by means of XML messages.

The mapping to OPC XML-DA services aims at exchanging process information required for operational purposes. Even though the WPP IM and IEM are intended to be preserved when mapped to OPC XML-DA services, the mapping of some complex data sets may not be available as defined in IEC 61400-25-2, and several IEC 61400-25-3 services cannot be supported.

In this mapping, the IEC 61400-25 server is implemented as an OPC XML-DA web server. Every OPC XML-DA WS is executed inside the web server according to the rules defined in the OPC XML-DA

**FIGURE 63.12** Conceptual OPC XML-DA mapping architecture.

specification. WPP LDs, LNs, and data objects are implemented as branches in the OPC hierarchy (see Figure 63.12). Primary data attributes are implemented as OPC items.

The WPP IM defined in IEC 61400-25-2 is mapped to a hierarchical structure. Again, the WPP IM must be preserved when mapped to WSs. This means the following:

- The server implements the hierarchical WPP IM according to IEC 61400-25-2. These IMs may be retrieved by means of IEC 61400-25-3 services.
- The client implements the WPP IM by configuration, or it can be retrieved by using self-description services.
- The client application accesses the hierarchical WPP IM through the services provided by OPC XML-DA mapping to WPP IEM.

Table 63.9 details the protocols used in this mapping.

A wide set of IEC 61400-25 services cannot be supported. For example, the management of complex data sets is the responsibility of the client. Also, due to the OPC XML-DA behavior, this mapping does not define how the authentication of the client must be implemented, requiring that client should authenticate at every request. However, the availability of commercial solutions that use this accepted and well-proven technology provides a strong advantage to the OPC XML DA approach when compared with the WS mapping.

### 63.5.3 Mapping to MMS

IEC 61850-8 describes the SCSM within the IEC 61850 series. More specifically, IEC 61850-8-1 is the part that defines the mappings to MMS (ISO/IEC 9506—Ed.2) [3].

**TABLE 63.9** OPC XML-DA Protocol Stack for IEC 61400-25 Communication Profile

OSI Layer	Specification		
	Name	Service/Protocol Specification	M/O
Application	OPC XML-DA	OPC XMLDA 1.01	M
	SOAP	SOAP ver. 1.1	M
	HTTP ver. 1.1	RFC 2616	M
	TLS ver. 1.0	RFC 2246	O
Presentation	—	—	—
Session	—	—	—
Transport	TCP	RFC 793	M
Network	IP	RFC 791	M
	ICMP	RFC 792	M
	ARP	RFC 826	M
Data Link Layer	Implementation specific and beyond the scope of IEC 61400-25		
Physical Layer	Implementation specific and beyond the scope of IEC 61400-25		

ISO 9506, Industrial automation systems—Manufacturing Message Specification (MMS), is an application layer communication specification according to the OSI communication model. It provides a set of communication services between automated equipment and systems used for control and monitoring purposes, and it follows the client–server paradigm. MMS is suitable over network technologies that support full-duplex, reliable communication. It is divided into two major documents: ISO 9506-1:2003, which provides the Service Definitions, and ISO 9506-2:2003, which provides the Protocol specification of the messages exchanged between client and server.

Most service models defined in IEC 61400-25-3 are mapped to ISO 9506 following the same approach defined in IEC 61850-8-1.

The WPP IM is mapped to a hierarchical structure and must be preserved when mapped to IEC 61850-8-1 MMS services. The mapping is illustrated in Figure 63.13. This especially means the following:

- The server implements the hierarchical WPP IM of IEC 61400-25-2 that can be retrieved by the services.
- The client needs to interpret the WPP IM.
- The client application accesses the hierarchical WPP IM through the services provided by IEC 61850-8-1 and ISO 9506.

This mapping requires the use of OSI protocols as defined on ISO MMS (see Table 63.10). These protocols cannot directly be implemented over the TCP/IP stack, so the RFC 1006 protocol specification (“ISO Transport over TCP”) must be added over the transport layer.

The IEC 61850-8-1 mapping is mainly intended to achieve real-time exchange of information between clients and servers. Clients need to receive real-time information from servers in order to monitor and control the power generation process and the related equipment. However, IEC 61850 service models such as Generic Object-Oriented System Event (GOOSE) or Sampled Value (SV) are not referenced in IEC 61400-25 since they require high-priority real-time communication protocols that are out of the scope of the IEC 61400-25 series.

The major advantages of using MMS are the reduction of bandwidth needs due to its binary data encoding, the fact that it is, up to date, the only tested protocol in real systems, and the possibility of making use of the full set of abstract communication services.

However, MMS uses the full OSI stack, so the processing requirements at the devices are relatively high. Also, the software complexity of the full stack makes the development of the applications difficult.

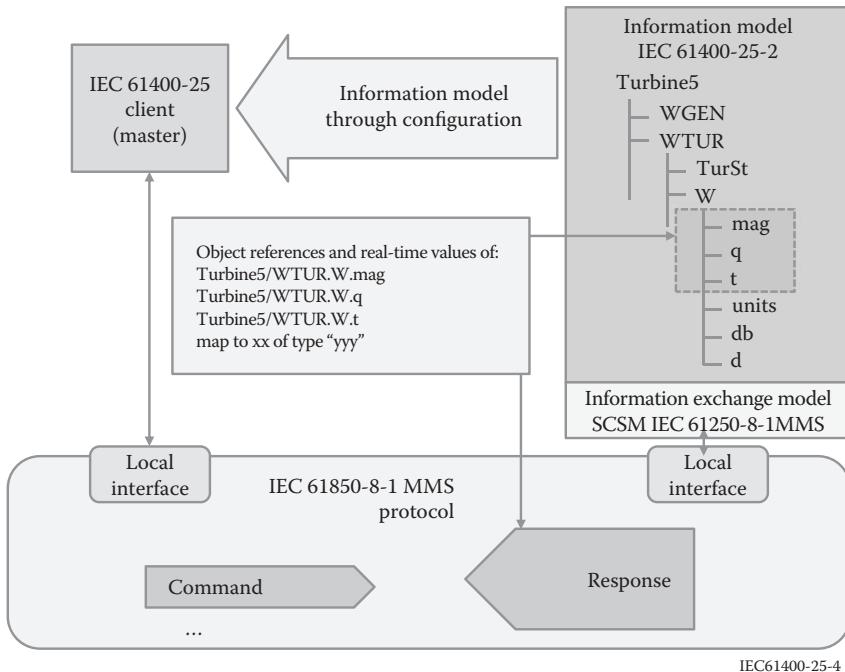

FIGURE 63.13 Conceptual MMS mapping architecture.

TABLE 63.10 MMS Protocol Stack for IEC 61400-25 Communication Profile

	Implementation specific and beyond the scope of IEC 61400-25		
	Physical Layer	Implementation specific and beyond the scope of IEC 61400-25	

### 63.5.4 Mapping to IEC 60870-5-104

In this mapping, the IEC 61400-25-3 service models are mapped to IEC 60870-5-104 according to the IEC/TS 61850-80-1 standard (Guideline to exchange information from a CDC-based data model using IEC 60870-5-101 or IEC 60870-5-104). This approach maps the IEC 61400-25-2 IMs with the attributes of CDC to ASDUs (Application Service Data Units) and the IEC 61400-25-3 services to the Basic Application functions defined in IEC 60870-5-104. This mapping is illustrated in Figure 63.14.

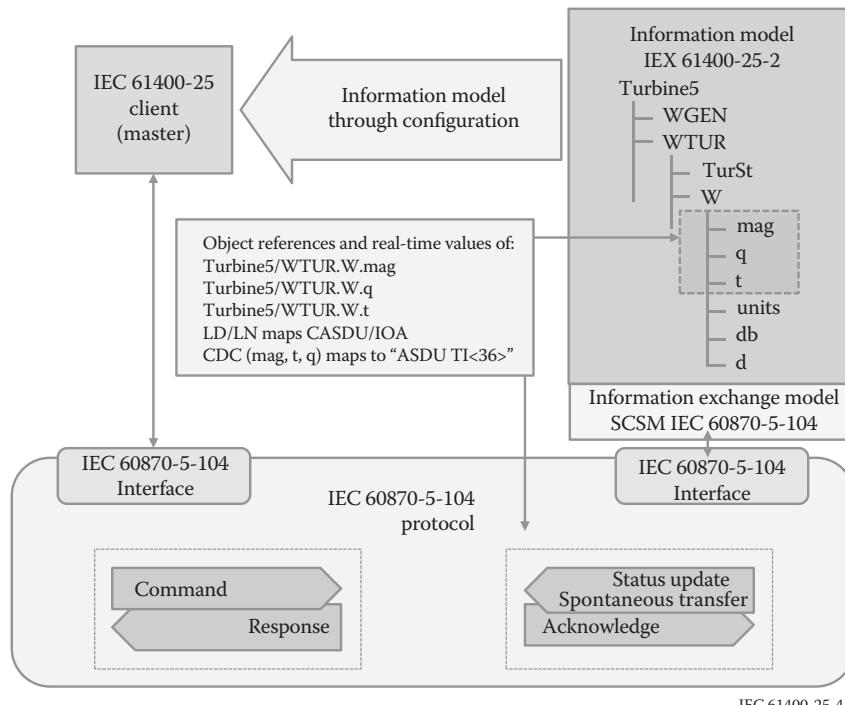

Again, the mapping between the IEC 61400-25-based object models and IEC 60870-5-104 defines the following:

- Both the server and client are configured with the specific WPP IM.
- The configuration can be done in different ways, either by online configuration or by using the Substation Configuration Language (SCL), defined in IEC 61850-6.
- The client application accesses the IM through the services provided by IEC 60870-5-104 to exchange real-time data.

The configured data is defined as Process Image (PI). The IM mapping is based on using the Common Address of ASDU (CASDU) and Information Object Address (IOA) within a standardized IEC 60870-5-104 ASDU. This accommodates the WPP IM and transfers real-time information data. It is recommended to use a Data Engineering tool to manage the use of CASDU and IOA following a unique numbering scheme.

The IEC/TS 61850-80-1 uses an SCL file that covers not only the mapping but also a broader scope of IEC 61850-based models. Selected parts of IEC/TS 61850-80-1 can be used for WPPs.

The WPP IES specified in the IEC 61400-25-3 IEM must be mapped to the services defined by IEC 60870-5-104. However, not all IEC 61400-25-3 services could be mapped due to the nature of the IEC 60870-5-104 standard.

**FIGURE 63.14** Conceptual IEC 60870-5-104 mapping architecture.

IEC 60870-5-104 is one of the most frequently used standards to control remote stations from control centers. However, as in other mappings, a wide set of IEC 61400-25 services cannot be supported, and management of data sets is not available.

### 63.5.5 Mapping to DNP3

Distributed Network Protocol 3 (DNP3) is an open and public protocol aiming at applications of tele-control of substations. DNP3 is a derived branch of the IEC 60860-5 protocol adapted to the North American application. DNP3 is administered by an independent organization called the DNP Users Group, which is a consortium of device vendors and users.

DNP3 uses data set prototypes to specify the structure and ordering of data within an entire data set or a portion of a data set. It uses name spaces to assign unique meaning to common names. The DNP3 Users Group accepts voluntary registration of name spaces submitted by any vendor or user. Once a name space is registered, the vendor or user is free to define, redefine, or delete any data set prototype(s) within that name space. Each data set prototype is assigned a UUID (Universally Unique Identifier) that identifies it.

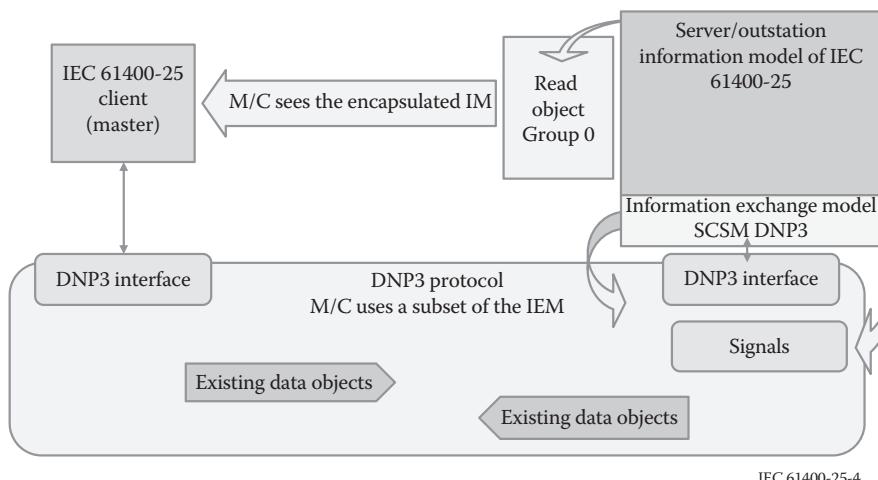

In DNP3, any IEC 61400-25-2 entity is mapped to a specific DNP3 data set prototype. A DNP3 UUID is reserved for each CDC in IEC 61400-25-2. The DNP3 name space assigned to the IM is "IEC 61400-25-2".

This mapping, illustrated in Figure 63.15, only provides services for process data exchange. Therefore, the following IEC 61400-25-3 services should be mapped to services defined in DNP3:

- Data model (GetDataValue, SetDataValue)
- Control model (Select, SelectWithValue, Operate, CommandTermination)

The specified mapping for IEC 61400-25 DCs can be based on either one of these mechanisms:

1. *Mandatory*: DNP3 XML schema mapping of DNP3 data points to IEC 61850 object models. This schema can be used to describe a mapping between DNP3 data points and the data attributes of the object models described in IEC 61400-25-2.
2. *Optional*: DNP3 Data Sets can transport the IM of the WPP components. If DNP3 Data Sets are used for the mapping of DCs, then the IEC 61400-25-2 WPP IM must be mapped to DNP3 Data Set descriptors with DNP3 objects.

**FIGURE 63.15** Conceptual DNP3 mapping architecture.

When the optional DNP3 Data Set mapping procedure is used, the DNP3 XML mapping procedure may be left unused.

Where DNP3 Data Sets are used for the mapping,

- The server encapsulates the WPP IM that can be read by the services by reading DNP3 Object Group 0
- The master/client station accesses the Data Attributes from the WPP IM through the services provided by DNP3

## 63.6 Condition Monitoring

---

Condition monitoring focuses on observing components or structures for a period of time in order to evaluate the state and changes at these entities and to detect early indications of failure. Condition monitoring is most frequently used as a predictive or condition-based maintenance (CBM) technique. In WPPs, condition monitoring includes tasks as vibration measurements and analysis, oil debris analysis, temperature measurement, or strain gauge measurement.

The information used by condition monitoring may be located at different physical devices. For example, some information could be located in a turbine controller device (TCD) while other information could be located in additional specialized condition monitoring devices (CMDs).

The purpose of IEC 61400-25-6 is to define the IM related to condition monitoring for WPPs and the information exchange of data values related to these models. It is based on the models and mappings defined in previous parts of the IEC 61400-25 standard, but it extends these models for condition monitoring purposes. For instance, LNs like WTUR (Wind TURbine general information) or WALM (Wind power plant ALarM information) are extended and new LNs are introduced as, for instance, WCON (Wind CONdition monitoring information). The condition monitoring data are defined in specific CDCs having different related categories and data types.

Many CDC attribute types such as analog value, time stamp or vector, and point are inherited from IEC 61400-25-2 or IEC 61400-25-3. However, additional specific CDCs are needed for condition monitoring such as SV or Data File (DAT).

The data types are divided into two groups of data types: one group is mandatory and another group is optional or vendor specific. The data types specified for the condition monitoring system for a particular part of the turbine are assigned a unique number. Then, this data type can be used in the data model as a reference when referring to measurements of a certain data type.

Due to the big amount of condition monitoring information over the WCON LN, it is necessary to relate many measurements to the specific location of the sensors on the WT. For this purpose, a methodology to specify specific measure locations is performed by IEC 61400-25-6.

## 63.7 Conclusions

---

The IEC 61400-25 standard has been defined aiming at providing a uniform communication backbone for the monitoring and control of WPPs in a multivendor environment. Based on the IEC 61850 standard, it specifically deals with establishing data objects to manage the relevant information of WPPs, the mechanisms to exchange information and the mapping to different, well-established, communication protocols.

The standard provides interoperability between the components of the plant and between the components and the external world, and, consequently, the time to market and development costs of control and supervision applications (usually SCADA) can be drastically reduced.

The IEM also takes into account the provision of mechanisms to manage history logs and reports containing a great amount of information that is very common in WPPs (the order is typically thousands).

On the other hand, in order to cover different communication requirements, it specifies mappings to very well-known protocols. Hence, the mapping to OPCX XML-DA allows integrating commercially available SCADAs. MMS covers the management of large WPPs. WS provides a universal access to small, delocalized WPPs. Finally, IEC 60870-5-104 and DNP3 cover the need of remote control in both European and American systems.

Far from being a standard with an unclear future, IEC 61400-25 appears to be a safe bet in the development of monitoring and control systems for WPPs. Besides, there are companies with a proven experience in the development of monitoring and control systems in the sector of management and distribution of electrical energy that are applying their experience with the IEC 61850 in the sector of WPPs. Besides that, companies that develop data acquisition and control systems applications are introducing IEC 61400-25 clients as an access mechanism to process data looking at enhancing their application environment.

### 64.1 Introduction

---

The main goal of a railway network operator is to provide a timely and safe train service to the customer. Automation and computer-driven train control are essential elements toward achieving such a service for large railway systems. Historically, interlocking systems were locally manned. Dispatchers controlled local train and shunting movements and exchanged the relevant information, following strict protocols, via landline.

Their tasks include route control and train supervision, as well as work gang protection and customer information. Today, some railway lines are still controlled this way. A major drawback of this approach is the limited support for automatic operations and dispatching. Automation of local interlocking systems eased and gradually replaced the work performed by local dispatchers and enabled train management on a large scale. With the interconnection and remote control of these automated interlocking systems, it is possible to supervise the train service for a large part of the railway network from one operational center.

The Austrian main line network, operated by Österreichische Bundesbahnen (ÖBB—Austrian Federal Railways), is supervised with one Network Management Center (NMC) and five Operation Management Centers (OMCs) as illustrated in Figure 64.1. Within the NMC, all information about the traffic situation on the whole network is available, and traffic is coordinated on a large scale. The OMCs perform regional disposition, control and management of traffic, as well as customer information and

**FIGURE 64.1** Operation management centers in Austria.

function as technical service centers. Each OMC connects numerous people and systems to fulfill its task. In this chapter, we will describe communication paths in these systems and their properties. These paths take us from operators, the automatic train routing system, and work gangs, through the OMC, down to the signals and switches of the railway network.

In the next section, we discuss general aspects of railway systems, before describing the Reliability, Availability, Maintainability, and Safety (RAMS) by construction approach in Section 64.3. This approach is the foundation for the TAS Control Platform and OCS concepts presented in Sections 64.4 and 64.5. The OMC architecture and its interfaces are outlined in Section 64.6, which is the basis for Section 64.7. There we follow example communication paths through the railway control systems and have a detailed look on the requirements and properties along these paths.

## 64.2 General Aspects of Railway Systems

Railway systems share common aspects regarding their general properties, which define their architecture. In the following, the most important aspects will be briefly discussed.

### 64.2.1 Standards and Certification

To ensure safe and reliable functionality of railway systems, they are subject to certification. Systems targeted for the European market are certified according to the corresponding CENELEC standards. Basis is the EN 50126 standard [1], which specifies RAMS requirements applicable for railway applications. EN 50128 [2] and EN 50129 [3] specify requirements for software development and electronic applications in general. These standards are the basis for railway system development and operation.

### 64.2.2 Safety

Less than  $10^{-9}$  safety-critical failures per hour are required by EN 50129, for systems where a failure may result in a catastrophic event. Within the context of an application, such safety requirements can

be reached using various strategies and methods for implementation. In the course of this chapter, we discuss different technical and conceptual methods for achieving safety in communication and computation.

### 64.2.3 Fail-Safe

Unlike other domains such as avionics, most railway applications can enter a safe state upon the detection of anomalies. An example for such a safe state is when all signals are set to red, that is, all trains stop. Here the difference of safe and available is evident. Setting all signals to red is safe, but the train service is not available. Please note that, in the context of rail, safe communication does not necessarily imply high availability.

### 64.2.4 Reliability and Availability

Apart from safety, high reliability and availability are essential for providing a quality railway service. This is equally true for applications, as well as for safe and nonsafe communication. As an example, the Austrian Federal Railway Authority requires less than one service interruption in 10 years.

### 64.2.5 Maintainability

Railway products typically have a long lifetime in the order of 20–30 years. This requires concepts for

- Hardware maintenance
- Software maintenance
- Function upgrades
- Delivery and replacement of faulty components

They are essential to achieve such long lifetimes. Again, this applies to the applications, as well as the communication systems.

### 64.2.6 Real Time

Since railway applications are fail-safe, they can be viewed as soft real-time systems. The most important time constraint is on the detection of anomalies to trigger an appropriate safety reaction. The time it takes from occurrence of anomalies to the safety reaction is influenced by the application architecture, as well as its communication. Here, supervised time-outs are key elements to ensure safety. These time-outs have to be carefully chosen by the application designer to guarantee fast failure detection on the one hand and avoid unnecessary failure reactions on the other hand. These time-outs implicitly define the tolerance of the system with respect to communication jitter.

## 64.3 RAMS by Construction

---

Conformance to the RAMS criteria is reflected by the architecture and behavior of a railway application and its components. With the use of basic concepts, generic architectures can be created for computation and communication. They in turn enable the modular construction of complex railway applications fulfilling the RAMS criteria.

### 64.3.1 Basic Concepts

The basic concepts presented here can be utilized for safety, reliability, and/or availability. Furthermore, breaking down the system architecture in such entities is a natural support, but no guarantee, for maintainability.

#### **64.3.1.1 Fault Detection**

With fault detection, a system can avert the sending or processing of possibly incorrect input and output caused by a fault. This is a technique suitable for fail-safe system, where upon the detection of a fault, the system is put into a safe state, and the service interrupted. Continuation of service is possible when either the system has verified that the fault no longer persists or appropriate maintenance actions have been taken to remove the fault.

#### **64.3.1.2 Fault Tolerance**

Fault tolerance enables continuous operation in the presence of a single or even several faults. For communication, fault tolerance can be achieved with, for example, redundant networking equipment, retransmission of messages, or error-correcting codes.\* Example architectures for computation are triple modular redundancy (TMR) and active replication for availability.

The correctness of the output generated by a TMR system is guaranteed by the fault hypothesis for the TMR architecture and the subsequent voting on the output. Output generated by an active replicated system for availability has to be valid for each replica on its own.

#### **64.3.1.3 Diversity**

Diversity is aimed at the detection of failures. Two computation or communication channels apply different methods to calculate or transmit output, using the same input. Based on the assumption that a failure occurring in one or both channels affects each method differently, the correctness of the output can be verified by voting. The diversity of these methods can be achieved in various ways, such as by using, for example,

- Different programming languages
- Different development teams (N-Version programming [4])
- Different hardware or software components
- Different designs, for example, compute and validate
- Different specifications
- Monitoring techniques
- Automatic transformation of one method to another

Another aspect of diversity is the possibility to protect against software bugs introduced during the development phase. Here, it is crucial that the bug was either introduced into only one channel or, if found in both channels, results in different output. With the consequent application of diversity methods, the existence of an undetectable software bug in the compound software system is extremely unlikely even when executed on the same hardware.

Apart from the explicit introduction of diversity, similar systems may expose diversity inherently. This is caused by having slightly different initial states or ordering of input and output events [5].

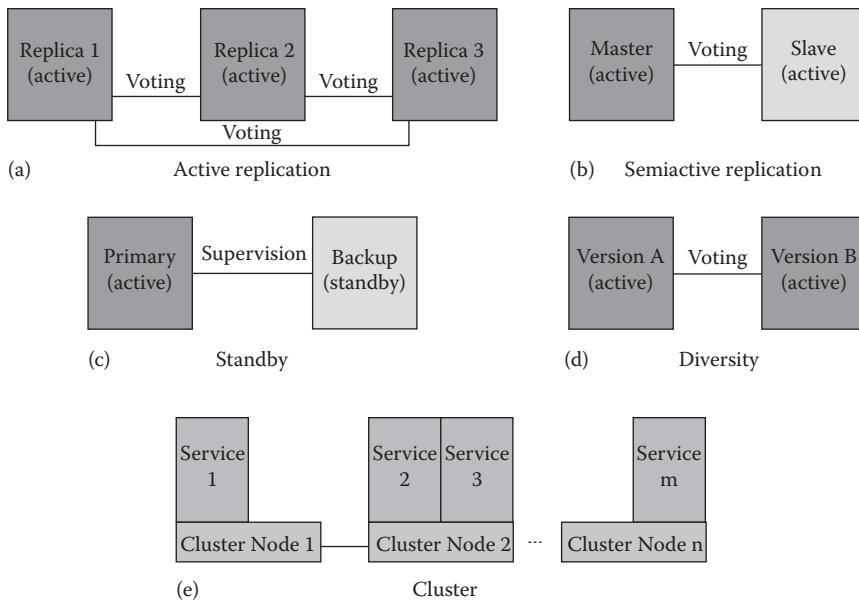

#### **64.3.1.4 Redundancy Concepts**

Redundancy can be used for availability, as well as for fault detection. Different redundancy concepts and architectures target various properties. Replication [6], diversity [4], and clustering are strategies for redundancy used within software railway systems. Figure 64.2 illustrates the different redundancy concepts.

Redundancy models for continuation of service in case of failure of one entity are active and semiactive replication (Figure 64.2a and b). The most prominent representative of active replication is TMR. Master-slave replication where both replicas actively compute the result is an example for semiactive replication.

---

\* Note that EN 50159 discourages the use of error-correction techniques and requires the use of a safety code for safe communication.

**FIGURE 64.2** Redundancy concepts for safety and/or availability.

Replication with cold or warm standby (Figure 64.2c) is suitable if a short interruption of the provided service is tolerable. This interruption occurs since the service has to be started on passive replica in case of failure of the active one.

Execution of services or replicas on top of a cluster middleware (Figure 64.2e) introduces a further layer of hardware abstraction. This enables a fast restart of such services or replicas, in case their executing computing channel fails. Whether or not the service was interrupted due to that failure depends on the replication mechanism of the individual service or replica. With the hardware abstraction of the cluster service also the scalability of a computing system can be increased. New computing channels may be simply added to the cluster for more performance. However, the application executed within the cluster has to support this concept through its design.

All redundancy models without active replication are purely applied for availability and cannot provide support for safety. They have no option to check the validity of a generated output.\* Diversity (Figure 64.2d), on the other hand, is a redundancy model for safety and not availability, which we discussed above.

Independent of the type of redundancy, all systems have to implement mechanism to ensure real-time properties and detect anomalies. Additionally, redundancy concepts can be combined for reaching both—availability and safety.

#### 64.3.1.5 Active Replication Concepts

Active replicated systems require their involved components to coordinate interact with their environment. The key here is to ensure the replica-deterministic execution of the replicated programs. Time base, voting, and membership services enable this coordination and are implemented either implicitly or explicitly in any active replicated system.

##### 64.3.1.5.1 Time Base

For fault-tolerant redundant systems, a consistent view of the environment is necessary to interact correctly with the latter. A common time base allows the ordering of observed events and

\* Note that also regular output may be interpreted as “heartbeat.”

triggering of time-outs and implicitly monitors progress of the redundant computing channels. Replica deterministically executed programs must not use any other time source, as not to break the determinism in their execution.

#### **64.3.1.5.2 Voting**

Voting is necessary for checking the correctness of redundant messages. It can be performed on the semantics or syntax of messages. Examples for syntax voting are bit-wise comparison and majority voting for failure detection. For systems utilizing diversity, voting on the semantics of the output might be necessary. However, equality of the datum is not the only criterion, as also the timeliness of the output has to be fulfilled. To check for timeliness, a voter might define time frames within which messages belonging together have to arrive.

Additional safety mechanism can be included in the voting process, for example, the green signal may be activated only by two messages, whereas one message may be sufficient for setting the red signal.

#### **64.3.1.5.3 Membership**

For identifying replicas participating in the redundant execution of a service, the internal membership service is used. This service is the basis for including and excluding replicas from execution and reflects the health state of the redundant entities. The timeliness of membership information is crucial for an accurate view of the system.

Please note that also semiactive and standby redundant systems have to provide some kind of membership service. They too have to identify the failure or absence of the master replica and designate a new one.

#### **64.3.1.5.4 Reintegration of Components**

Fault-tolerant systems require the reintegration of components, after they have been excluded due to a transient fault. This is crucial for providing an interruption-free service. Without this reintegration capability, also called recovery, a TMR system would degrade to a redundant system with two replicas after the first fault and interrupt its service at the second. Two prerequisites are required to provide recovery in the first place. First, enough communication and computation resources have to be available to satisfy the additional load during recovery. Second, the recovery algorithm has to exactly know which parts of an application to recover.

### **64.3.2 Computation**

Safe computation can be realized with a wide variety of architectures and concepts. Different architectures and safety concepts enable the achievement of objectives with respect to maintenance and costs.

#### **64.3.2.1 Health Monitoring**

Computing channels usually monitor their health by executing a set of hardware tests as well as incorporating information retrieved by the membership service. Health monitors are particularly targeted against accumulated stochastic faults, which are not immediately detected by the functional implementation of the service.

#### **64.3.2.2 1-out-of-1 (1oo1)**

A 1-out-of-1 system achieves safe program executing on a single computing channel. The common approach for ensuring safety on such a system is software diversity. Naturally, fault tolerance is not possible with one 1oo1 system alone.

#### **64.3.2.3 2-out-of-2 (2oo2)**

Two computing channels are used for a 2oo2 system. In this setup fault detection of replica-deterministic applications, but no tolerance is possible. For fault tolerance, a 2oo2 system would need to ensure that each of the two entities functions as 1oo1 on their own.

#### 64.3.2.4 2-out-of-3 (2oo3)

2oo3 is the classical TMR architecture. Replica-deterministic execution of the safety-critical software components is essential in this architecture. In case of failure of one entity, the system switches into a 2oo2 configuration. When the excluded replica is eventually tested successfully for being free of persistent failures, it is recovered, and operation continued in the 2oo3 configuration.

### 64.3.3 Communication

As with computation, communication in railway systems is heterogeneous and incorporates safe and nonsafe communication networks next to each other. An example for nonsafe communication is a command requesting the setting of a route from the automatic train routing system to the interlocking system. This is not safety critical, since the interlocking system guarantees the safe setting of routes. However, a command from the operator to the interlocking system changing the state of a switch marked as occupied is safety critical. This command overrules the route protection of the interlocking system, thus, the safe execution has to be guaranteed.

Safe communication is subject to EN 50159 [7]. This standard defines requirements for communication between safety-related railway equipment. The key properties for safe communication are

- Authenticity
- Integrity
- Timeliness
- Sequence

The standard discriminates network architectures in three categories:

Category 1 applies to closed transmission systems with a fixed number of participants, negligible risk of unauthorized access, and static physical characteristics of the transmission system during its life cycle.

Categories 2 and 3 concern open transmission systems, which may have

- A changing set of participants
- Possibly unknown participants, which are not part of the railway application and may generate arbitrary communication loads
- Changing properties of the transmission media
- Changing message routes through the system

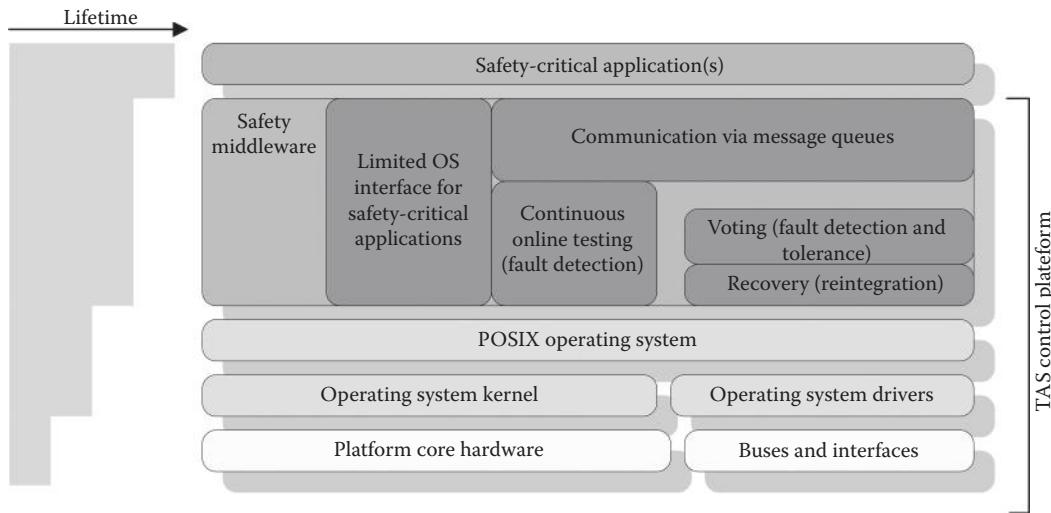

Only in category 3, the open transmission system may also be subject to unauthorized, malicious access.

Based on this categorization, the standard identifies possible threats and lists measures and methods that can protect the safety-related communication against these threats. The appropriate measures have to be implemented in an independent layer above the transmission system according to EN 50128 and EN 50129. However, safety is not the only criterion for communication systems, as all RAMS requirements have to be taken into account.

## 64.4 TAS Control Platform

---

The idea of TAS Control Platform [8] is to build railway applications on top of a generic computing platform and, with this approach, support the fulfillment of the overall RAMS requirements. This separation reduces the direct dependency of long-lived railway applications on short-lived hardware. TAS Control Platform includes all necessary generic elements for constructing replica-deterministic fault-detecting 2oo2 or fault-tolerant 2oo3 architectures. A basic set of services is also provided for 1oo1 architectures. The services include global time base, voting, membership, recovery, and fault management services, as well as a health monitor. The use of POSIX as generic interface for applications enables the transparent integration of fault-detection mechanisms. Applications can build upon the generic TAS Control Platform safety concept and safety case to reach their targeted safety goals.

**FIGURE 64.3** TAS Control Platform layer structure.

#### 64.4.1 Structure and Interfaces

The TAS Control Platform itself is structured in layers as depicted in Figure 64.3. The safety middleware layer enables safe application execution on top of a Component off-the-shelf POSIX operating system with its kernel and drivers. Within the safety layer, all safety-relevant platform services are executed to ensure detection and/or tolerance of faults occurring in the layers below. The figure also shows the relative lifetimes of components in the individual layers. This illustrates how the safety and operating system layers are used to achieve a long lifetime for the interface to the application, as well as the application itself.

The common time base, membership, and voting are implemented within the voting service of the safety layer. They are provided to the application via a message queue interface. Continuous online testing is performed by the health monitor service, and recovery is implemented as a separate service.

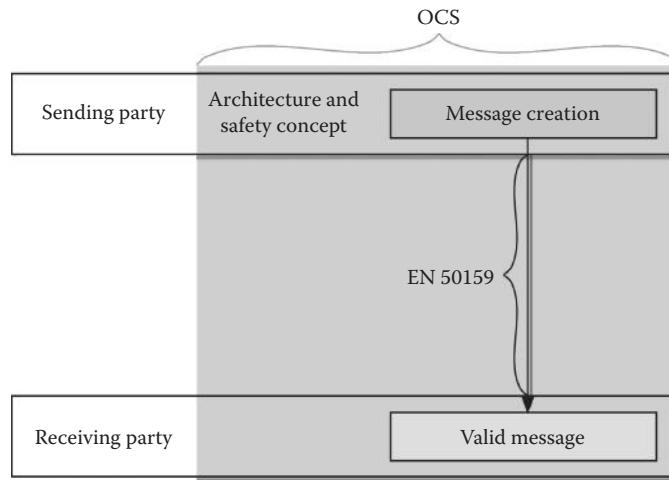

#### 64.4.2 Application Properties

TAS Control Platform Applications are structured in sets of closely related processes called *task sets* (TSs). They communicate by message passing through message queues. These message queues are used as transparent and generic interface to the communication system of TAS Control Platform. Each TS is assigned a redundancy model (1oo1 to 2oo3), and messages are distributed and voted accordingly. Replica-deterministic execution is enforced through the delivery strategy of messages and time. Thus, the applications do not need to implement these mechanisms themselves. However, time-outs on the interarrival and processing times of messages still have to be defined and evaluated in the application context. This ensures timeliness of the services and possible failure reactions.

For communication between applications, the concept presented in the next section is suitable.

### 64.5 One Channel Safe Concept

The fundamental idea of the *one channel safe* (OCS) communication concept is to establish a safe communication channel via one physical link. This channel is established without assumptions on the properties of this link, other than the failure rate and failure behavior. The application can be certain that a datum received via an OCS link is correct in the value and time domain (Figure 64.4).

**FIGURE 64.4** Components of OCS-based communication.

To reach this level of assurance, the OCS communication must, first, implement the required measures of EN 50159 in accordance with the nature of the underlying link. Note that this is where properties described in Section 64.3.3 of the underlying channel are taken into account. Second, the construction of these messages by the sending party has to be consistent with the sending parties' architecture and safety concept. This enables to interconnect applications having different architectures and safety concepts. However, guarantees with respect to timeliness are still achieved by the applications and OCS together and must be treated as such in each application's safety concepts.

#### 64.5.1 Message Creation

Depending on the used architecture and safety concept, different approaches may be used for safe message creation. It is important to note that voting and safety code creation before sending the message is not sufficient, as the voter might fail. One approach for replica-deterministic 2oo2 or 2oo3 configurations is to create different parts of the safety code on different replicas and combine them for the message sent to the receiving party. That way, no replica on its own can create a valid safety code, and the detection of faults is ensured.

#### 64.5.2 OCS and Availability

The OCS concept can be extended with availability by applying redundancy. Due to the nature of OCS, this is possible either by introducing redundancy transparently on the underlying link or by adding another link, which is handled by OCS itself. In the latter approach, the messages can be sent via one or both links, depending on the replication model. Due to the safety property of OCS messages, duplicate messages received on different links can be simply ignored.

### 64.6 Operations Management Center

After presenting the RAMS requirements and basic concepts for railway systems, we will now illustrate how these are used within the system for operative train control by the example of the OMC [9] and its communication structure. The OMC integrates all necessary systems to handle the operative train

services for large railway networks of up to 100 local interlocking systems. These interlocking systems are called substations within the context of the OMC. The functions provided for operative train control are

- Shunting
- Automatic train traffic control
- Train tracking
- Monitoring of train traffic
- Manual train control
- Dispositive planning

These functions are complemented with a recording service and a central administration and diagnosis service. The recording service documents critical events and human actions, whereas the administration and diagnosis service is used for the technical supervision of the computerized systems. Furthermore, each OMC workplace provides an interface to the automatic time-tabling service ARAMIS.

Within the OMC, all aspects of communication in train control are found: safe systems communicate with nonsafe systems; some systems have to be highly available, whereas others are not as crucial. All of these systems communicate using many different protocols and interfaces. Still, the RAMS criteria have to be met by the overall OMC to provide a satisfactory train service to the railway customers.

### **64.6.1 Overall Architecture**

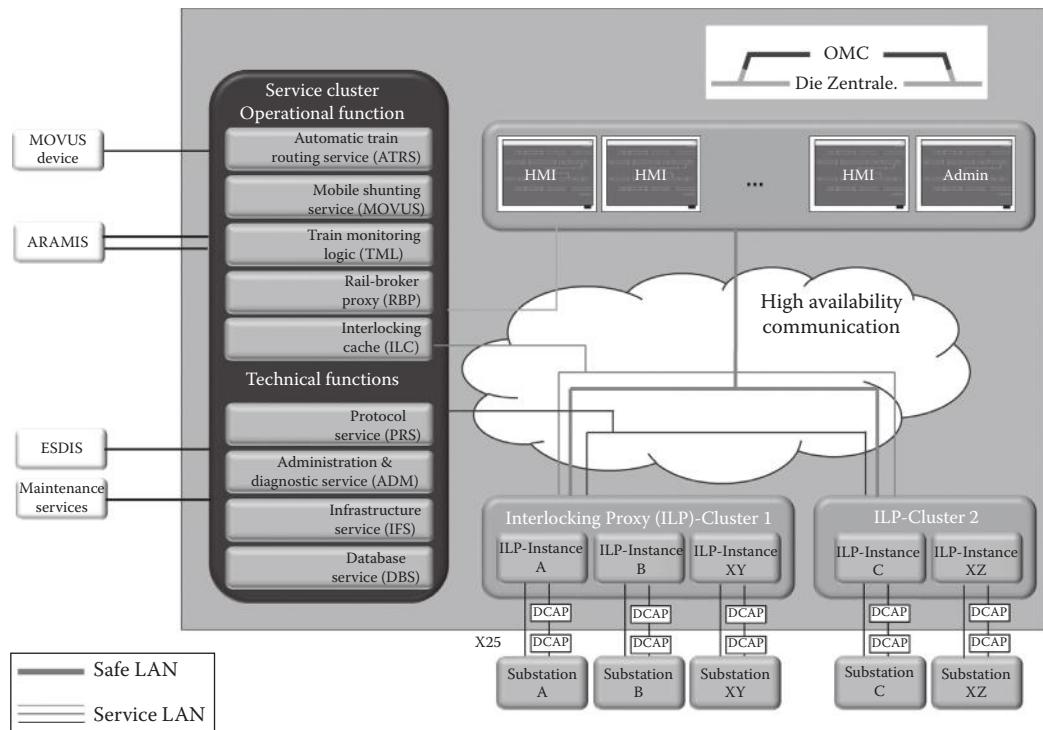

A key element in the OMC architecture is the breakdown of functionality in smallest replaceable units (SRUs). This enables continuous service for all components that are not directly affected by the failure of such an SRU. Furthermore, a clean separation of safe and nonsafe components and services ensures that the safe part of the system is not influenced by failures within the nonsafe part. This includes the separation of safe and nonsafe interfaces for human planners or operators. Such a separation also provides a scope for certification and subsequently enforces the underlying structure of the system. Another requirement affecting the architecture of the OMC is the support of the stepwise integration of existing local interlocking systems.

Following this philosophy, the OMC architecture is divided in safe and nonsafe components. Figure 64.5 gives an overview of the individual components of the OMC. Nonsafe components are illustrated with the dark background, whereas safe ones on the right-hand side have a brighter color. The human machine interface (HMI), the Interlocking Proxy Clusters, and their Interlocking Proxies (ILPs), as well as the interconnection of these components are safety-critical and strictly separated from all other components within the OMC.

From each HMI, that is, workplace of the OMC, operators can issue commands to, and view the network state of, all substations connected with the OMC. Within each OMC, several of these workplaces are installed. Their safety concept is based on a 1oo1 diverse architecture, as presented earlier, and a method for safe human interaction. The HMI workplaces exchange data with the ILPs, which safely and timely provide the state of the railway network elements at their corresponding substation. Only with the use of these ILPs it is possible to remotely control substations, since communication links to the substations are restricted in bandwidth and have a nonnegligible transmission delay. Furthermore, they provide first feasibility checks of safety-critical commands before forwarding these to the substation. ILPs and substations are organized in cells, where each cell is controlled with a dedicated ILP cluster. This increases the availability of individual ILPs and enables the stepwise integration of substations. The connections between OMC workplaces and ILPs are independent from each other, such that the failure of one workplace or ILP affects only this very part of the system.

The ILP also provides the elements' states to the nonsafe interlocking cache (ILC), which fulfills a similar function as the ILP for all nonsafe components of the operational functions:

- Automatic train routing service (ATRS), which is the interface to ARAMIS
- Mobile Shunting Service (MOVUS), providing a direct shunting interface to shunting personnel

**FIGURE 64.5** Architectural components and interfaces of the OMC.

- Rail-broker proxy, which is used by the ATRS for finding free train routes
- Train Monitoring Logic (TML), a service tracking train-specific information like the number of passenger wagons

They all exchange commands and states for the ILPs via the ILC and send information necessary for the notification of the operator to the HMI.

All nonsafe components are restricted to issue commands, which will later be checked by safe components for their validity and freedom of harm. For availability and the ability to increase computational power, the components of the operational functions are executed within a cluster.

The high-availability communication system within the OMC is realized with a redundant network of switches and cables based on Ethernet.

## 64.6.2 Common Interface for Substations

A prerequisite for the integration of a substation into the OMC is a suitable interface for the OMC at the substation. The X25 protocol has been defined to provide a generic protocol for railway automation and is an application layer protocol for the Austrian railway network. It is used for all communication between OMCs and substations. This requires that substations either already provide this interface or are extended with it.

## 64.6.3 Versatile Communication Interfaces

Many different systems using numerous interfaces are integrated through and within the OMC. ARAMIS is connected via an XML-based interface over TCP/IP, as well as through the X25 protocol. This protocol is also used for connections of substations to the OMS, as already outlined. The mobile

shunting devices exchange their information with the OMC via GSM-R. The OMC components use TCP/IP with VLANs internally for the high-availability network and also different protocols within this network. Additionally, firewalls are placed at the TCP/IP interface to ARAMIS, as well as to the error-reporting system of the railway network operator and remote maintenance service for the OMC.

Again, these interfaces can be divided into safe and nonsafe ones, but security is still an issue here, since the communication channels may be connected via open networks according to EN 50159. All these properties are discussed in the next section, where we follow different paths through the system.

## **64.7 From Human and System Action to Signals and Switches**

As presented in the previous section, the OMC connects and provides various systems and services by applying the basic concepts for RAMS. After the architectural aspects, we now present example communication paths through the OMC and connected systems, which are representative for many different command sources and destinations. They exhibit not only various communication requirements in railway but also the organizational structure and safety philosophy.

### **64.7.1 From Planner to Operator**

Each workplace for planning or operation within the OMC has the layout as shown in Figure 64.6. The separation of safe and nonsafe interfaces is not explicitly visible to its user, but the underlying systems are completely separated. The interface for time-tabling and general planning information of the regional railway network, that is, ARAMIS, has no direct connection to the HMI of the OMC. Their interfaces are physically close at the workplace, but they are two completely different systems. ARAMIS is connected to the OMC only via the nonsafe part of the OMC. Here the strict separation of nonsafe and safe functions, that is, planning and operation, is apparent.

The HMI is controlled through method safe operation, that is, safety-relevant information is exchanged twofold and has to be acknowledged by the user. For (nonsafe) planning, no such procedure is required. Within the OMC, different roles are assigned to the personnel. These roles define the

**FIGURE 64.6** OMC workplace.

capabilities available at the workplace and allowed actions. In our example, a planner changes the schedule for a specific train, and we follow the path of communication to the operator observing a different arrival time of the train.

The planner issues his change request in the planning interface. For these changes, it is guaranteed that they will be executed on time, provided they are issued at least 5 min before their schedule. Via a standby redundant IP connection, the change request is sent to ARAMIS. This communication is nonsafe and uses time-outs to detect a broken IP connection. Furthermore, a closed IP network is provided for this traffic. When the train route is scheduled, the ARAMIS system forwards the route to the OMC via the same network structure and protocol. The nonsafe ATRS then sends the information in XML format via TCP/IP to the nonsafe ILC. The ILC forwards the command to set a route to the corresponding ILP, again through TCP/IP. The ILP and substation check the validity of the set route command. However, the details of the communication path for setting the route are explained in the next section.

The ILP is implemented in a diverse manner on a 1oo1 TAS Control Platform, with the concepts for RAMS as presented earlier. It forwards the changes performed by setting a route from the substation to the HMI. It does so by using safe message construction according to OCS and uses the SAHARA protocol for EN 50159-conform communication. Availability within the OMC is achieved through the transparent high-availability network. The SAHARA protocol implementation has to conform to the open network classification without malicious attacks according to EN 50159. This is required since the internal network is logically separated via VLANs, but uses the same physical infrastructure as nonsafe VLANs.

Finally, the HMI will display the set train route via its interface on the OMC workplace.

#### 64.7.2 Operator to Switch

An operator altering the position of a switch marked as occupied, that is, a switch that is already used within a train route, is an example of a communication path involving only safe components within the OMC. This is an override situation, where the operator has to guarantee the safety of his operation. The OMC provides a checklist of safe preconditions as support, but does not check the validity of the operation. However, the system has to ensure the correct execution of the command.

There are no explicit time restrictions on when the execution of this command is executed by the switch. The operator himself is provided with a timely view of the railway network elements, which only depicts the actual state and no pending commands. Should a command fail, for example, a switch's motor is broken, the operator will observe it by the absence of a reaction.

The operator method-safely issues the switch change command to the HMI. The HMI forwards this command via the SAHARA protocol to the ILP. Through one of two X25 connections, the command is then sent from the ILP to the substation. Either these X25 connections can be directly used in closed networks or datacryptors can be added on both ends for use in any open network. The redundancy model here is standby, and only heartbeat messages are sent on the passive channel to check its availability. A loss of the active connection is detected with a time-out. In such a case, the channels are switched, and the ILP requests the state of all connected elements of the substation. Until it has new information, the ILP notifies the HMIs that no valid state of the network elements is currently available.

The substations themselves are implemented with different architectures and safety concepts. These architectures may be one of 1oo1, 2oo2, or 2oo3. Also NX interlocking systems, which are based on relay logic, can be connected when extended with a suitable electronic interface. This is one of the main challenges for the introduction of the OMCs: the integration of substations with largely differing technology and age. This is solved with the X25 protocol as described earlier. The substation forwards the state change command to the switch. There the switch motor will change its state. On completion, the substation sends the new state of the switch back to the ILP. The ILP in turn notifies the HMI of the new switch state and, by this, the human operator.

### 64.7.3 ILP to Substation via Datacryptors

A common scenario in Austria is the connection of the ILP to the substation via two X25 channels, where one channel is routed through a closed network and the other via an open one [9]. In the latter one, measures against malicious attacks have to be provided according to the classification of EN 50159.

The X25 protocol itself does not include any security measures suitable for open network communication. This functionality is added with the use of a special device, the datacryptor. This device can encrypt and decrypt the communication received via its interfaces. It is used at both ends of the X25 communication, that is, the ILP and the substation. Its interfaces to the ILP and OMC behave like interfaces for data communication equipments and toward the open network like data terminal equipment. An example datacryptor is DCAP-LE, which is mounted in the substation and OMC on a regular 19 in. rack as shown in Figure 64.7. Defined by its configuration, it either uses the advanced encryption standard or data encryption standard method for encryption and decryption.

With the use of datacryptors, the X25 connection can also be routed through these open networks.

### 64.7.4 Mobile Shunting Device to ILP

Shunting personnel working at the tracks can use a mobile shunting device for interaction with the OMC to set and monitor shunting train routes. This eases shunting tremendously, when compared to the method of phoning the operator and requesting the same while following a strict protocol on the landline. The mobile device sends the request for a shunting train route by GSM-R to MOVUS in the OMC. MOVUS then requests the route at the ILC using an XML-based protocol via TCP/IP. All these components are nonsafe, and again the border between safe and nonsafe components is crossed between ILC and ILP. If the requested route cannot be set, an error is reported to MOVUS. MOVUS forwards this error to the mobile shunting device, as well as the HMI.

### 64.7.5 Ensuring ETCS Conform Trains on ETCS Tracks

The European Train Control System (ETCS) is a standard for systems designed to provide signaling information and other services through on-board equipment of the train to its driver. ETCS classifies

**FIGURE 64.7** Datacryptors.

signaling systems in levels. With the use of the ETCS system, all segments of a railway network conforming to ETCS Level 2 or 3 can omit signals along their tracks. Such tracks must be used only by trains that are equipped with the corresponding ETCS on-board devices.

Within the OMC, a supervision is implemented to prevent the inadvertent entering of insufficiently equipped trains into such segments. The ARAMIS system provides the train ID and other train-related data. This includes the availability of an ETCS on-board device, to the OMC via its TCP/IP interface. Within the OMC, the TML collects these data and provides the train information to the automated train routing service on request via XML-formatted messages over TCP/IP. This service then denies the setting of a train route, when no ETCS is available on board. It, furthermore, informs the HMI, again through XML and TCP/IP, of the failed attempt. The operator in front of the OMC workplace must then resolve this conflict, for example, by setting a different route. The task of the ETCS check can be performed within the nonsafe part of the OMC, since an additional system is installed at the end points of the ETCS segments. This system stops the train if it fails a further ETCS on-board device check.

### 65.1 Ethernet in TCN

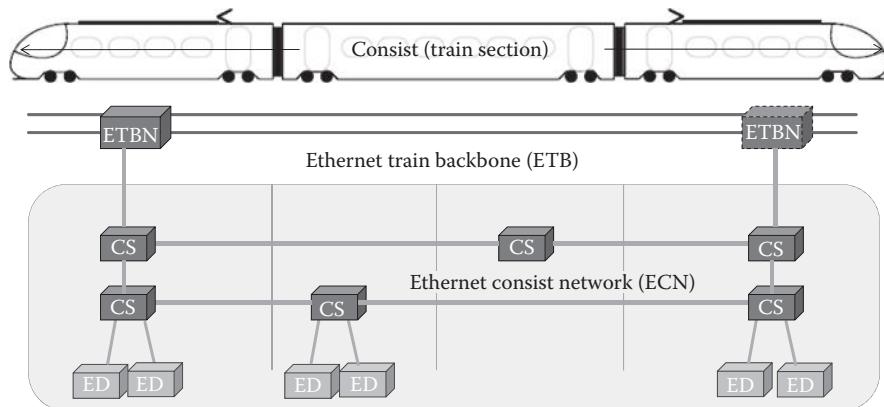

The Train Communication Network (TCN) represents a fieldbus, which is used in railway vehicles. This established fieldbus has been standardized as an IEC standard by an international alliance of railway manufacturers (IEC 61375-1, see [1]). The TCN according to the IEC standard is structured in a hierarchical way with the following components: (1) the interconnection of train segments (so-called consists) is handled by a Wire Train Bus (WTB) and (2) the interconnection of devices within each train segment is controlled by a Multifunction Vehicle Bus (MVB).\*

Like in other industrial applications and in avionics, there is also an Ethernet-based version for the TCN on the way. It is also specified by an international IEC working group and currently in progress (for the current state, please refer to the dashboard of the TC-9 at Ref. [1]). The Ethernet-based version of TCN comprises the specifications IEC 61375-3-4 (Ethernet Consist Network [ECN], representing the MVB) as well as 61375-2-5 (Ethernet Train Backbone [ETB], representing the WTB). Thus, it follows the same principles as IEC 61375. Figure 65.1 shows the overall architecture.

The figure shows that the Ethernet-based TCN maintains the hierarchical architecture of the IEC 61375-1. Within a train segment, devices are controlled via an ECN, which interconnects end devices (EDs) by consist switches (CSs). As one train may contain multiple train segments (cars, consists), the segments (which are, respectively, consist networks) are interconnected via Ethernet Train Backbone Nodes (ETBNs).

The network topology within a Consist Network (ECN) is not restricted by the standard. For instance, ring topologies can be applied in combination with a protocol providing ring redundancy.

\* For additional information on TCN, see *The IEC/IEEE Train Communication Network*, Hubert Kirrmann and Pierre A. Zuber, Industrial Communication Technology, CRC Press, 2005.

ETBN: Ethernet train backbone node (Router) CS: Car switch, consist switch (Ethernet switch) ED: End device

**FIGURE 65.1** Ethernet-based TCN architecture.

Apart from the ring configuration indicated in the figure, there are other typical requirements in the vehicle network, which need to be met by the Ethernet-based TCN:

- Real-time (RT) processing
- Fault protection at ECN and ETB level
- Redundant ETBN configuration
- Separation of vital process data from other traffic (measurements, announcements, passenger information, surveillance cameras, etc.)
- Network organization at Ethernet and Internet Protocol (IP) level
- Safety protocols

One specific requirement on a train is the dynamic organization of the network: Unlike a road vehicle or an airplane, a train may need to be reconfigured while stopping at a railway station. One reason may be that it needs to drive in the opposite direction at a head station, which changes the driver's position and the head of the train. Another reason is that a train segment may be added or dropped. Such changes affect the network topology and thus need to be supported by the TCN.

While driving, the network topology is stable. Still the TCN represents a complete Layer 3 network including routing functions and administration of IP addresses. Thus, the TCN does not represent a simple Ethernet-based subnetwork (respectively, Layer 2 network).

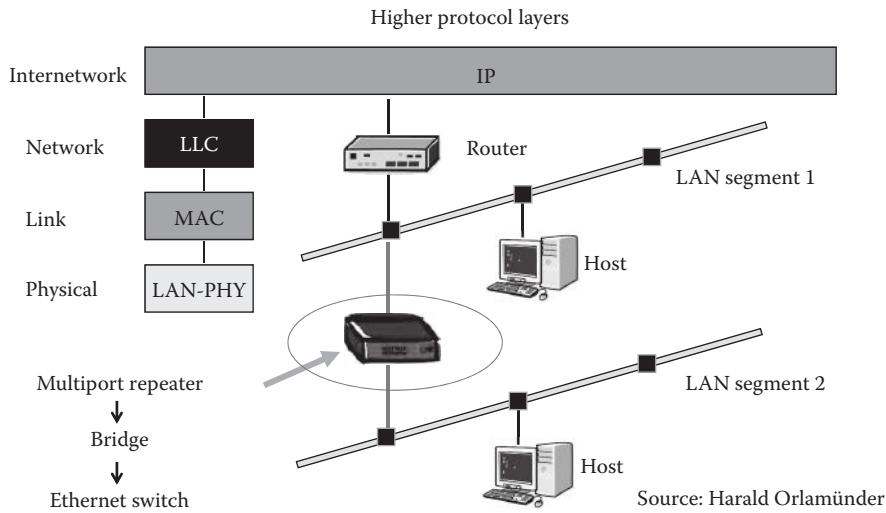

Moving from any proven technology to a new generation is not a trivial step. In the case of TCN, the fundamental conditions are

- The need for a full functional equivalent to WTB and MVB on the new network technology
- The need for embedded network products, which suit the specific requirements in railway systems

Native Ethernet technology did not have any of such applications in mind. However, Ethernet has been following an evolutionary approach concerning its specifications and thus has been capable to adjust to a huge variety of applications.

## 65.2 Native Ethernet Technology

Ethernet originated some 30 years ago in computer networks in the office environment. Since the 1980s, Ethernet has been spreading fast as a universal medium to interconnect computers and all sorts of peripheral devices. One reason for this success is that the Ethernet specifications take an evolutionary approach.

**FIGURE 65.2** The origin and structure of Ethernet.

Ethernet protocols are structured in a layered and modular way (Figure 65.2). The basic specification of Ethernet contains the Layer 2 protocols: MAC (medium access control, IEEE 802.3) and LLC (logical link control, IEEE 802.2). This specification could be extended by further control protocols, such as IEEE 802.1 that—among others—contains the spanning tree protocols, virtual local area networks (VLANs), and port-based access control, as well as application-specific extensions (IEEE 802.4 and higher).

At the lowest layer (the physical layer), Ethernet protocols accommodate different media, such as Ethernet cables at a variety of speeds, Wi-Fi (wireless LAN), or optical fibers. This way, the elementary protocols for MAC and LLC could grow beyond their original physical medium.

The function of an Ethernet switch is based on the Ethernet message format (Ethernet/bridging protocols), that is, the Layer 2 protocols. This layer contains local network addresses (MAC addresses). Elementary Ethernet switches (hubs) have been simple multiport repeaters, that is, a message received on one port is repeated to all other ports. Devices connected to such a network receive all messages and respond only to messages, which are directed to their own MAC address.

With the growth of networks, bridges have been introduced, which only transmit traffic intended for the specific network segments connected to the bridge. In order to filter the traffic, bridges had to learn the MAC addresses of devices connected to their ports. In a subsequent step, the traffic capacity of the Ethernet bridges was increased: Ethernet switches allow all ports to operate at their nominal speed.

Layer 2 protocols have been evolving and today typically include link aggregation (802.3ad), VLANs (802.1Q), spanning tree (802.1D, 802.1w), quality of service (QoS) (802.1p), flow control (802.3x), as well as GVRP (dynamic VLAN registration) and GMRP (dynamic L2 multicast registration).

With larger networks and for wide area connectivity, it made sense to break down the network infrastructure into segments: local area networks (LANs), which are organized by the Layer 2 Ethernet and MAC addresses, and a higher network layer—wide area networks (WANs), which are organized by Layer 3 protocols, that is, the IP and IP addresses.

From the perspective of the higher network layer, the local networks are operated as IP subnetworks. This allows the use of private IP addresses for hosts and devices in home and office networks. Also, the network can be structured flexibly at the Layer 3. In such a network, IP routing protocols may be applied. More sophisticated Ethernet switches also support Layer 3 protocols such as OSPFv2, RIPv2, Virtual Router Redundancy Protocol (VRRP), IGMP snooping, IPv4 forwarding, DiffServ, ARP, ICMP, as well as DHCP client/server to receive or distribute IP addresses.

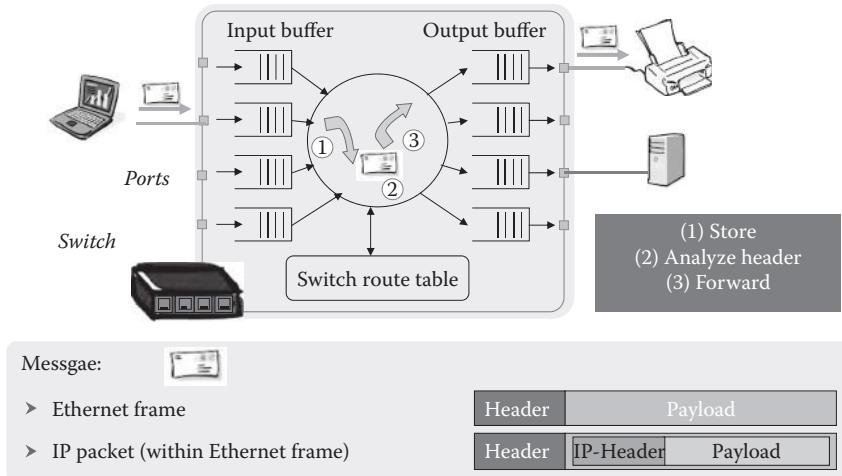

FIGURE 65.3 Ethernet switches.

Because of their many configuration options, advanced Ethernet switches need a user interface, which allows operation via a command-line interface (CLI), remote terminal (Telnet), or browser (web server), as well as a management interface (SNMP). Devices with these options are known as *managed switches*. Such switches also receive an IP address because they need to be addressed as hosts for configuration.

Irrespective of protocol diversity, every Ethernet switch operates in basically the same manner. Acting in a similar way as a post office, a switch receives messages at one of its ports (message in), analyzes the destination address of the message, and forwards it to a suitable port (message out). The source address and destination address (MAC addresses) of each message (Ethernet frame) are contained in the frame header.

The switch matches ports with addresses from the source addresses that are received at the input port. Addresses and matching ports are maintained in a table (switch route table), which can be looked up each time a message is received. If a destination port is known, the message is forwarded to this matching port only. Otherwise, the message is repeated to every port. Figure 65.3 shows the storage and forwarding of messages in an Ethernet switch.

As shown in the Figure 65.3, an Ethernet switch receives messages at a port, analyzes the destination address, and forwards it to a suitable port. The MAC address of each message is contained in the frame header. The header of an Ethernet message (IEEE 802.3 Frame) may contain further information beyond source and destination addresses, such as VLAN tags, which qualify different traffic classes. This information classifies a category or group a message belongs to and may also decide which way to forward the message. Depending on its classification, a message can be placed in a priority queue on a port. If a message is part of a multicast group, it will be copied and forwarded to all members (destination addresses) of the group.

In the same way, IP header information, which is part of an Ethernet frame's payload, can be accessed by the switch and used for the classification and handling of messages. This, for instance, allows mapping IP multicasts into MAC multicast over Ethernet ports. This so-called IGMP snooping may be used in to reduce unicast streams. Ethernet switches, which support Layer 3, sometimes provide such features.

Figure 65.4 shows a message forwarded to a group of receivers. To do so, the sender sends a message to a multicast address (i.e., an address representing the group). The Ethernet switch resolves the multicast address into individual addresses and repeats the message to all respective ports. This is much faster and more efficient because it avoids generation of many unicast messages by the sender.

The use of VLAN tags within an Ethernet frame's header allows bigger LANs to be broken into segments or a VLAN. Figure 65.5 illustrates the principle by using the colors as VLAN tags on Ethernet frames and switch ports. In this case, the Ethernet switch is configured so that the ports are allocated to specific VLANs. The switch marks all incoming messages to such a port with the corresponding VLAN tag and

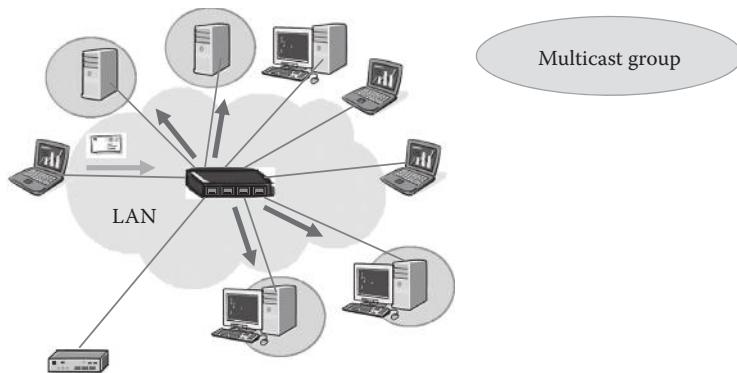

FIGURE 65.4 Multicast transmission.

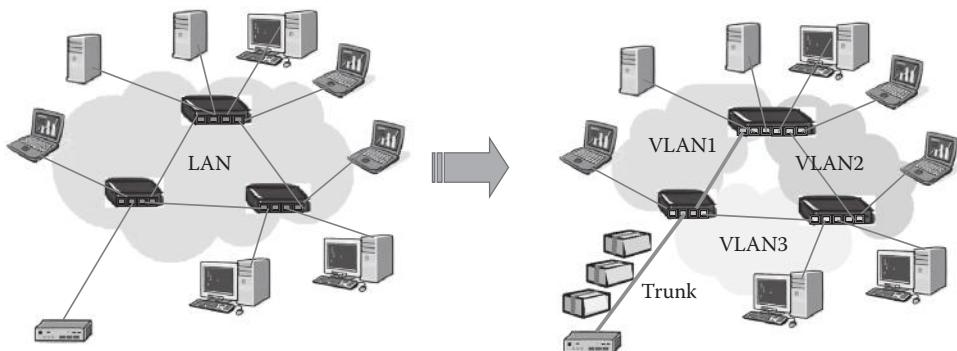

FIGURE 65.5 VLANs.

forwards packets received with a VLAN tag only to those ports that match the corresponding VLAN. For traffic from multiple LAN segments, ports can be configured to provide such interconnection: the trunks.

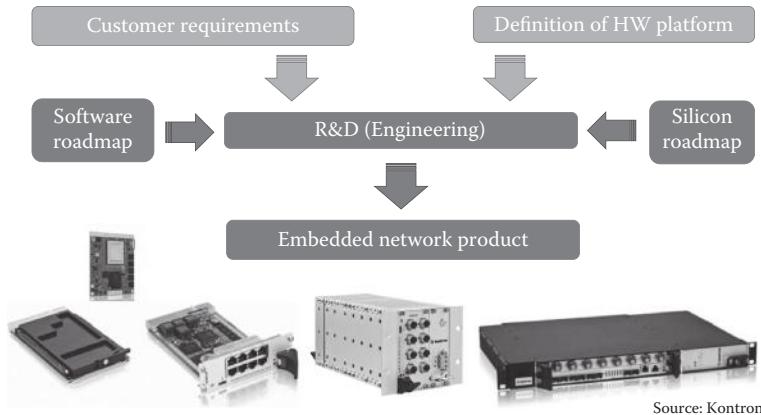

Multiple LAN segments can also be implemented physically using enough Ethernet switches. In VLANs, the segmentation is achieved by configuring the switches accordingly. Layer 2 features like multicast, VLAN, or priority queues for traffic classes are entirely based on information contained in individual frames, the port configuration, and address tables. They do not need any state-based information and can be performed at wire speed by Layer 2 switches.

Layer 3-based functions, such as the organization of networks with IP addresses (such as assigning IP addresses via DHCP or the routing of IP packets), the handling of sessions (which needs state-based information beyond the context of the individual Ethernet frame), or the processing of sequence numbers (which needs to keep the sequence in memory), are usually handled by routers or hosts in the network.

### 65.3 Ethernet in Embedded Environments

Ethernet has been also adopted in the industrial applications. Controllers and drives in industrial automation are increasingly being interconnected and controlled via Industrial Ethernet (see [2–5]). Ethernet is also used as fieldbus in aircrafts (see [6]). Such applications demand RT performance and safety levels beyond the scope of native Ethernet. Embedded network products also need to meet the specific nonfunctional requirements (such as environmental conditions, EMC, shock and vibration, materials used). So far, Ethernet has been growing and meeting new demands.

Ethernet switches for embedded systems are implemented to match specific environmental conditions such as an extended temperature range (between  $-40^{\circ}\text{C}$  and  $+70^{\circ}\text{C}$ ). Embedded network products are

Source: Kontron

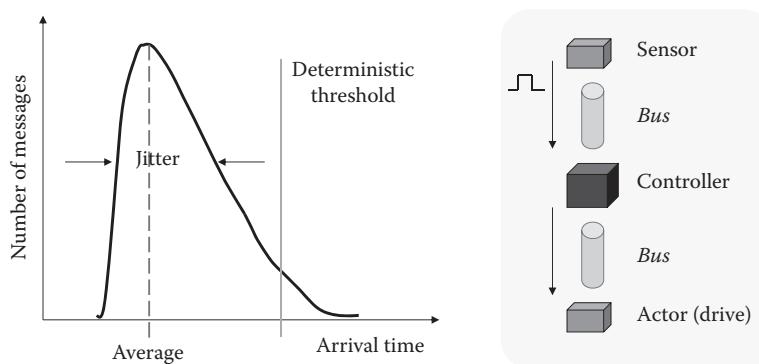

**FIGURE 65.6** Embedded network platforms.

hardened to withstand greater electromagnetic irradiation and support strict limits for its emission. Switches used in vehicles, aircraft, and industrial plant must also withstand severe shock and vibration and be resistant to dust, humidity, and many other hazardous substances. Moreover, embedded systems are frequently adapted to individual customer requirements and must match specific needs in terms of product availability, maintainability, service, and repair.

The functional composition of an embedded switch, or router, follows the process shown in Figure 65.6. Depending on the application- and customer-specific requirements, the set of feature is defined and an appropriate hardware platform is chosen. Embedded hardware offers a choice of standardized form factors and modular components to support specific application areas and customer-specific setups.

If Ethernet is used as a fieldbus to control drives or vehicles, the network must respond within a certain period of time. An industrial environment demands RT responsiveness within a specified interval. Figure 65.7 illustrates the environment and RT requirements. As shown on the right, a fieldbus transmits control messages from a controller to an actor (e.g., a drive) and from a sensor to the controller.

Message transfer times between devices and the controller are subject to variable delays called jitter. While a constant delay can easily be compensated for in an industrial control with a high level of accuracy (see [7]), delay variations cannot. The challenge is to keep the variations of delay (jitter) low with respect to the response times, which vary according to the application. Controlling drives needs a response time way below 1 ms. For controlling a process, response times of below 10 ms may be sufficient. Machines or vehicles operated by a user terminal typically need response times in the same order of magnitude as the human response time: about 100 ms.

**FIGURE 65.7** RT requirements on the fieldbus.

RT performance typically demands deterministic response times. Sensors and devices do not change their state within a deterministic threshold. But when knowledge of their state is requested in a cyclic interval, they do respond. The response times that an Ethernet-based fieldbus can achieve depends upon network size and topology, transmission speed, and message size in bytes. One reason is the storage and forwarding of messages within each switch. Ethernet cannot ensure deterministic response times.

Figure 65.7 shows the arrival of messages over a fieldbus as a histogram (number of messages arriving at a variety of delay times). The variations of delay (jitter) depend on the traffic conditions on the network, in just the same as for road traffic. If roads are crowded with vehicles and trucks, arrival times become hard to predict.

In an industrial environment, a fieldbus also will need to handle different traffic classes, such as process data relevant to control, diagnostics data, and status messages, as well as any other traffic. Response times matter for control, which depends on process data. Other traffic is less critical or not critical at all. Such traffic may travel in a lower class with a lower priority.

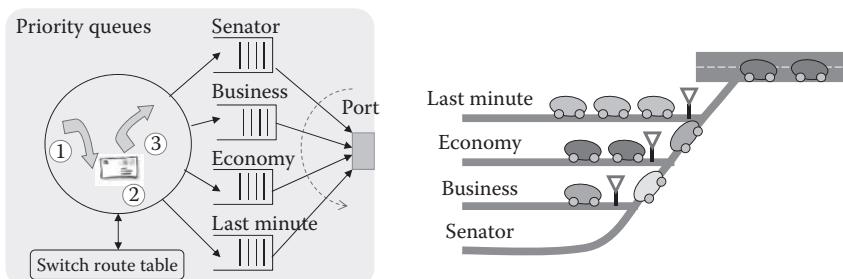

Different approaches may be used to meet specific requirements. Some of these approaches are compatible with IEEE 802 and some are not. The handling of traffic classes, for instance, is part of regular Ethernet and IP standards as applied to Internet-based telecommunication networks. Under QoS, suitable methods for handling different classes of traffic are described both for Layer 2 (IEEE 802.1p) and for Layer 3 (DiffServ, corresponding to RFC 2474 and 2475, as well as some supplementary request for comments [RFC]).

The principle is based on the classification of messages (Ethernet frames or IP packets) in a specified field in the respective message header. At each node (Ethernet switch or IP router), messages are handled according to their traffic class. Higher-class messages are handled with priority. The procedure corresponds to an airline check-in: for each flight (port), there is a counter and a queue for each traffic class. The highest-class passenger (message) is dispatched with priority and forwarded to the gate first. This procedure rearranges the order of messages to a specific destination according to their priority (class of service) at each node (switch or router).

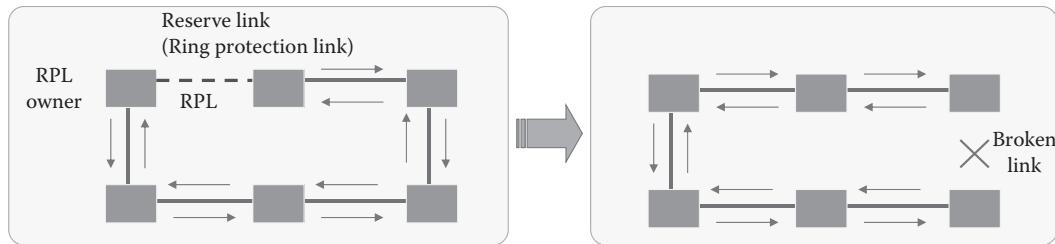

This procedure cannot guarantee a specific response time, which depends upon the total traffic volume. Regarding the highest class of service, the amount of process data that needs to be communicated in this class is known, so the traffic situation within the class can be regulated using suitable cycles and the corresponding volume of data and messages.

Still there is interference with traffic from the lower classes. For instance, while a second-class message (*Business* class in Figure 65.8) is in transmission over the destination port, the first-class message (*Senator* class in Figure 65.8) needs to wait. The delay depends on the length of the lower-class message. The length of Ethernet frames can vary significantly between 64 and 1518 bytes (9000 bytes for *Jumbo* frames). IP packets may extend up to 64 kB.

By not discarding *Jumbo* frames, the length of *vehicles* (data frames) on the data highway varies by a factor of more than 1000. At 100 Mbps transmission rate (fast Ethernet), a *Jumbo* frame takes 0.7 ms to transmit. The transmission of a 64-byte control message would have taken just 5 µs. Depending on the number of nodes between sender and receiver, delays and jitter accumulate.

**FIGURE 65.8** Priority for process data.

**FIGURE 65.9** Redundant ring configuration.

There are some simple measures to limit delays and jitter: (1) limiting the maximum frame size and (2) limiting the size of the network. For instance, a maximum frame size of 512 bytes/message corresponds to a 40  $\mu$ s transmission time. Total delay and jitter then depend on the number of network nodes. In a control application, the network topology and number of control segment nodes can be designed accordingly.

Not allowing different classes of traffic to use the same network could avoid interference between process data and any other traffic altogether. This does not necessarily mean that physically separated networks (LANs) need to be used. The same effect can be achieved by configuring VLANs in a suitable way (see Section 65.2). A VLAN can assign a *private* port to process data, which avoids the conflict.

For operation in an industrial environment, some redundancy is desirable allowing protection against failures. A ring topology achieves such protection in a very simple and cost-effective way. It provides fault protection for single failures. Figure 65.9 shows the configuration of Ethernet rings. In general, network administrators do not like loops in the network, because they lead to pointless traffic situations. As the figure shows, the ring only exists on physical layer.

The nodes (Ethernet switches) are cabled such that the linear topology cabling becomes a ring. The nodes still operate as in a linear topology with one link representing a reserve link—the so-called ring protection link (RPL)—which is not used to transmit regular messages. If one link of the network fails, the reserve link is activated. After recovery, all nodes are still connected to each other and form a new linear topology. Failover to the new topology needs to be fast enough to meet the demands of the industrial environment concerned—typical failover times are below 500 ms.

Detecting failures, activating the reserve link, and failing over to a new topology mean extra tasks that need a suitable control protocol and controller. One of the switches takes charge of this task and becomes owner of the reserve link (RPL owner). To check the ring for potential failures, the RPL owner sends control messages in both directions across the ring (including the reserve link, which does not carry conventional traffic).

If the RPL owner receives messages from both directions, the ring is operational. If a broken link occurs, the RPL owner activates the reserve link and changes the topology. Because messages now need to be passed along different ways, switches need to change their MAC address tables accordingly. To allow the interoperation of switches from different manufacturers, a standardized procedure for ring supervision and failover is required (such as in [8]).

## 65.4 Specific Requirements in TCN

Most requirements in TCN can be met with methods, which are specific to embedded Ethernet applications but not necessarily specific for TCN. Thus, an Ethernet-based TCN may benefit from mainstream embedded Ethernet applications such as in industrial automation, energy provision, and avionics. In general, the requirements on RT processing and fault protection for rail vehicles are comparable to those for industrial automation.

Concerning the RT requirements, a controller for drives has much harder time constraints than railway vehicles, which are controlled by a human via an human machine interface (HMI) (see response times in Section 65.3). Concerning redundancy, requirements in transportation are higher than in industrial automation but still within the range of the more demanding applications there. At the level of ECN, the same type of ring topologies can be applied as in industrial control in combination with a ring redundancy protocol: like MRP and HSR; see [8] and [9], respectively.

The ETBN can be implemented in a redundant way. The connections between the train segments via ETB can also be implemented by using dual Ethernet links. If fault tolerance and recovery time allow, protocols such as Ethernet link aggregation could be used on the ETB connections. Operating redundant ETBNs requires extra attention at Layer 3. At IP level, there can be only one active ETBN per consist in a redundant configuration. This situation may be covered by native Layer 3 redundancy protocols, such as Virtual Router Redundancy Protocol (VRRP) (IETF RFC 5798).

The CSs represent regular Layer 2 switches. In order to separate process data from all other traffic (measurements, announcements of camera images, etc.), they should support different classes of services (QoS) according to the native procedures of Ethernet and IP. The use of VLANs in a ring or line topology would require an extra port and extra cabling for process data. Whether such an effort can be justified depends on the specific situation.

As with other fieldbuses, the concept and data models of the proceeding fieldbus may be kept and implemented at application layer. This way, the process data may be migrated from the WTB/MVB type of TCN. As in other traditional fieldbuses, WTB/MVB devices operate on a shared medium (much like the original yellow cable Ethernet). Figure 65.10 shows the traditional fieldbus in operation.

When operating at a transmission rate of 1 Mbit/s, the transmission of a single bit takes 1  $\mu$ s. This time corresponds to a length of 200 m at a propagation rate of  $200 \times 10^6$  m/s over the bus cable. The extension of MVB corresponds to the length of one car or one consist, which is much lower, so the bus operates in a quasistationary mode concerning signal propagation.

The lower part of Figure 65.10 shows the bus cycle. The bus master arranges communication over the shared medium, that is, by sending cyclic requests to each device on the bus. The devices respond in a specified way, that is, following reception of a request. The duration of each bus cycle depends on the number of devices and the size of the messages. For instance, with 10 devices and a message size of 100 bits (12 bytes), the minimum bus cycle takes 2 ms. This number results from 100  $\mu$ s transmission time per message, 10 devices on the bus, and 2 messages per device.

Concerning signals and response times, Figure 65.11 shows a sample scenario. In this scenario, a sensor is placed as device number 2, the controller as device number 8. While the bus master operates the bus cycle, messages from devices are transmitted over the bus in their corresponding time slot. As soon as the state of a sensor changes, its signal is buffered in its I/O device and transmitted in a message in the appropriate time slot.

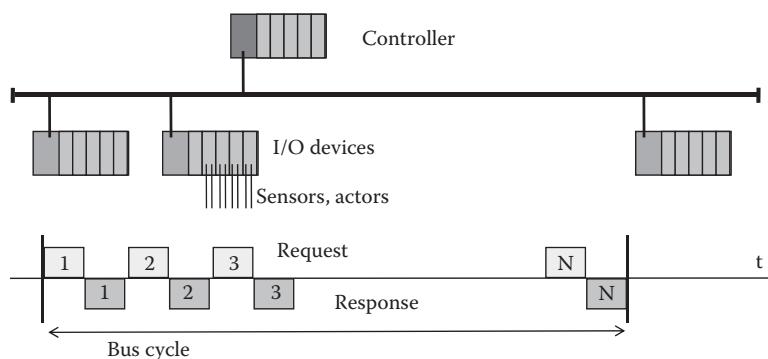

FIGURE 65.10 Traditional fieldbus (WTB/MVB).

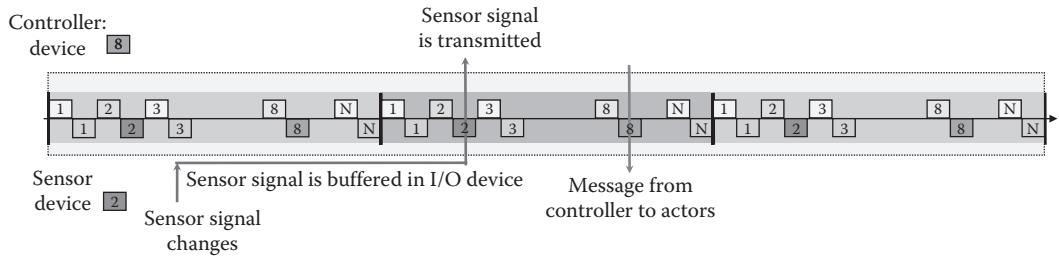

FIGURE 65.11 Signals and response times on the bus.

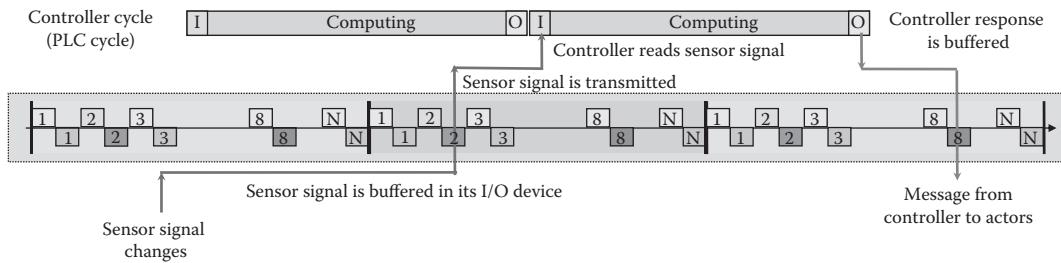

FIGURE 65.12 Response times including controller.

Depending on the time it takes the controller to compute an instruction based in the message, the controller response could be transmitted within the same or the following cycle. If the controller is operating in its own cycle, the response is transmitted as indicated in Figure 65.12.

How does the traditional fieldbus operation translate to Ethernet-based TCN? In the simplest case, the bus cycle is maintained and placed upon the Ethernet-based bus. The response times depend on the chosen bus topology, as well as number of devices, message size, and transmission rate. Ethernet can be operated in a variety of topologies, such as a star topology, tree topology, or linear topology (which includes the redundant ring topology). Figure 65.13 shows a star and a ring in combination with the bus cycle, with the controller at the center, respectively in front. The linear topology corresponds to both ECN and ETB.

Most Ethernet fieldbuses today operate at transmission rates of 100 Mbit/s (fast Ethernet). The minimum message size is 64 bytes (including header information). Hence, the transmission of one message takes about 5  $\mu$ s. With 10 devices and 2 messages per device, this results in a minimum bus cycle of 100  $\mu$ s. Thus, Ethernet-based TCN would be significantly faster than MVB (minimum of 2 ms for the same number of devices). This figure is correct when using a star topology for the bus.

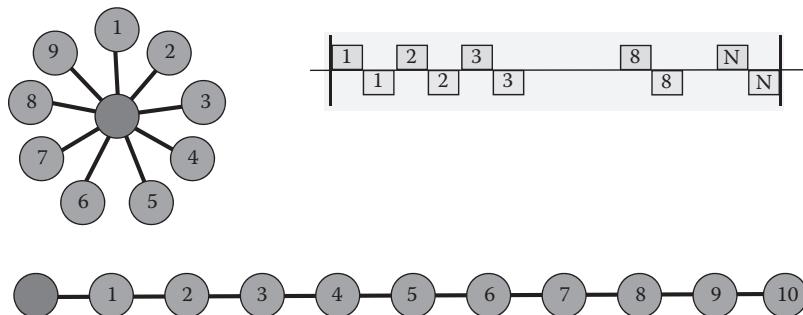

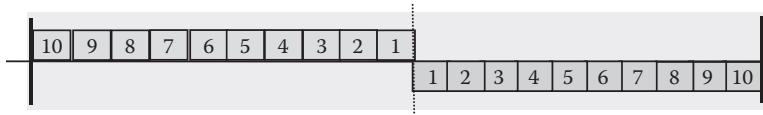

FIGURE 65.13 Ethernet bus topologies.

**FIGURE 65.14** Optimized request pattern.

While the linear topology looks close to the traditional configuration, it does not use a shared medium but connects devices over a chain of Ethernet switches. At each stage, the messages are stored and forwarded, which consume about 5  $\mu$ s for the collecting and processing of header information. In a chain of 10 devices, it takes 50  $\mu$ s for one message to travel from the front to the end. When addressing devices on the bus in a randomly chosen cycle, requests need to be placed at intervals of 100  $\mu$ s to allow responses traveling back the chain. Hence, the minimum bus cycle for 10 devices results in 1 ms (which still is slightly lower than the MVB cycle).

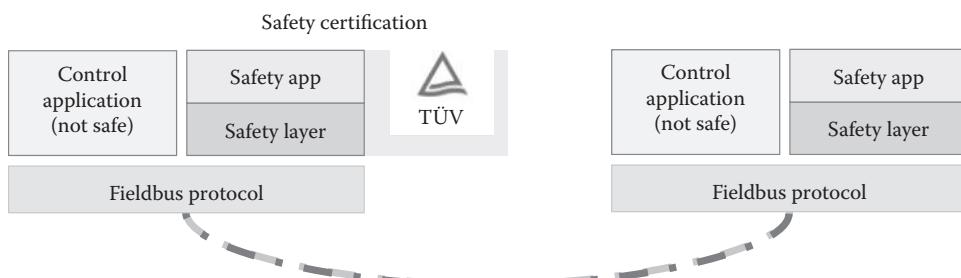

Still, the same cycle time (100  $\mu$ s) as the star configuration may be achieved in a linear topology with a specific request pattern, which starts requesting the devices at the end of the chain, as shown in Figure 65.14. This way, it will take half a bus cycle for a request to travel to the most distant device and another half bus cycle for the response to travel back. The overall bus cycle with 10 devices then takes 100  $\mu$ s.

In industrial automation, there are other mechanisms in place to optimize linear topologies, such as discarding the processing of MAC addresses to pass messages between the switches in a chain. In this case, the switches take information for their connected devices from the message, as it is passed by (see [2]). In TCN, there is currently no need for such optimization, because response times of 10–100 ms are perfectly acceptable.

In TCN, a dedicated role is assigned to the ETBN. While the train is in driving mode, it simply operates as an ordinary router, which connects train segments at Layer 3. While driving (moving), it allows the translation of local IP addresses, for example, by Network Address Translation. Before entering the driving state, there is an initial phase, at which IP addresses are allocated dynamically via DHCP, with the SHCP server implemented on the ETBN.

On the train, a segment may be added or removed, and the direction of driving may be changed. At such changes, the ETBN discovers the topology and enumerates all train sections correctly. This is important, so as to, for example, confirm that when the driver clears doors for opening at a station, doors will only open on the platform side of the train.

At higher protocol layers, an Ethernet-based TCN may handle safety issues in much the same way as it is applied in industrial automation. In this approach, a safety application is used to check the integrity of the system, as shown in Figure 65.15. The safety application, its supporting libraries, as well as a safety protocol need to be certified by an authorized institution.

**FIGURE 65.15** Safety layer.

This concept is based on surveillance of the system integrity, that is, whether all components are operational and whether the system operates within the specified boundaries. If the system leaves the operational boundaries, for example, by losing a mission-critical component, the safety processor initiates the transition into a safe state (in most cases by shutting off the system).

For the communication between devices over a fieldbus, the safety layer introduces a safety protocol. Messages between safety controllers and safety devices are communicated just as any other messages (i.e., Ethernet frames) and may be mixed with other TCN traffic. Examples for a safety controller and an associated safety device are a controller and an associated HMI (e.g., communicated the actual speed for display at the HMI or sending a command from the HMI to the controller), respectively, the controller and actors like drives, breaks, and doors.

A safe communication means that the integrity of messages on the bus is maintained. In any communication network, loss of messages cannot be prevented, neither accidental messages nor misplaced messages. Apart from error conditions, the communication between mission critical devices should also be protected against manipulation. Table 65.1 shows a summary of fault conditions and corrective measures, which are applied for a safe communication protocol. An “x” in Table 65.1 indicates, that a specific fault condition may be covered by the corrective measure in the respective column.

The unintentional repetition of a message should not repeat the action invoked by this message. The safety protocol may simply detect a duplicated message by using sequence numbers with each message. A duplicated message will have the same sequence number as the original one and can be discarded by the safety protocol.

A measure to protect against message loss takes a watchdog timer, which is set to the expected response time. Should the message not have arrived within this period, it is considered as lost. The safety protocol will repeat the message. Other indicators for lost messages is a missing sequence number, as well as a checksum, which indicates that the message has been corrupted and thus also has to be discarded and is lost.

A simple way of manipulation is to record and later replay a message. In an unprotected system, this could invoke an action. The way of protection is simple: a recorded message would have an unacceptable sequence number and thus may be discarded. A more clever kind of attack, which manipulates the content of a message (masquerade), could easily time out, respectively not have a matching checksum.

The figure shows that just three corrective measures (sequence numbers, watchdog timers, and checksums) allow covering many fault conditions. Another corrective measure against misplaced messages is the use of connection IDs or session IDs. Such an identifier classifies all messages belonging to the same connection, for example, a dialog between a controller and a specific actor.

**TABLE 65.1** Fault Conditions and Safety Measures at Protocol Level

Fault Condition	Corrective Measures			
	Sequence Number	Watchdog Timer	Connection ID	CRC (Checksum)
Unintentional repetition	x			x
Message loss	x	x		x
Inserted message	x			x
Incorrect sequence	x			x
Manipulation				x
Unacceptable delay		x		
Masquerade		x		x
Memory fault in switches	x			x
Incorrect transmission between segments			x	

## Acronyms

ECN	Ethernet Consist Network
ETB	Ethernet Train Backbone
ETBN	Ethernet Train Backbone Node
HSR	High-availability seamless redundancy
IP	Internet Protocol
LAN	Local area network
MVB	Mobile Vehicle Bus (IEC 61375-1)
MRP	Media Redundancy Protocol
PLC	Programmable logic controller
RPL	Ring protection link
RT	Real time
TCN	Train Communication Network
WAN	Wide area network
WTB	Wire Train Bus (IEC 61375-1)

## 66.1 Introduction to SEMI

Semiconductor Equipment and Materials International (SEMI), founded in the United States in 1970, is a global industry association with a worldwide membership of companies, representing semiconductor-related industries. SEMI has 26 subcommittees that include, among others, the subcommittees for Automated Test Equipment, Environment, Health and Safety, and Information and Control.

This chapter will give an overview of the fundamentals of the SEMI Equipment Communication Standards, commonly referred to as the SECS, its interpretation, the available software tools, and case study applications.

## 66.2 SEMI Equipment Communication Standard

The SECS defines the computer-to-computer communication protocols intended to assist in the automation of electronics-manufacturing facilities. SECS enables the automation, communications, and control of semiconductor process equipment, from a variety of vendors, using a set of standards and reliable protocols. These standards have the capacity to resolve/define the physical layers, signals, block semantics, etc., thus ensuring repeatable, nondeadlocked communications from simple to extended-hierarchy networks.

In its basic form, SECS provides a one-to-one link between a particular unit of equipment and a host computer. The equipment can be in the form of wafer processing equipment, test and metrology equipment, die/package assembly equipment, surface mount equipment, and others.

Similarly, the host computer can range from minicomputers, small-dedicated desktop PCs, and laptops to a network of embedded systems. In many cases, the host computer system manages and coordinates the equipment on the factory floor via cell controllers, line controllers, and material controllers. These must be compatible with current *manufacturing execution systems and manufacturing legacy systems (MLS)*.

### 66.2.1 Four Main SEMI Communications/Control Standards

SEMI Equipment Communications are based on four main standards, namely, the SECS-I, SECS-II, High-Speed SECS Message Services Standard (HSMS), and Generic Equipment Model (GEM) Standard as shown in Table 66.1. Both SECS-I and HSMS define the message transport layer of the protocol. SECS-II defines the message format and GEM defines the equipment behavior.

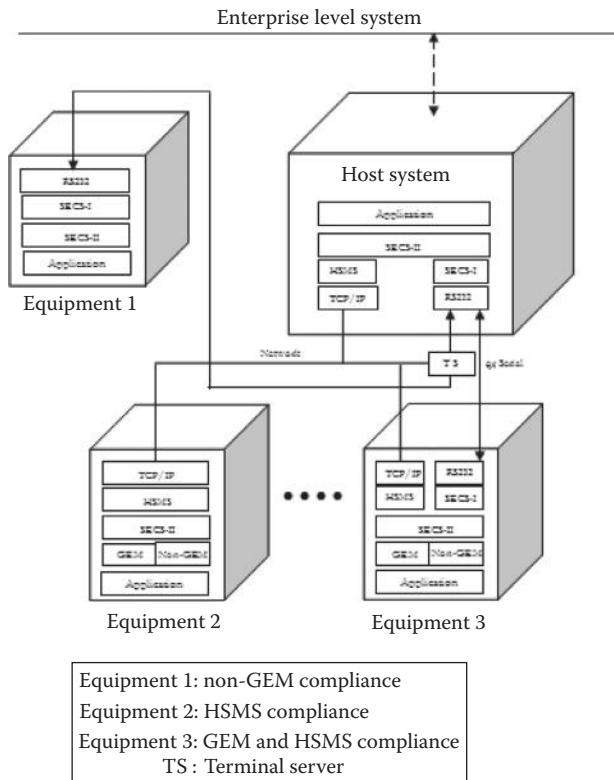

#### 66.2.1.1 Components for Executing the SECS Protocol

Host systems are linked to different equipments that have to be SECS compliant (i.e., based on SECS standards). The connectivity to the host can be through serial (RS-232) or TCP/IP ports. GEM is incorporated in some of the newer equipments. Older equipments are generally not GEM compliant, having only serial connectivity. An example of SECS *Implementation Architecture* is shown in Figure 66.1.

*Host system:* The main function of the host system is to manage the connectivity to a group of equipments via a configuration file, recipe management, equipment load balancing, equipment monitoring, and connection to enterprise-level applications. The host systems that manage the same type of equipment are referred to as cell controllers. Similarly, the host systems that manage and coordinate different equipments are referred to as line controllers.

**TABLE 66.1** SEMI Equipment Communication Standard

Protocol	SECS-I	SECS-II	GEM	HSMS
Date of launch	1978 →	1982 →	1992 →	1994 →
Message definition	Communication protocol and physical definition.	Message format.	Additional SECS-II sequences define document for communication.	Supersede SECS-I for TCP/IP compatibility.

**FIGURE 66.1** The components for the execution of SECS protocol.

*Terminal server:* It is a serial hub (also sometimes called a *serial device server*) that allows equipment with serial port connections to connect to this hub and provides information sharing among other equipments through Ethernet-ready TCP/IP connections.

*Equipment 1 (Non-GEM compliant):* This is normally the older semiconductor equipment that is not GEM compliant but supports SECS-I and SECS-II messages. Most of the older equipment will only provide serial connections to the host system.

*Equipment 2 (HSMS compliant):* This is typically the newest semiconductor equipment that *has* point-to-point communication protocol for TCP/IP Ethernet communications. Some of the equipments are already GEM compliant for host/equipment communications.

*Equipment 3 (GEM and HSMS compliant):* These are typically the up-to-date models of semiconductor equipment that are both GEM and HSMS compliant, having both serial and TCP/IP connections. Nevertheless, some of these equipments are expected to be *simultaneously serial port and TCP/IP capable*. Usually there is a problem of *connectivity to MLS*, which we cannot easily ignore.

### 66.2.2 SECS-I

SECS-I is also called SEMI E4 standard. It was launched in 1978 and released in 1980. It describes a transmission interface for passing messages between the equipment and a host over the RS-232 communication as shown in Figure 66.2. This standard defines point-to-point communication of data, utilizing a subset of the international standard EIA RS-232-C for the connector and voltage levels. The communication is bidirectional and asynchronous but is half duplex. The communication speed normally varies from 9,600 to 19,200 baud rate. SECS-I protocol establishes multiblock transfers based on blocks of 256 bytes.

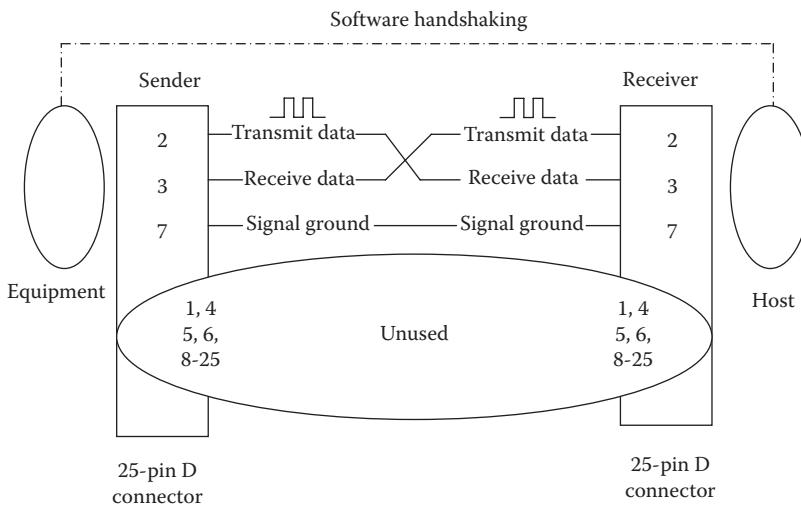

FIGURE 66.2 Three-wire serial data configuration for SECS-I (with software handshake).

TABLE 66.2 Layer Definition of the SECS-I Standard

SECS-I Layers	Definitions
Transaction layer	Primary message
Message layer	Block header
Block layer	Block format, block protocol, packet format, packet protocol
Physical layer	Physical connector, voltage, bit coding, baud rate

SECS-I includes specifications for the electrical connection between two communicating entities. It defines the message header structure, the block transfer protocol, and the message transfer protocol. The block transfer protocol is the procedure used by the serial line to establish the direction of communication and to provide the environment for passing messages. The message transfer protocol details how the block transfer protocol is used to send and receive messages.

Table 66.2 shows the layer definition of SECS-I standard. The physical layer defines the physical connectors, electrical characteristics, bit and character coding, and baud rate. The block layer defines the block or packet format and protocols that are used to transfer a single block. The message layer defines the block header. The transaction layer defines how primary messages and its corresponding reply messages are related.

### 66.2.2.1 SECS-I Message Structure

Figure 66.3 shows the structure of the SECS-I message. This message structure allows multiblock messages with one stream and function. The alphabet in Figure 66.3 can be described as follows:

- The first byte represents the length of the message.
- Byte 0-1 of the header represents the device ID. The device ID is to identify the equipment in the factory. There is no device ID for the host system. Bit 8 of first byte is a reserved bit, or R-bit, that is used for indicating the direction of the message, that is, host to equipment or equipment to host. If the R-bit is 0, it means that the message is from the host to the equipment. If the R-bit is 1, it means that the message is from the equipment to the host.
- Byte 2 of the header represents the stream number for the message. The stream represents the category of the messages that are defined in SECS-II.
- Byte 3 of the header represents the function numbers within the stream.

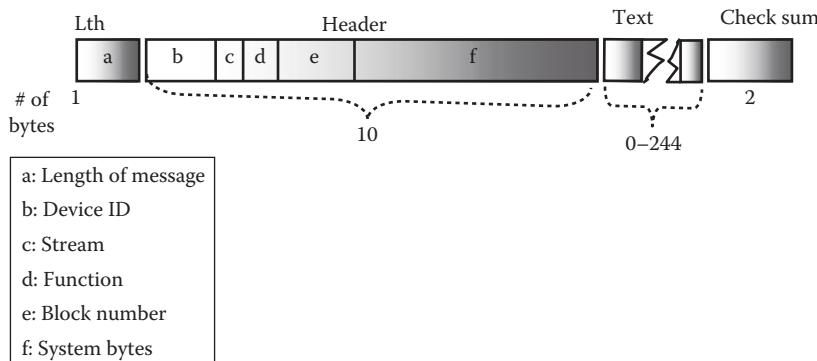

FIGURE 66.3 Structure of SECS-I message.

- Bytes 4–5 of the header represent the block number of the message. If the message is longer than 244 bytes, the message will be broken into multiple blocks. The system will use these 2 bytes to identify the sequence of the block number.
- Bytes 6–9 of the header represent the system bytes. The purpose of system bytes is to avoid duplication of message.

#### 66.2.2.2 Synchronization Mechanism

SECS-I uses software-based time-outs to handle communication synchronization between the host system and the equipment. As is shown in Figure 66.4, time-outs (T1 to T4) are used in SECS-I for managing the transmission of blocks between the sender and receiver. Each time-out has a special function, as explained in the following:

T1 defines intercharacter time-out in the block transfer protocol. It measures the duration of characters transferred within the same block. T1 time-out will be activated if the host system does not receive the block of characters within the defined time.

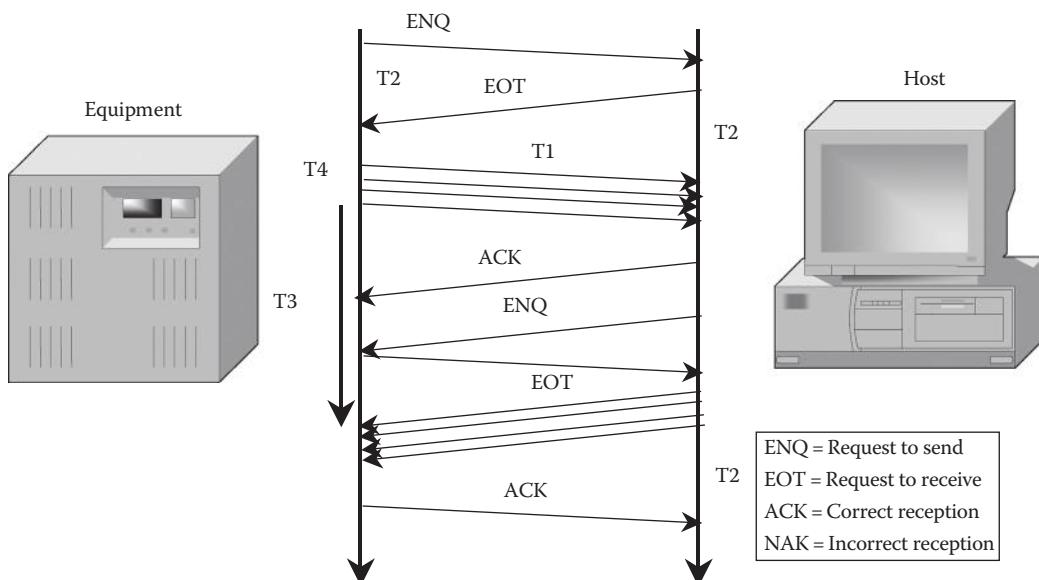

FIGURE 66.4 Establishing synchronization via time-outs (T1 to T4).

**TABLE 66.3** Time-Out (T1 to T4) Definition

Time-Out	Description
T1	Intercharacter time-out
T2	Protocol waiting time time-out
T3	Time-out for reply message
T4	Interblock communication time-out

T2 defines the protocol time-out. It limits the time required to communicate among the following messages:

- Request to send (ENQ) and request to receive (EOT, end-of-transmission)
- EOT and the receipt of the block of characters
- Sending block of characters and correct reception (ACK)

T3 defines the time-out for the reply message. It sets the maximum waiting time for multiple block message communications. Within a specified time, if the last block is not received, T3 time-out will be triggered.

T4 defines the time-out for interblock communications. It sets the time limit to receive the next block of message within the multiblock communications. If the next block of message is not received within the specific time, T4 will be activated.

SECS-I provides a mechanism for synchronization and software-deadlock resolution via 4 time-outs (T1 to T4) as shown in Table 66.3.

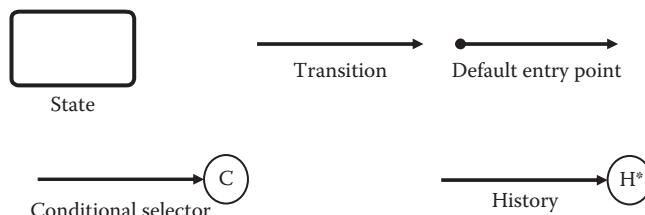

### 66.2.3 High-Speed SECS Message Services Standard

With the increasing trend toward network communication for high-performance components and hardware, HSMS was introduced in 1995. HSMS (also referred to as E31 standard) defines a communication interface suitable for the exchange of messages between computers via TCP/IP. HSMS uses TCP/IP streams to provide reliable two-way simultaneous transmission of streams of adjoining bytes. It can be used as a replacement for SECS-I communication as well as other more advanced communication environments.

It was intended as an alternative for applications where higher-speed communication is needed or when a simple point-to-point topology is insufficient. Most of the new SECS/GEM implementations use this standard for the message transport layer. HSMS was designed with the intention that existing SECS-II and GEM-compliant applications could be easily converted to use HSMS instead of SECS-I. HSMS also provides the means for independent equipment manufacturers to produce their own SECS-II/GEM implementations while still maintaining interequipment compatibility.

#### 66.2.3.1 HSMS State Model

The *state model* is a methodology developed by David Harel and adapted by SEMI to describe the expected functionalities in the standard. As shown in Figure 66.5, a state is a static condition of an operation.

**FIGURE 66.5** Harel's notation of state models.

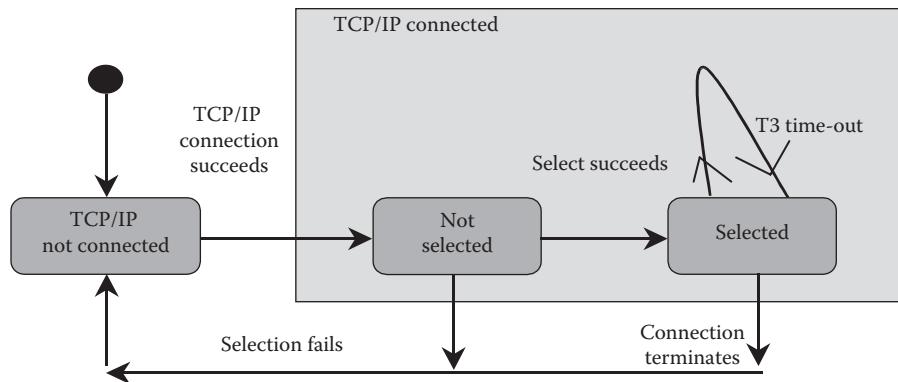

FIGURE 66.6 State model of HSMS.

A state could have multiple substates. The arrows represent the transitions from one state to another state. In Figure 66.6, the round black dot is the start of the process. When HSMS first starts, it will be in *TCP/IP not connected* state. If the TCP/IP connection is successful, then the process will move to *TCP/IP connected* state. In *TCP/IP connected* state, there are two substates, namely, *not selected* and *selected*. The system could be *connected on TCP/IP but HSMS has not been selected*. When HSMS is selected, it will go into a substate called *selected* and stays there until a T3 time-out occurs. When *connection terminated* or *selection fails* occur, the state will go back to *TCP/IP not connected*.

#### 66.2.3.2 HSMS Message Structure

Figure 66.7 shows the structure of the HSMS message. The message structure is similar to SECS-I, but it is for TCP/IP network communication. The alphabets in Figure 66.7 describe as follows:

- Bytes 1–4 represent the length of the message. HSMS can handle about 8 Mb of data. The length defines the total length of the header and the actual message.
- Bytes 0 and one of the headers represent session ID. Session ID is used to identify whether the communication message is a control message or subsequent data information.
- Bytes 2–3 of the header represent the stream and function number or status code of the message.
- Byte 4 of the header represents the presentation type (or P-type) of how the message is encoded. A value 0 means that it will be used in SECS-II. Value 1–127 is reserved for *subsidiary standards*. Value 128–255 is reserved but is not used.

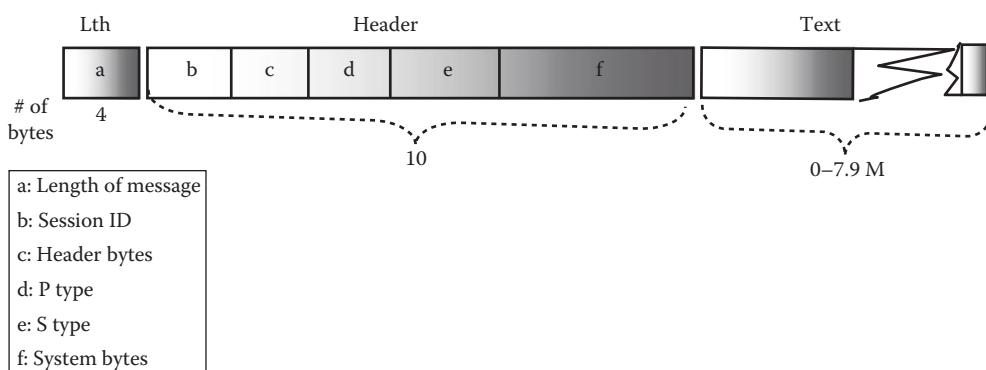

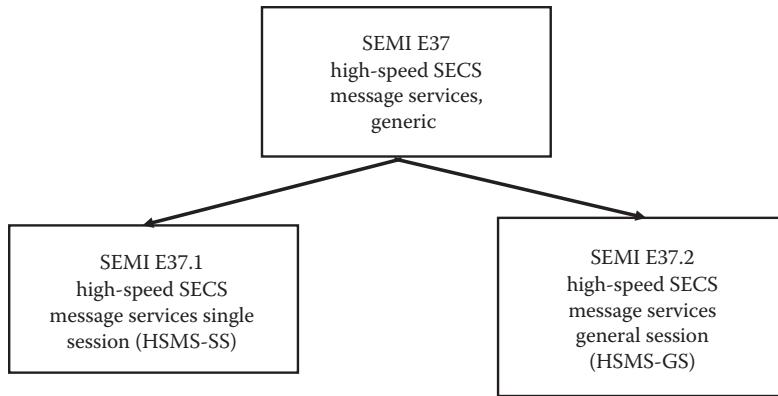

FIGURE 66.7 Structure of HSMS message.

**FIGURE 66.8** Subclassification of HSMS.

- e. Byte 5 of the header represents the session type or S-type. Value 0 means that the session is sending data information. Other values indicate that the message is *control information*.
- f. Bytes 6–9 of the header represent the system bytes. The purpose of system bytes is to avoid duplication of message.

#### 66.2.3.3 HSMS Subclassification

SEMI has subclassified HSMS into single session (HSMS-SS) and general session (HSMS-GS) as shown in Figure 66.8. HSMS-SS defines single session equipment connection so that the implementation does not have to consider other equipment or knowledge of other systems. It will be similar to SECS-I connection, which is a one-to-one connection. The HSMS generic definition and structure will still apply. HSMS-GS is used for complex systems that have many independent equipments as subsystems. HSMS-GS defines the convention for identifying independent system entities.

#### 66.2.4 SEMI Communication Standard (SECS-II)

This SECS-II standard was released in 1982. SECS-II (also referred to as the E5 standard) defines the message content passing between the equipment and the host. SECS-II specifies the format of the text and the minimal unit of semantics, but it does not specify the exact action that a recipient machine should take. With the definition of SECS-II, the host/equipment software may be constructed with minimal knowledge of each other. In addition, SECS-II allows the creation of *user-specific* messages.

SECS-II defines the method of conveying information between the equipment and the host in the form of messages. Every SECS-II message is identified by a stream and a function number. Each of the streams represents the category of service available as shown in Table 66.4. The stream will contain specific messages called functions. It also defines the *request for information* and the corresponding data transmission. Each combination of stream and function represents a distinct *message classification*. In every stream, function 0 is reserved for aborting transactions and the others are constructed in pairs. For example, Table 66.5 shows that each pair odd number function code is reserved for the primary message and the even number function code is reserved for the reply or the secondary message. If the primary message does not require a reply message, the even number message is discarded.

##### 66.2.4.1 Data Structure

The messages that are sent through the physical layer through serial (RS232) or TCP/IP (Ethernet network) are broken down by SECS-I or HSMS definitions, yielding the length, header, and data blocks. SECS-II defines the structure of messages into entities called items and *lists of items*. This structure allows for a self-describing data format to guarantee proper interpretation of the message. Interchange

**TABLE 66.4** Streams Defined in SECS-II

Stream	Description
1	Equipment status
2	Equipment control and diagnostics
3	Material status
4	Material control
5	Exception handling
6	Data collection
7	Process program management
8	Control program transfer
9	System errors
10	Terminal services
11	Host file services
12	Wafer mapping
13	Data set transfer
14	Object services
15	Recipe management
16	Processing management
17	Equipment control and diagnostics

**TABLE 66.5** Odd/Even Message Numbering of SECS-II Functions

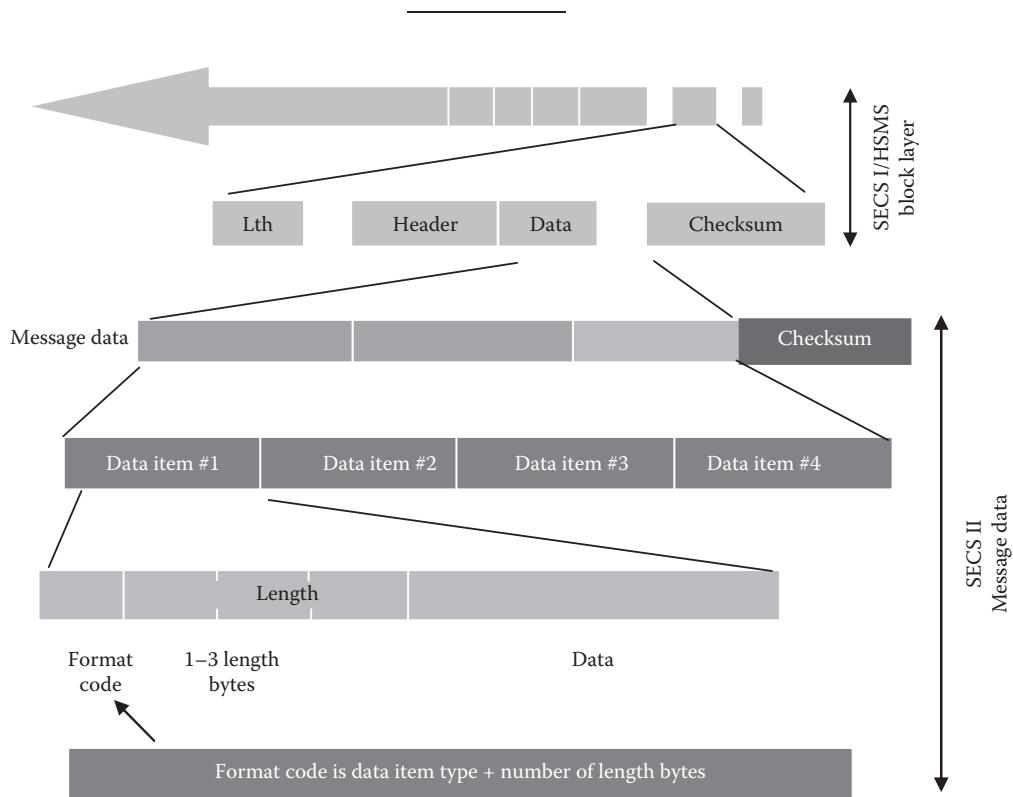

Stream	Function	Description
1	0	Abort transaction (S1 F0)
1	1	“Are you there” request
1	2	Online data
1	3	“Select equipment status” request
1	4	“Select equipment status” data
1	5	“Formatted status” request
1	6	“Formatted status” data
...	...	...

of messages is governed by a set of rules for handling messages called the transaction protocol. SECS-II further defines the data into multiple blocks structure, yielding the format code, length, and data item. All messages are packed into multiple data blocks with headers and checksums as shown in Figure 66.9.

#### 66.2.4.2 Streams and Functions in SECS-II

Table 66.4 shows the category of various SECS-II messages that are classified under the different streams. As an example, all messages in stream 1 will be part of the equipment status category. This category will help the user and the integrator in understanding, designing, and developing their SECS solutions.

Each stream can specify multiple functions, as shown in Table 66.5, where an example for stream 1 is explained. Function 0 is reserved for *abort* purposes. The remaining functions are operated upon in pairs of requests (odd function or primary message) and reply/acknowledgments (even function or secondary message). The primary message is the *request message* sent by either the host or the equipment. All the odd number functions, for example, S1 F1 and S2 F1, are examples of primary messages. The user can indicate if a reply is needed for the primary message using the wait bit (W-bit). The W-bit is the first bit from the header byte, which is used to indicate that the sender of a primary message expects a reply. The *secondary message* is the reply message. All the even number functions, for example, S1F2

**FIGURE 66.9** Data structures of SECS-I/II/HSMS.

and S2F2, are examples of secondary messages. For any messages that cannot be processed by the equipment, the appropriate error message on stream 9 will be used. Upon detection of a transaction time-out, the equipment sends S9 F9 to the host. Upon receipt of function 0 as a reply to a primary message, the related transaction is terminated. No error message should be sent to the host by the equipment.

#### 66.2.4.3 Conversation Protocols

A *conversation* is a series of one or more related SECS-II messages used to complete a specific task. A conversation should include all transactions necessary to accomplish the task and leave both the originator and interpreter free of resource commitments at its conclusion. There are a few types of conversations, as follows:

##### 66.2.4.3.1 Primary Message with No Reply

Once the W-bit is set to zero, the primary message will not require a reply. It is the simplest conversation. The primary message will send a single block of information without reply. This conversation is used where the originator can do nothing if the message is rejected.

##### 66.2.4.3.2 Primary Message with Data Return (Request/Data Conversation)

Originator will need to get information from interpreter. The W-bit will have to be set to one and data is returned as secondary reply message.

##### 66.2.4.3.3 Send/Acknowledge Conversation

Originator sends data in a single block and expects an acknowledgment.

#### 66.2.4.3.4 Inquire, Grant, Send, and Acknowledge Conversation

Originator must ask for permission from the interpreter. The interpreter will grant permission as well as set *time-out* for getting the information. If the wait time is longer, then *time-out* time, S9 F13, will be sent out. Once the information is received, the acknowledgment will be sent. This type of conversation is commonly used in equipment-to-host conversations and only the equipment should send error messages to the host.

#### 66.2.4.3.5 Unformatted Data Set Conversation

Stream 13 is used for unformatted data conversation. Unformatted data could be in the form of a bitmap file or a binary file.

#### 66.2.4.3.6 Material-Handling Conversation

Stream 4 is used for material control and handling of material between equipments.

#### 66.2.4.3.7 Conversation with Delay

The originator may request information from the interpreter, which requires some time to obtain. The interpreter could collect the information immediately and return. The interpreter could also indicate if the information has been obtained or returned in the subsequent transaction.

Messages can also be transferred as single-block messages or multiblock messages. The SECS-I maximum message length for a single block is 244 bytes. The maximum message length for HSMS is 7.9 megabytes. For longer messages, SECS-II will have to use multiblock messages. For example, if messages that are longer than 244 bytes are needed, they have to be sent by multiple blocks or packets. Each packet will have a block number so that the receiver will be able to join all the blocks together.

### 66.2.4.4 Sample of SECS-II Message

#### 66.2.4.4.1 Stream 1 Function 1

Figure 66.10 shows the S1 F1 and S1 F2 message structure and description.

S1, F1 Are There Request (R)<sup>a</sup>

S,H <-> E, Reply<sup>b</sup>

*Description<sup>c</sup>: To establish if the equipment is online. A function 0 response to this message means the communication is inoperative. In the equipment, a function 0 is equivalent to a time-out of the receive timer after issuing S1, F1 to the host.*

*Structure: Header only<sup>d</sup>*

The above example is from the SEMI standard E5

S1. F2 On line data(D)      S,H <-> E

Description: Data signifying that the equipment is alive.

Structure<sup>e</sup>: L, 2

1. <MDLN>
2. <SOFTREV>

**FIGURE 66.10** S1 F1 and F1 F2 message structure.

**TABLE 66.6** Status of Streams and Functions (Reserved/Unreserved)

Stream	Status
1–14	Currently defined in the standard
15–63	Reserved for standard messages
64–127	Reserved for user-defined messages
Function	Status
1–63	Reserved for standard messages
64–255	Reserved for user-defined messages

Exception: The host sends a zero-length list to the equipment:

- Shows the stream (S), function (F), and title of the function (R).
- Shows the type of message. S represents single-block message. Multiblock message will be represented by M. H ↔ E means the message could be sent from either the equipment (E) or the host (H). Other alternatives are E → H, which means *the equipment sends to the host*, and H → E, which is from the host to the equipment. The message requires *reply*. Other alternatives are *optional to reply* or *blank*, which means no reply is needed.
- The description of the message.
- Shows the structure of the message. In this case, it is just the header of the message and there are no data.
- Shows the structure of S1 F2. L, 2 means that it has two listed items. The first listed item is <MDLN>, which represents the equipment model type with maximum 6-byte length. The second item is <SOFTREV>, which represents software revision with maximum of 6 bytes as well.

As shown in Table 66.6, SECS-II only uses streams 1–14 and functions 1–63. In order to provide for expansion of features, streams 15–63 are reserved for future SEMI standards. Streams 64–127 and functions are available for custom messages.

While SECS-II makes room for vendor-independent compatibility, problems do arise when vendor applies different semantics for the same message pairs. This creates intervendor incompatibility. GEM was created to define *generic equipment* features so that intervendor compatibility can be established.

### 66.2.5 Generic Equipment Model

The GEM standard (also referred to as the E30 standard) was published in 1992. It defines which SECS-II messages should be used, in which situation, and what the resulting activity should be.

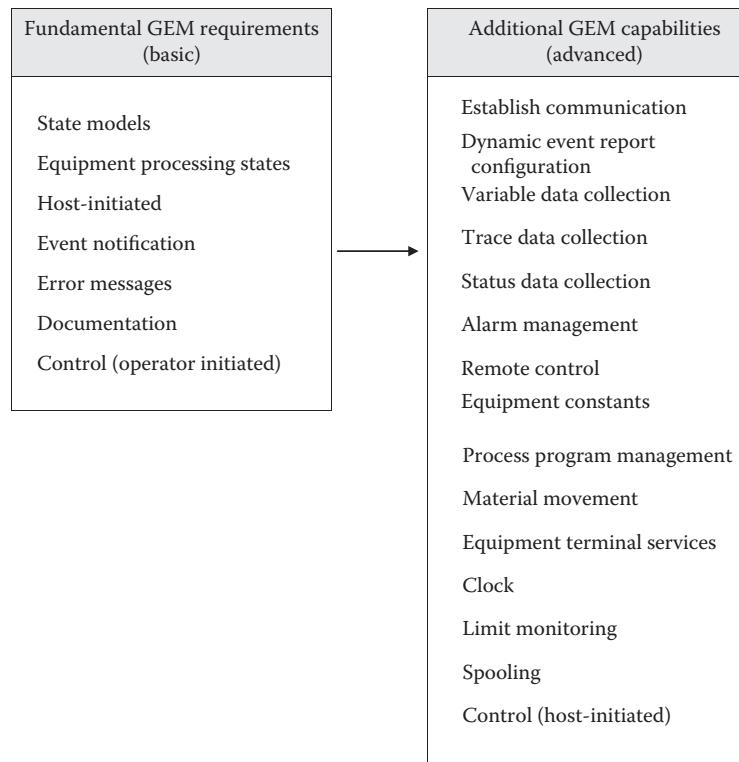

GEM is intended to specify the following:

- A behavior model of semiconductor equipment in a SECS-II communication environment
- A description of information and control functions needed in a semiconductor-manufacturing environment
- A definition of the basic SECS-II communication capabilities
- A single consistent means of accomplishing an action when SECS-II provides multiple possible methods
- Standard message dialogs that is necessary to achieve useful communication

The GEM standard contains two types of requirements:

1. Fundamental (or foundation) requirements
2. Requirement for additional GEM capabilities

As shown in Figure 66.11, the fundamental GEM requirements form the foundation of the GEM standard, which are basic requirements for all types of semiconductor equipment. The additional GEM

**FIGURE 66.11** GEM requirements.

capabilities provide the functionality required for some instances of factory automation or functionalities that are applicable to specific types of equipment. Capabilities are operations performed by semiconductor-manufacturing equipment. Each of the capability consists of a statement of purpose, pertinent definitions, detailed description, requirements, and various scenarios. A *scenario* is a group of SECS-II messages arranged in a sequence to perform a function. These *scenarios* handle communications that involve more than one pair of messages.

### 66.2.5.1 GEM Fundamental Requirements

#### 66.2.5.1.1 State Models

State models describe the behavior of the equipment from a host perspective. The same model can be used in different equipment for identical functions. The fundamental GEM specifies the state model of process (equipment specific), communication, alarm, control, material movement, and spooling.

Figure 66.12 shows a sample state model for equipment processing. There are also step numbers defined in the diagram. Here is how the state model can be interpreted:

Step 1: The process will be initialized (INIT). After being initialized, the process could be in “Idle” state.

Step 2: The next state is “Processing Active.” It will be in the substate of “Process” doing an operation of “Setup.” The setup operation could be semimanual, as the operator needs to log on and fine-tune the equipment.

Step 3: After setup, the equipment will be in “Ready” state for operation.

Step 4: In normal processes, the equipment should be either in the “Executing” state, producing some part/component, or in Step 5, which is “Idle” waiting for the next part/component.

Step 5: The equipment is idle and waiting for the next part.

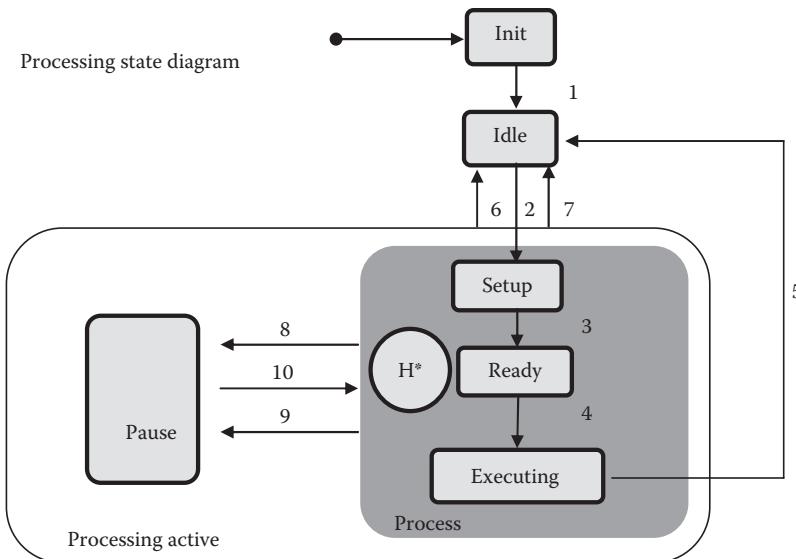

FIGURE 66.12 Equipment processing states.

Step 6: The equipment could be in “Processing Active” and receive a “STOP” command from the operator or the host system. This will put the equipment back to “Idle” state.

Step 7: The equipment could be in “Processing Active” and receive an “ABORT” command from the operator or the host system. This will put the equipment back to “Idle” state.

Step 8: The equipment may receive an alarm and it will then be in “Pause” state.

Step 9: The equipment may receive a “Pause” command by the operator or the host system.

Step 10: The equipment may receive a “Resume” command by the operator or the host system.

An example of the GEM transactions for event-reporting setup is illustrated in Table 66.7.

Step 1: The host defines the report and request for reports:

- The host initiates a report definition by sending S2 F33. Stream 2 is the equipment control and diagnostics stream and function 33 is to define report. This message allows the host system to define and to request the group of reports available from the equipment. A unique ID identifies each report.
- The equipment receives and acknowledges by replying with S2 F34. If the primary message has errors or the report ID is not found, the primary message will be rejected.

Step 2: The host sets an ID for the required reports:

- The host initiates an *event and report* link definition by sending S2 F35. Function 35 will only link the reports that are requested by the host, with an ID. The link will be disabled until the equipment is ready to send.
- The equipment receives and acknowledges by replying S2 F36. Again if there is any error condition, the whole message will be rejected.

Step 3: The host enables sending of the reports:

- The host sends the event-enabling definition by sending with S2 F37. At this stage, the equipment knows what reports the host requires and the host will enable the sending process.
- The equipment receives and acknowledges by replying with S2 F38. After the equipment acknowledges the message from the host system, it will then proceed to send the reports to the host system.

**TABLE 66.7** Example of GEM Transactions for Event-Reporting Setup

Step	Host	Direction	Equipment
1	Send report definitions S2, F33.	→	
		←	Send acknowledgment S2, F34.
2	Send event and report link definitions S2, F35.	→	
		←	Send acknowledgment S2, F36.
3	Send event-enabling information S2, F37.	→	
		←	Send acknowledgment S2, F38.

#### 66.2.5.1.2 Host Initiates S1 F13, S1 F14

It is a fundamental requirement in GEM that the required equipment is able to accept a connect request from the host. The host can request connections by sending S1 F13 to the equipment. Upon receipt of the message, the equipment will send the S1 F14 “Connect Acknowledge” reply.

#### 66.2.5.1.3 Event Notification

This capability provides data to the host at specified points during the equipment operation. The equipment will send S6 F5 to get permission from the host. The host will reply with S6 F6 to grant permission. Once the permission is granted, the equipment will send the report using S6 F11. The host will acknowledge the report using F6 F12.

#### 66.2.5.1.4 Online Identification

Online identification is the most basic SEMI requirement. The originator (which could be the host or the equipment) will send S1 F1 to ask if the interpreter (which could be the equipment or the host) is there. The interpreter will then reply using S1 F2, which has the information of the equipment type and revision.

#### 66.2.5.1.5 Error Messages

Fundamental GEM requires the system to be able to detect communication link errors in SECS-I and detect SECS-II and GEM format errors. It will also need to support all stream 9 messages and provide appropriate error-handling routines.

#### 66.2.5.1.6 Documentation

Fundamental GEM requires that the equipment should be able to provide a detailed specification document for the SECS/GEM interface on the equipment.

#### 66.2.5.1.7 Operator-Initiated Control

Fundamental GEM requires that the equipment should have operator-initiated control-related capabilities to allow the configuration and manipulation of the control state model. In this way, the host and/or user may modify the equipment’s control-related behavior. For example, in equipment report event scenario, the operator at the equipment will send S6 F5 to the host. The host will send S6 F6 to grant online link to the equipment. The equipment will send control state local event report using S6 F11. The host will acknowledge the report with S6 F12.

### 66.2.5.2 Additional GEM Requirement

*Additional GEM* requires that the system should be able to support communication state model, operator communication state display, operator enable/disable commands, enabled or disabled power-up states, and establishment of communications timer equipment constants.

#### **66.2.5.2.1 Establishment of Communications**

*Establishment of communications* capability provides a means of formally establishing communications upon system initialization or upon any loss of communication between communication partners. Notification of the period of noncommunication is then possible. The host system initiates communication by sending S1 F13 and the equipment will reply using S1 F14.

#### **66.2.5.2.2 Event Notification**

This capability provides data to the host at specified points during equipment operation. The equipment will ask the host for permission to send by using S6 F5 message. The host will give permission using the S6 F6 message. Once the permission is given, the equipment will send the event report using S6 F11, and the host will acknowledge the report using S6 F12 message.

#### **66.2.5.2.3 Dynamic Event Report Configuration**

This capability provides the data-reporting flexibility required in some manufacturing environments. The host will send S2 F39 to request permission from the equipment and will get the permission from the equipment using S2 F40. Having received the permission, the host will send S2 F33 to define the report requirements. The equipment will acknowledge the report requirements by S2 F34. The host will send S2 F35 to collect the report from the equipment and the equipment will then send the report using S2 F36.

#### **66.2.5.2.4 Variable Data Collection**

This capability allows the host to query for the equipment data variables and is useful during initialization and synchronization. The host will send S2 F19 to ask for the variable data and the equipment will send the data using S2 F20.

#### **66.2.5.2.5 Trace Data Collection**

Trace data collection provides a method of sampling data on a periodic basis. The host will initiate the trace of certain data using S2 F23. The equipment will initialize the trace data and acknowledge using S2 F24.

#### **66.2.5.2.6 Status Data Collection**

This capability allows the host to query the equipment for selected information and is useful in synchronizing with the equipment status. The host will send S1 F11 to request for the variable equipment status and the equipment will reply the variable status using S1 F12.

#### **66.2.5.2.7 Alarm Management**

This capability provides for host notification and management of alarm conditions occurring on the equipment. The host will ask for the alarm data and text using S5 F5. The equipment will send the alarm data to the host using S5 F6.

#### **66.2.5.2.8 Remote Control**

This capability provides the host with a level of control over equipment operations. The host will send the remote command using S2 F41. The equipment will acknowledge using S2 F42 and send the data report using F6 F11. The host will acknowledge the report using S6 F12.

#### **66.2.5.2.9 Equipment Constants**

This capability provides a method for the host to read and change the value of selected equipment constants on the equipment. These equipment constants include nonvolatile storage, validation/verification of equipment constants, host equipment constants, and name-list request messages. The host will send the new equipment constant using S2 F15 and the equipment will set the equipment constant using S2 F16. The host will then send S2 F13 to request for the equipment constants and the equipment will send the equipment constants using S2 F14.

#### 66.2.5.2.10 Process Program Management

This capability provides a means to transfer process programs and share the management of those process programs between the host and the equipment. The host will ask for the equipment process program using S7 F19 and the equipment will send the process program data using S7 F20. To upload the process program, the host will send S7 F5 and the equipment will send the process program using S7 F6. To download the process program, the host will send S7 F1 and the equipment will grant permission using S7 F2. Once permission is received, the host will send the process program using S7 F3 and the equipment will acknowledge with S7 F4.

#### 66.2.5.2.11 Material Movement

This capability includes the physical transfer of material among equipment, buffers, and storage facilities. The transfer of material can be performed by the operator, automated guided vehicle (AGV) robots, tracks, or dedicated fixed material-handling equipment. The equipment will send the collection of event using S6 F11 and the host will acknowledge with S6 F12.

#### 66.2.5.2.12 Equipment Terminal Services

This capability allows the host to display information on the equipment's display device or the operator of the equipment to send information to the host. The host will send the textual information to the equipment using S10 F3. The equipment will display the information and acknowledge with S10 F4.

#### 66.2.5.2.13 Clock

The clock capability enables the host management of time-related activities and occurrences to associate with the equipment and across multiple pieces of the equipment. The equipment will send S2 F17 to request time information from the host and the host will respond with time value using S2 F18.

#### 66.2.5.2.14 Limit Monitoring

This capability relates to the monitoring of the selected equipment variables. The host will get the equipment's current limit-monitoring status using S2 F47 and the equipment will send the status using S2 F48.

#### 66.2.5.2.15 Pooling

Spooling as a capability whereby the equipment can query message intended for the host during times of communication failure and subsequently deliver these messages when communication is restored. The host will define messages that need spooling in case of communication failure using S2 F43. The equipment will reset the spooling message and acknowledge with S2 F44.

#### 66.2.5.2.16 Host-Initiated Control

The control-related capabilities allow for configuration and manipulation of the control state model. In this way, the host and/or user may modify the equipment's control-related behavior. The host will request to be offline using S1 F15. The equipment uses S1 F0 to abort transaction, sends S1 F16 to acknowledge, and uses S6 F11 to send event report. The host will acknowledge with S6 F12.

### 66.2.6 Limitations of SECS/GEM

The limitations faced by currently defined SECS/GEM standards are as follows:

1. *Manual integration that cannot be totally avoided.* The factory automation system cannot query SECS/GEM software to determine its full capabilities because different vendors have customized the same message pairs for different applications. Therefore, SECS standard requires significant manual intervention/customization efforts for each application function.

**TABLE 66.8** Trends of the SEMI Standard

First Generation	Second Generation	Third Generation	Next Generation
<i>Characteristics</i>	<i>Characteristics</i>	<i>Characteristics</i>	<i>Characteristics</i>
Simple text-based reporting	Some recipe management	Full recipe management	Intelligent control
	Some equipment performance matrix	Equipment performance matrix	Remote diagnostics/monitoring
	Low standardization	SEMI standardization	Mainstream: distributed computing standards
	<i>Standards</i>	<i>Standards</i>	<i>Standards</i>
	SECS-I	SECS-I/-II	Object-Based Standards
	De facto	GEM	
	Proprietary	HSMS	
	<i>Technology</i>	<i>Technology</i>	<i>Technology</i>
	Serial	Serial	Middleware
	TCP/IP	TCP/IP	
	<i>Issues</i>	<i>Issues</i>	<i>Issues</i>
	Limited solution opportunities	Highest integration cost	Nonsemiconductor-specific PC-to-PC communication
	Highest integration cost	Long lead time	Lower integration cost
	Longest development	Semiconductor-specific interfaces	Object-oriented approach

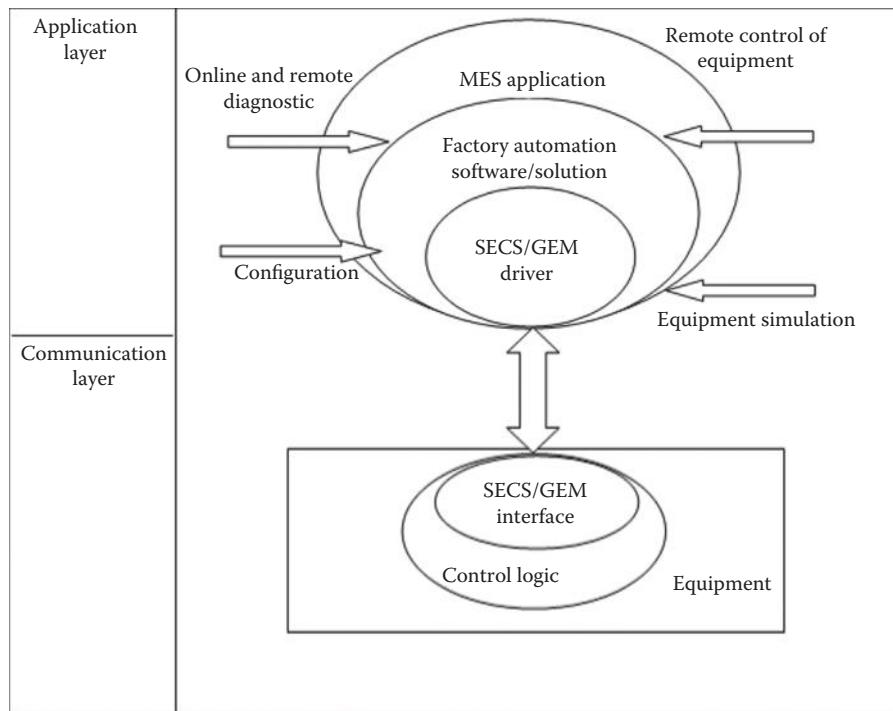

2. *Weak security mechanism.* SECS is weak in its *security mechanism*. There is no concept of client authentication or access permission in SECS. Issues of security are becoming important operational considerations because of the need for remote equipment engineering and remote diagnostics.
3. *Single-client architecture.* The implementation of SECS is based on a point-to-point link, and there is only one software process (i.e., one point) on the factory side. This is a critical limitation because the newly developed factory applications such as advanced process control (APC), factory automation, and advanced planning and scheduling (APS) systems require a steady stream of accurate real-time data, even in the form of peer-to-peer communications to facilitate a decision-support process.

### 66.2.7 Emergence and Evolving New Standards

The industry associations such as SEMI and SEMATECH as well as universities have tried to develop a new standard that can handle the various applications needed by today's semiconductor-manufacturing environment. SEMI communication and interface standards have adopted some of the popular object-oriented programming like the XML and distributed computing techniques, but these are still not very commonly used. Table 66.8 shows the trend in the SEMI communication standards.

### 66.3 Survey of SECS/GEM-Compliant Toolkits

SECS/GEM-compliant software comes in different layers. In this section, a survey of different toolkits that are available in the market is presented together with their different features. The different features that are provided by each vendor are summarized in one table to highlight the capabilities among them.

**FIGURE 66.13** Application layer and communication layer of factory automation software.

### 66.3.1 Overview of Equipment Integration Software

The equipment integration software is an important part in semiconductor manufacturing or wafer fabrication. The factory automation software must accommodate various factory applications such as equipment configuration, online and remote diagnostics, remote control, and equipment simulation. These applications are the essential functionalities in today's semiconductor wafer fabrication. Most of the software vendors would like to provide solutions across the span of *process control, system automation, production data acquisition, and communication systems*.

The factory automation software can be divided into two levels: the application level and the communication-enabling level. The function of the application level is to carry out the various applications such as remote diagnostic, data collection, tracking of materials, and testing and simulation. The function of the communication enabler is to interface the factory networks or host with the equipment, which may be SECS/GEM-compatible or non-SECS/GEM-compatible equipment such as programmable logic controller (PLC)-controlled machines. Figure 66.13 gives an overview of the factory automation software.

Software toolkit comes with different features and functionalities. They can be conveniently classified as toolkits for MES application, factory automation software/solution, and SECS/GEM drivers.

### 66.3.2 SEMI Equipment Communication Software

Some of the commercially available factory automation software are described in this section. These products are obtained from company-provided information. The survey is based on several important features listed in Table 66.9. A few software vendors provide the complete solution, but most of them provide solutions for the application level. They generally use the communication-enabler component from prominent players in the market such as Cimetrix in conjunction with their application package.

**TABLE 66.9** Comparative Analysis of the Available Software

Software Vendor	Yokogawa		Cimetrix		Peer Group		Hume

### 66.3.3 Analysis of Current Available SECS/GEM Solutions

An analysis of the SECS/GEM solutions is shown later, based on the features of the software and the intended application.

#### 66.3.3.1 Analysis Based on the Features of the Software

The analysis on the current available solutions is consolidated from public information provided by the companies. Feedback from vendors is also used to compile this analysis.

#### 66.3.3.2 Analysis Based on the Intended Application

Due to the fact that SECS/GEM communication software has the propensity of being tailored to a variety of applications, it is necessary to map such applications to varying communication levels as shown in Figure 66.14 and Table 66.10. For example, it can be used by the equipment manufacturer for developing the host interface just as it can also be used by the semiconductor manufacturer to communicate with the equipment, to test the equipment for its interface, etc. Figure 66.8 shows one example that highlights the application of the SECS/GEM software. Further, Table 66.10 compares the application intent of the software.

#### 66.3.3.3 Case Study I: Design and Implementation of SECS/GEM for a New Semiconductor Back-End Machine (Implementation of SECS/GEM Compliance on a Virgin Machine)

This section presents a case study in the design and implementation of SECS and GEM for a case where a back-end semiconductor machine is to be built with SECS/GEM compliance. We shall see how facile it

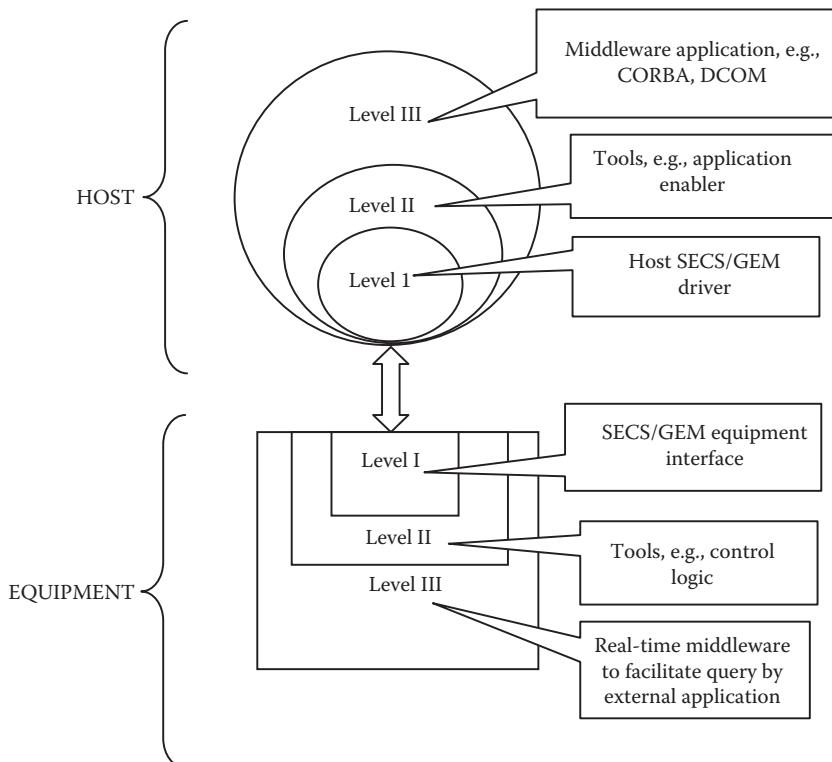

FIGURE 66.14 The functionality of SECS/GEM software.

**TABLE 66.10** Analysis of the Software Based on Communication Levels

is to implement SECS-II and GEM for a PC-based equipment controller by leveraging on commercially available software. We have chosen a package from GW Inc. We will show the steps toward the implementation of a SECS/GEM, in the case where the equipment initiates the communication with the host system:

a. A statement of the specifications and requirements

The equipment maker is required to develop a GEM-compliant equipment. This equipment is required to be directly integrated into existing SECS-II-enabled host (cell control) system. The detailed requirements and capabilities are as follows, being able to

1. Connect the network to the host system with both SECS-II and HSMS protocols
2. Upload and download process programs for equipment configuration
3. React to the host's requests, based on the process state of the equipment
4. Send event or alarm reports to the host system in the event of predefined events or *alarms occur*
5. Time-synchronize with the host system on equipment power-up
6. Implement GEM fundamental requirements

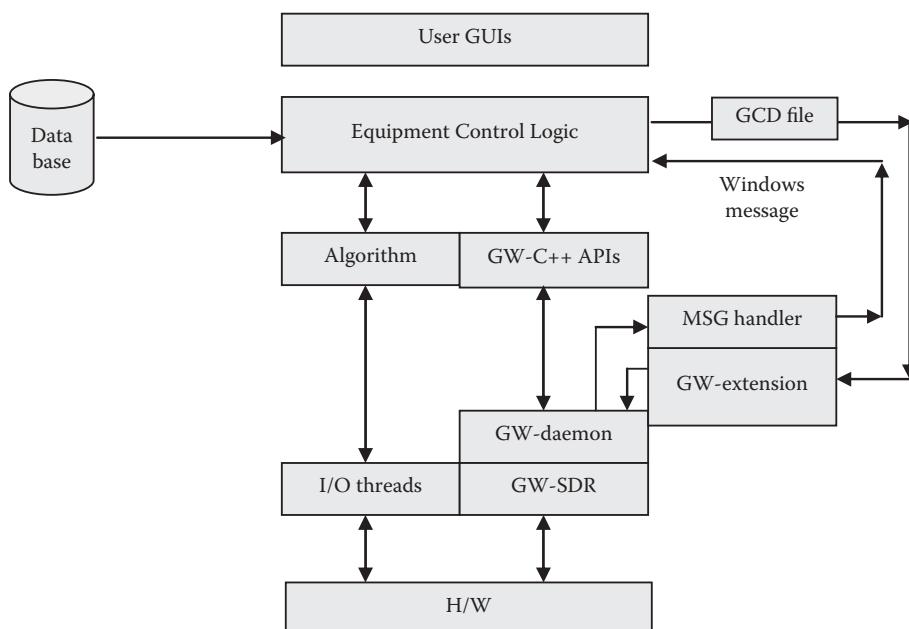

b. System architecture and software tools

Figure 66.15 shows the recommended system architecture and communication interfaces. The SECS/GEM software package from GW Inc. is utilized in this example.

The package includes

- GEM configuration data (GCD) file
- GWGEM daemon
- GWGEM extension task
- GWGEM primary message handler task
- GWGEM application programming interface (API) in C++

As we mentioned in the earlier section, in order to run GEM application that is built on the earlier four major GWGEM components, the SDR must be installed and run as a message driver (HSMS) to communicate with the host system.

**FIGURE 66.15** System architecture for SEMI interface creation.

c. Functional mapping of modules

The GWGEM daemon process coordinates all the communications between user applications, GWGEM extension, and message handler tasks. The GCD file defines all SECS variables such as status variables, equipment constants, and data variables. The extension task is a process that contains various GWGEM extension routines that are called by the GWGEM daemon process from time to time. Extension routines are user-written application programs that provide application-specific or equipment-specific handling of GEM messages.

d. Message partition

A primary message handler task is used to process a particular type of incoming SECS primary message from the host system. It must provide for the following conditions:

- Messages that are beyond the GEM standard set
- Messages that vary from one equipment type to another
- The ability to override GWGEM built-in handling of a particular incoming primary message
- The ability to scan (peek at) an incoming SECS-II message without actually processing it

e. Levels of implementation

In this project, the following GEM fundamental requirements are implemented:

1. State model
2. Equipment processing status
3. Host-initiated S1 F13/F14 scenario
4. Event notification
5. Online identification
6. Error message
7. Documentation
8. Control (operator-initiated)

By implementing the GEM fundamental requirements, the equipment is GEM compliant, which means that this equipment is able to communicate with any GEM-compliant equipment no matter which hardware vendor it comes from. In addition to the aforementioned, some additional GEM capabilities are also implemented. These include

1. Initialization and establishment of communications
2. Alarm management
3. Equipment terminal services
4. Process program management
5. Clock

GWGEM C++ encapsulates the GEM requirements into several classes. The developer treats the GEM functionalities as some objects. GWGEM C++ for Windows packs as Windows dynamic link library (DLL). It takes advantage of window programming for WIN32-based applications such as Microsoft Foundation Class (MFC). GWGEM C++ uses Windows event notification and message service to notify or trigger WIN32 application to handle incoming SECS-II primary messages.

f. Integrate GWGEM C++ with an MFC-based equipment controller

Normally, the development team of GEM-compliant semiconductor equipment is made up of mechanical engineers, control engineers, and SECS/GEM consultants. The first step for the consultant is to work with the mechanical and control engineer to collect equipment data, status data, event data, and alarm data. The consultant needs to translate these data related to the equipment's operation into variables defined in the GCD file; see GCD file sample.

Once the control engineer completes code writing including GUI portions and I/O control logic, it is time to integrate GWGEM C++ with the control program. To improve the real-time performance, GWGEM C++ maps events such as equipment state change, process state

## Code samples

**FIGURE 66.16 (continued)** (g) C++ sample, remove GWGEM object. (h) C++ sample, fire an event. (i) C++ sample, disable the communication link. (j) C++ sample, send S1F13 to the host.

change, or the arrival of SECS-II primary messages with window's message handler so that these events are handled concurrently without performance trade-offs. Due to space limit, the code samples in Figure 66.16a through j only show the necessary steps for declarations: initialization and deletion of GEGEM objects in an MFC-based application.

By using GWGEM C++ for Windows, there is no need for the developer to code the low-level communication details as shown in Figure 66.17. GW daemon and its supporting components such as GWGEM extension tasks do the process of incoming SECS-II messages. As a result, it significantly shortens the development cycle and reduces software bugs.

Typically, after 2 months of development and testing, the equipment successfully passes the GEM tests and is declared fit for delivery.

**FIGURE 66.17** Design of intercommunication process.

#### 66.3.3.4 Case Study II: Design and Implementation of SECS-I, SECS-II, and GEM Driver

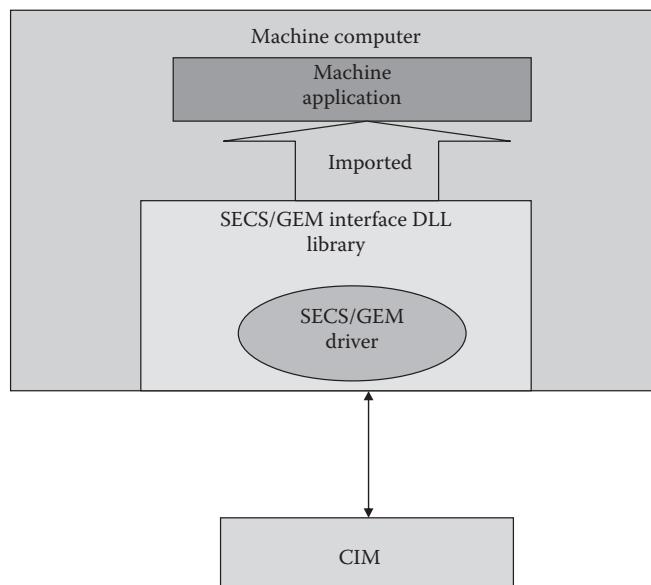

This section presents a case study in the design and implementation of SECS-I (serial port using RS232), SECS-II, and GEM driver for a case where a new machine is to be integrated with a computer-integrated manufacturing (CIM) system.

##### a. Software design

The driver is developed using Microsoft C#.Net version 4.0, and it provides communication between host computer system and the equipment using SECS-I serial communication (RS232) with specifies SECS-II message format content. Figure 66.18 shows the software architecture of the driver in the form of DLL and is statically linked to the machine application.

The SECS-I and SECS-II define communication interface standards between the semiconductor equipment and the host CIM system. The SECS-I standards describe details for physical connection, signal size, data rate, and protocol logic, and SECS-II standards describe message (information) exchange between the equipment and the host. All the messages are transferred based on the SECS protocol, and each of the message transfer is processed as one transaction. Combinations of those transactions control and manage the semiconductor fabricating process. Table 66.11 shows the SECS-II messages transferred between the equipment and the host CIM system. In this *equipment-driven scenario*, the equipment sends an S1 F13 representing communication establishment to the host in order to start the semiconductor fabricating process. The host transfers an acknowledgment message S1 F14 to the equipment in order to respond to the message from the equipment. The equipment then sends an S1 F1 to the host, which is a query inquiring whether the host exists and receives an acknowledgment message of S1 F2 from the host. Subsequently, the equipment transfers S6 F11, which represents a mode change from offline to online of the host and receives an acknowledgment message S6 F12 from the host. The operator for the equipment puts a product on the worktable prior to starting the semiconductor fabricating process.

After a product is loaded to the worktable, the equipment sends an S6 F11 representing the material that has been set up at the worktable to the host and then receives an acknowledgment message of S6 F12 from the host. The equipment sends an S7 F5 to request for process recipe for this product to the host and then receives S7 F6, the recipe data from the host. Upon receiving

**FIGURE 66.18** Software architecture.

**TABLE 66.11** Equipment-Driven Scenario

Host	SECS Message	Equipment
	←S1F13S1F14→	Establish COMM request.
	←S1F1S1F2→	Online request.
	←S6F11S6F12→	Online report event.
		Operator puts a product on the worktable prior to starting the semiconductor fabricating process (product loading).
	←S6F11S6F12→	Material setup event.
	←S7F5S7F6→	Request recipe program.
	←S6F11S6F12→	Process start event.
	←S6F11S6F12→	Process completed event.

Sn,Fm	Function	Transfer direction	Response required

L, 3  
 <DATAID>  
 <CEID>  
 L, 2  
 <RPTID>  
 L, 3  
 <PORT>  
 <LOTID>  
 <PPID>

**FIGURE 66.19** Example of SECS-II message.

the recipe data, the equipment starts the process fabrication procedure according to the data defined in the recipe program. After the fabrication process is completed, the equipment sends an S6 F11 representing the completion in fabrication to the host and then receives an acknowledgment message of S6 F12 from the host.

Figure 66.19 shows an example of a SECS-II message transferred between the equipment and the host. Each SECS-II message presents a unique expression thereof such as S6 F11, a combination of one of stream number (S1–S128) and one of function numbers (F1–F128). S6 F11 is message for Event Report Send (ERS) from the equipment to the host, and it is necessary for the host to respond to the message toward the equipment. The structure of the SECS data in S6 F11 message is “L,3,” which means three data lines: the first line contains <DATAID> representing a series of “data ID,” the second line contains <CEID> representing “collective event ID,” and the third line contains “L,2” composed of two lines. The first line of “L,2” contains <RPTID> representing “report ID,” and the second line of L,2 is composed of another three lines “L,3,” which contain <PORT> representing “port number,” <LOTID> representing “lot or product ID,” and <PPID> representing “process program ID.”

A SECS-II message comprises of data variables that have unique data format. The data format is defined as the data type with “,” as separator, followed by data length and data value inside

**TABLE 66.12** Data Format

Data Format	Description
A, (1 – n)	ASCII char array, array max size $n = 65,535$
B, (1 – n)	Binary number array, array max size $n = 65,535$
11, (1 – n)	1-byte signed integer, array max size $n = 65,535$
12, (1 – n)	2-byte signed integer, array max size $n = 35,535$
14, (1 – n)	4-byte signed integer, array max size $n = 65,535$
18, (1 – n)	8-byte signed integer array max size $n = 65,535$
U1, (1 – n)	1-byte unsigned integer array max size $n = 65,535$
U2, (1 – n)	2-byte unsigned integer array max size $n = 65,535$
U4, (1 – n)	4-byte unsigned integer array max size $n = 65,535$
U8, (1 – n)	8-byte unsigned integer array max size $n = 65,535$
F4, (1 – n)	4-byte float number array max size $n = 65,535$
F8, (1 – n)	8-byte float number, array max size $n = 65,535$
Bool, (1 – n)	1-byte Boolean number array max size $n = 65,535$
L, (1 – n)	List number, max size $n = 65,535$

the “<>.” Data type comprises of various numeric numbers and string characters, with length in single (1) or array type (1<). Table 66.12 shows the various data types used in SECS message.

SECS-II message is formed by both header and data blocks. Header block stores the system information, and data block stores the information of data variables. The message is constructed with the structure and format as defined in Figure 66.20 where header block stores system information such as byte length, device ID, stream ID, function ID, block number, system byte, and checksum value. Data block stores data variables, which are grouped within a list element. A list allows the grouping of related data items, which can have different formats. A list can contain sublist elements. Figure 66.20 also showed the value before and after conversion between text and binary format of SECS-II message.

Data format: data type, data length <data value>

String data: A, 18 <This is an example.>

Unsigned array data: U1, 5 <1 2 3 4 5>

#### b. Communication method

The communication method between the host and the machine is by RS232 connection with the following master and slave relationship. The master is referring to the party that initiates the communication, and the slave responds to the requests. The master is usually referred to the host, and the slave to the machine. In Figure 66.21, a handshake ENQ/EOT is required before the sending of the message, and followed by a handshake to acknowledge message, ACK/NAK is successfully passed or not. Upon message contention as shown in Figure 66.22, where both parties request to send messages at the same time, in this situation, the machine will back off and allow the host to send first. The sequence of the communication is the same as the earlier communication when the direction is opposite.

A single message can only send max 256 bytes. In multiblock message, E-bit of block number in Figure 66.23 is used to track the block number of the multiblock message. A handshake ENQ/EOT is required before the sending of the message, and followed by a handshake to acknowledge message, ACK is successfully passed. E-bit incremented by 1 and followed by the sending of the subsequent message and so on. If there is any negative acknowledge NAK from the receiving party, the message transmission is abruptly terminated.

#### c. GUI for SECS-I interface (RS232)

As shown in Figure 66.24, the GUI comprises of various panels, namely, “control and data table” panel, “message to host” panel, “message from host” panel, and “history data log” panel:

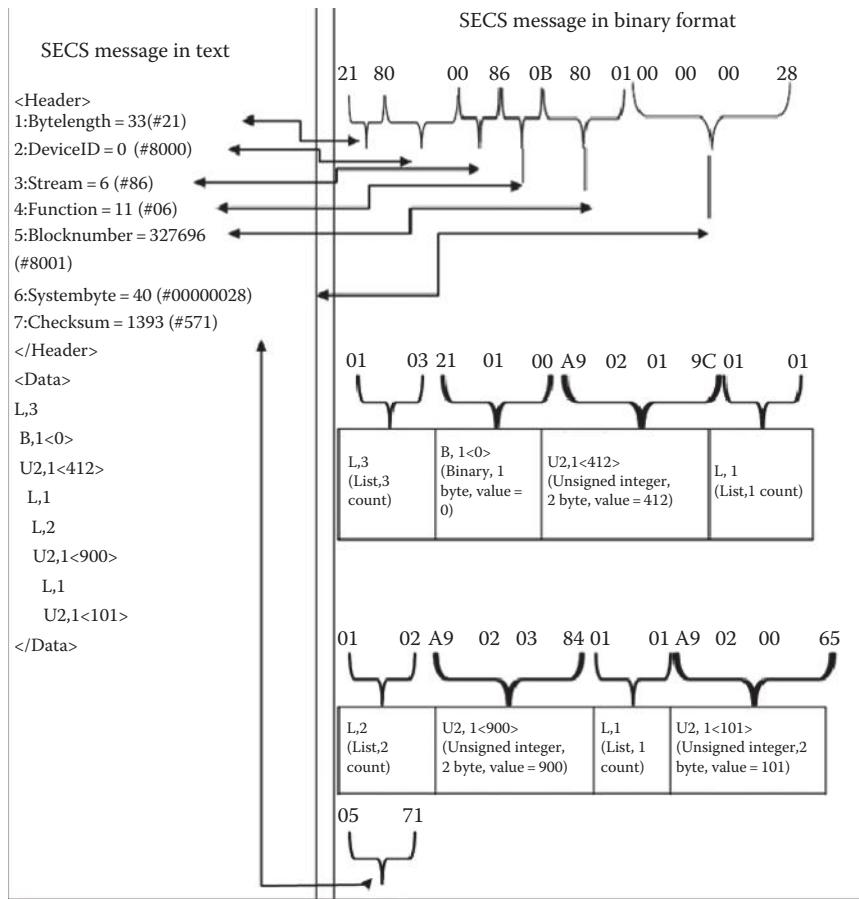

FIGURE 66.20 Format and structure of SECS-II message.

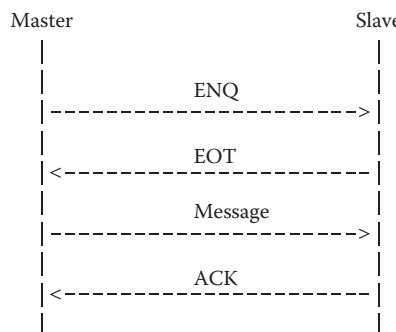

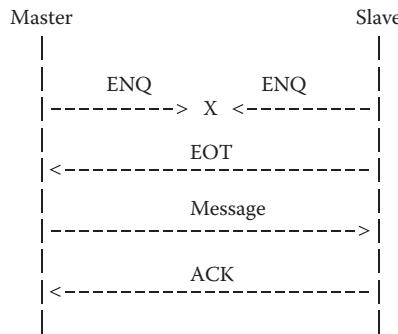

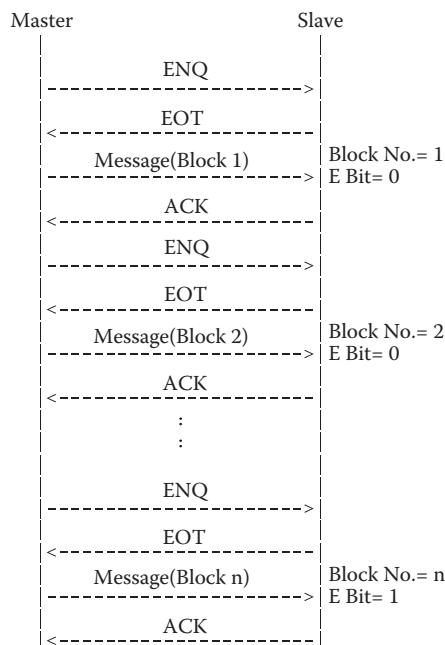

FIGURE 66.21 Single-block message.

1. “Control and data table” panel consists of user interfaces that allow users to control and monitor the communication state between the equipment and the host. Establishment of communication mode can be either operator- or host-initiated. There are altogether 6 timers (T1 to T6) in place to monitor the health of the communication link; time-out value can be remotely changed by the host or locally changed by the operator. The communication port number is selectable and checked on the button above to open port. The interface also

**FIGURE 66.22** In case of contention.

**FIGURE 66.23** Multiblock message.

provides an auto or manual selection for user to run the driver in two different modes. The start button is for starting the driver's process, and the initialize button is for resetting the driver's process to its initial state. The update button is for updating SECS data value to the data tables of the software driver.

Figure 66.25 shows the detail "data table" panel box. Data table stored various tables for SECS parameters and data. These are equipment constant ID (ECID), collective event ID (CEID), remote command ID (RCMD), report ID (REPID), process program ID (PPID), data variable (DV), status variable (SV), alarm ID (ALID), etc. These variables are the key data elements for the data exchanges between the host and the machine. For stream and function panel, predefined streams and function's messages are defined here. Each individual function panel consists of a textbox in which SECS-II message and variables are formulated.

2. As shown in Figure 66.26, the "message to host" panel consists of panel boxes where SECS binary data are computed. Information, such as device ID, Reply expected, and

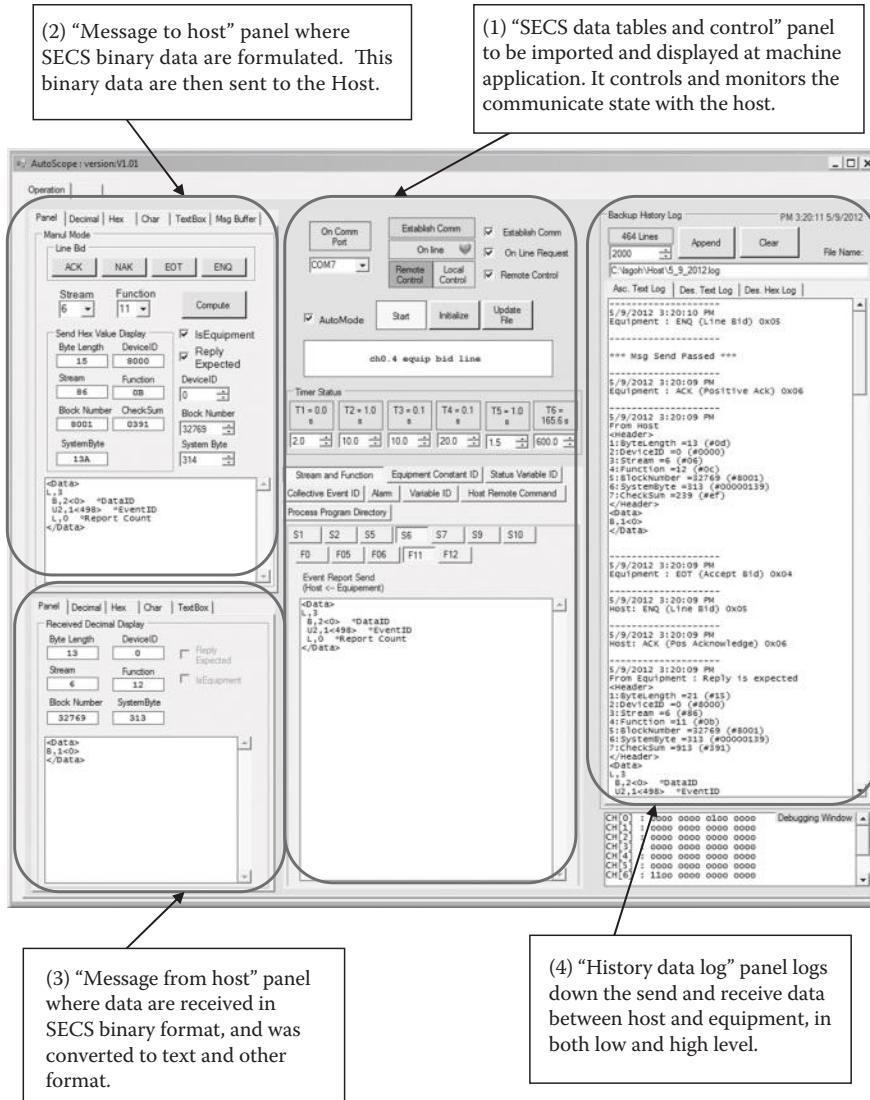

FIGURE 66.24 GUI for SECS-I interface driver.

Is-Equipment status, forms the header block, and the data at the panel's textbox formed the data block. The message that is ready to be sent to the host can be viewed in various formats, namely, hexadecimal, char, decimal, and text as shown on the right side of Figure 66.26. Buttons such as ENQ, EOT, ACK, and NAK are used for communication's hand-shake with the host. The "Compute" button is used to start text to SECS binary format conversion.

3. "Message from host" panel consists of panel boxes where SECS binary messages from the host are received and displayed. The binary message is decoded to text format, and header and data block information are then extracted and archived to the respective data tables. The received SECS message is displayed in various formats, namely, hexadecimal, char, decimal, and text as shown on the right side of Figure 66.27.

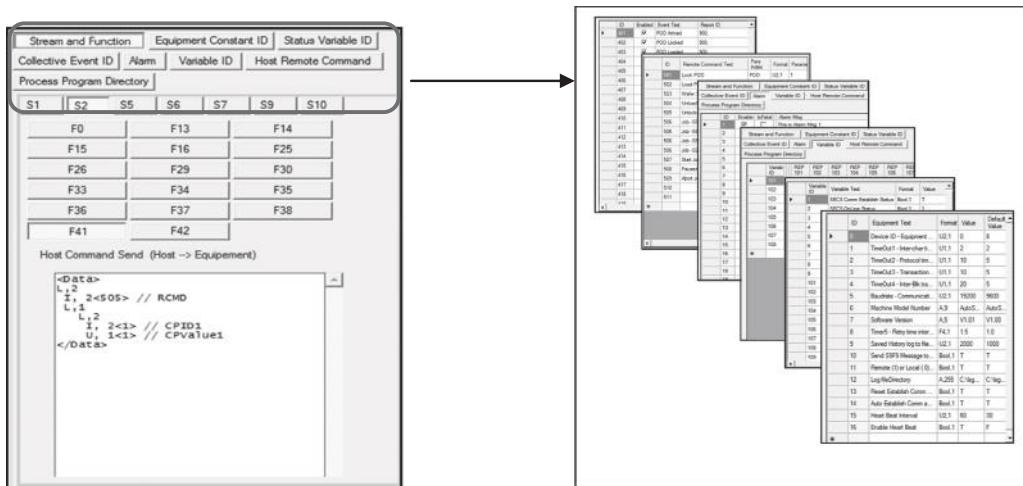

FIGURE 66.25 “Data table” panel box.

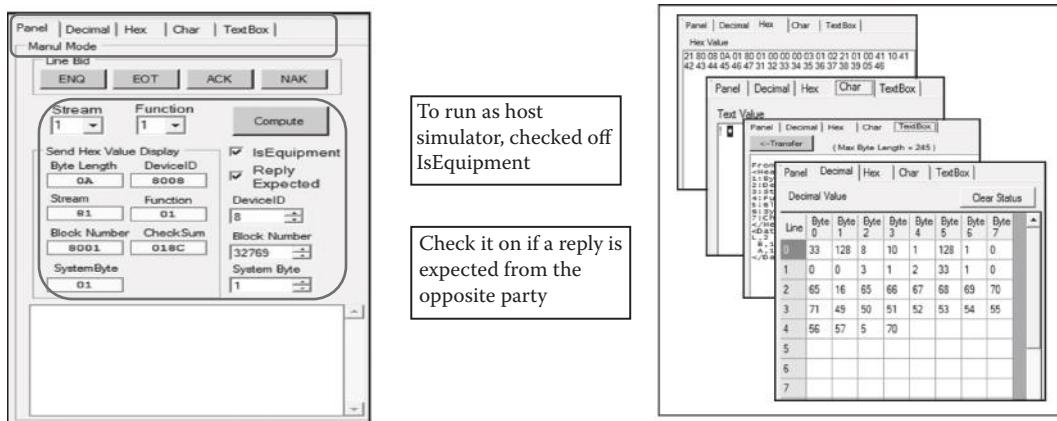

FIGURE 66.26 “Message to host” panel box.

- As shown in Figure 66.28, the “history data log” panel boxes contain transmitted and received log data between the host and the equipment, in both SECS binary and text format with date and time stamp. Handshakes and communication status, for example, timer status, are saved in the data log too. When the data lines are greater than the preset count, the log is automatically saved, with the “today” filename at the user’s predefined directory.

#### d. Software integration method

The integration of SECS driver with machine application software is direct and simple. Basically, it consists of the following three parts. The first and second parts are mandatory, while the third part is optional.

The first part is the “Message In” that is from machine application to SECS driver. These messages are, for example, machine’s event and alarm, to be sent from the machine to the host through the SECS driver. The message is pushed into the input message storage by machine application and is retrieved in first-in-first-out (FIFO) order by the driver. In the event of communication breakdown at the RS232 link, the message from the machine is spooled in the buffer and can be retrieved by the driver and send to the host when communication is up again.

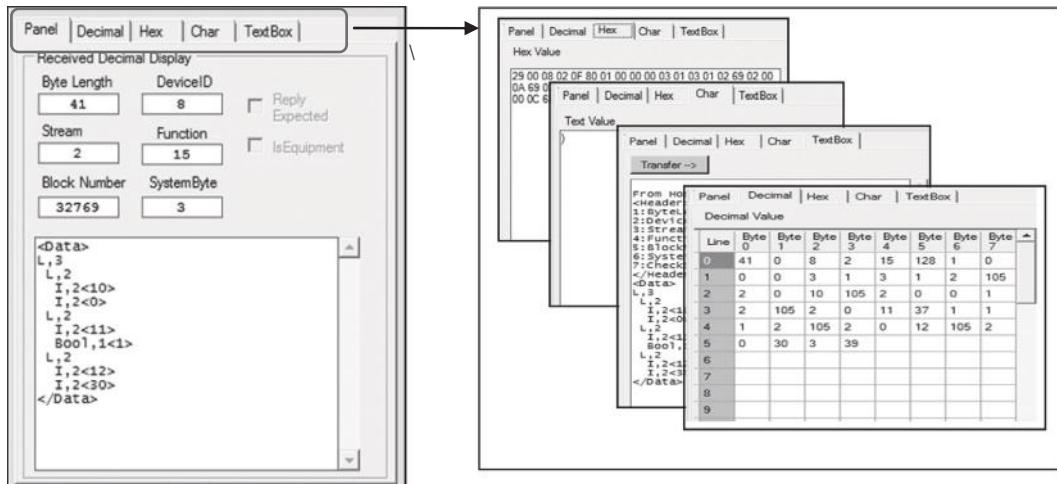

FIGURE 66.27 "Message from host" panel box.

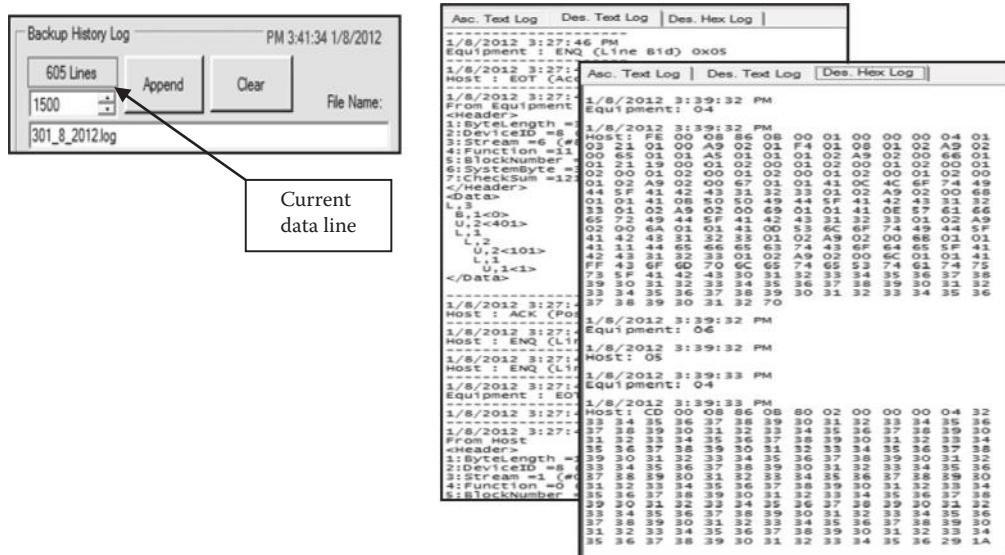

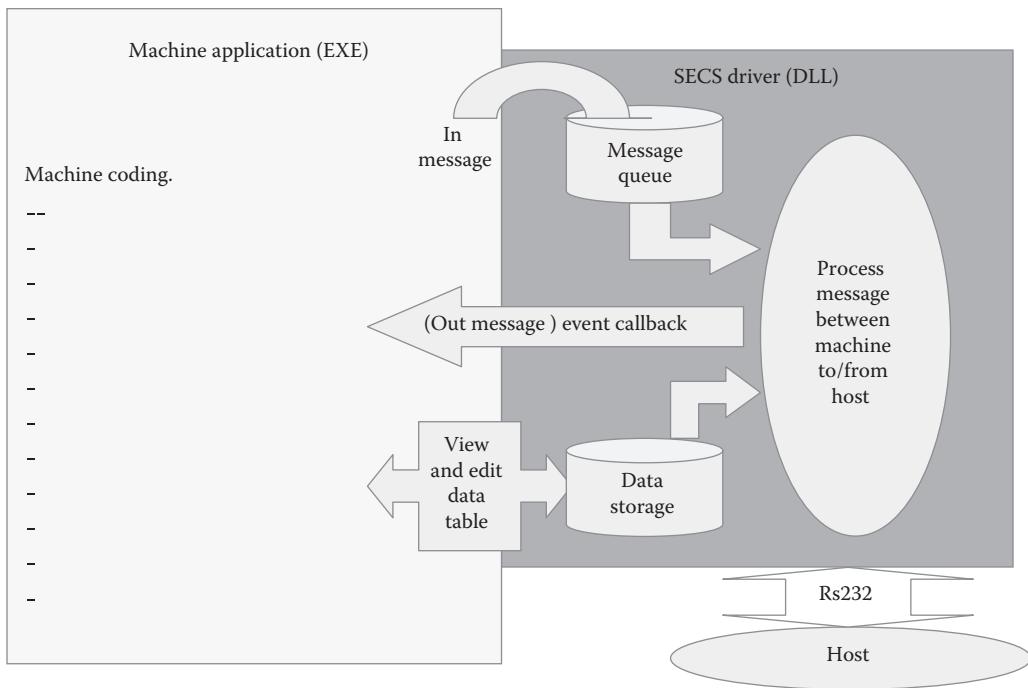

FIGURE 66.28 Data logging.

As shown in Figure 66.29, the second part is the “Message Out” that is from the SECS driver to machine application. These messages could be the process’s result of the driver or message from the host. These messages are passed to the caller, which is the machine application in the form of *event callback*. With these two methods of conversation, it formed a closed loop communication system between the machine application, the SECS driver, and the host.

The final part is an optional feature that allows the data tables to be directly accessible by the machine application. User can manually or by software program method view, edit, and update the data table that resides at the SECS driver side.

Figure 66.30 shows the imports of “data tables and control” panel from the driver to the machine application. A software example is also given to illustrate the “Message In” and “Message Out” or call-back methods. In the example, an alarm “Message In” is sent from the machine to the driver’s message queue. Upon the detection of message available at the

**FIGURE 66.29** Integration diagram.

queue, the driver popped out the queued Message In FIFO order and searched through the data table to look for data item related to the message's ID. Once the item is found, the message's ID (ALID) with data is formed to text message, converted to SECS-II binary format, and sent over through the RS232 connection to the host computer. After the message is sent successfully or not, a "Message Out" event callback is triggered and sent back to the machine application.

## 66.4 Conclusion

This chapter has given a brief overview of the standards of SEMI SECS-I/-II/GEM. While keeping within the special (and at time strange) nomenclature and conventions adopted by SEMI, the authors have provided ample comments and interpretations on the pertinent points to enable the reader to understand the complexity and integrity of SECS equipment. A survey of existing SECS-compliant software is also conducted.

Two case studies are also introduced to illustrate how SECS/GEM compliance can be implemented on virgin machines and interfaced to host system.

Presently, there are no systematic alternatives to SEMI standards. Although the SEMI communication standard is still evolving, it continues to be critical as a means of sustaining maximum functionality/availability in the wake of new semiconductor processes and new semiconductor-manufacturing automation.

## Acknowledgment

The authors would like to express their sincere thanks to Dr. Zeng Xianting, Director of Knowledge Transfer Office of SIMTech, for his support leading toward the completion of this chapter.

### 67.1 Protocol Overview

---

The BRAIN (Braided-Ring Availability Integrity Network) is a novel communication architecture supporting fault-tolerant time-triggered communication. As the name suggests, the BRAIN is built upon a braided-ring topology. This topology augments the standard ring topology with increased connectivity. In addition to the *direct link* connections between a node and its immediate neighboring nodes (as is used in simple rings), a braided-ring node also is connected to its neighbor's neighbor via a link called the braid or skip link (see Figure 67.1). The BRAIN utilizes the additional connectivity to achieve both high-coverage integrity and availability concurrently. This is in contrast to previous braided rings, which use these additional links only for availability. The BRAIN can use almost any existing local area network (LAN) technology to implement its communication links, including any of the IEEE 802.3 Ethernet variants.

The BRAIN uses the least amount of hardware to achieve single fault tolerance (including Byzantine failure) of any known data network. The BRAIN also can tolerate two benign faults with no additional redundancy. The BRAIN topology enables adjacent nodes to collaboratively form self-checking pairs (SCPs). This allows standard simplex computational hardware to be run-time configured into high-integrity fail-silent computational platforms, which provides the high fault coverage for processing that one would find in architectures supported by SAFEbus (see Chapter 48) but without requiring any special SCP hardware for the processors.

The BRAIN's benefits derive from its time-triggered data flow and its use of high-coverage fault tolerance.

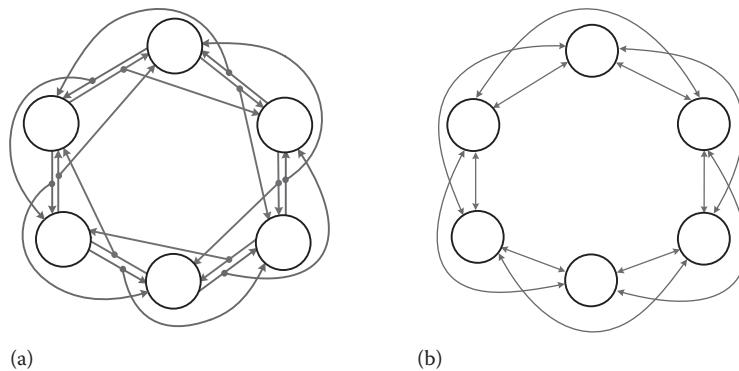

**FIGURE 67.1** BRAIN’s braided-ring basic architecture.

### 67.1.1 Development History and Design Goals

The BRAIN was originally conceived as a field-bus-type protocol, targeting low-bandwidth applications. Acknowledging the simplicity of high-coverage self-checking architectures, such as SAFEbus (see Chapter 48), the BRAIN was conceived to apply these techniques to a field-bus protocol. The intent was to deliver SAFEbus levels of integrity and availability within a field-bus environment. Exploiting lessons learned from the application of other field-bus protocols in safety-relevant applications, the BRAIN has been designed with two principles in mind: (1) limited reliance on in-line error detection mechanisms such as cyclic redundancy codes (CRCs) for error detection needs and (2) the avoidance of dedicated guardian hardware commonly used in other field-bus protocols targeting safety-relevant deployment [1]. The BRAIN has evolved to become a more general-purpose architecture, and it continues to evolve.

*Limited reliance on coding-based techniques for error detection.* It can be argued that the error detection properties of code-based in-line error detection like CRCs are not strong enough to cover the failure modes of active interstages. Active interstages are defined as relaying stations with active circuits (e.g., integrated circuits). These typically are a network switch or hub in a communication architecture [2]. Codes like CRCs have been designed for good error detection coverage of typical failure modes of wires, such as occasional bit flips and burst errors. The failure modes of interstages and the potential for correlated failures are unlikely to fit these assumptions. Hence, the goal of the BRAIN is to not rely on coverage of CRCs or similar error detection schemes for interstages. This is described in more detail in [2].

*Avoidance of dedicated guardian hardware.* The requirement for local or central guardian hardware constitutes an intolerable overhead in cost-constrained applications. They also introduce complexities when the guardian action needs to be verified within a deployed system. Similarly, each fault-tolerance feature needs scrubbing logic—logic that tests whether the fault-tolerance mechanism is still operational. Such scrubbing logic needs to detect latent faults of the logic implementing the fault tolerance, in order to ensure the logic is available when needed. More allegorically explained, scrubbing ensures that the guard is awake and well when really needed. Distributed, built-in guardian logic as

**FIGURE 67.2** The two BRAIN connection duplex configurations. (a) Full-duplex BRAIN configuration and (b) half-duplex BRAIN configuration.

deployed in the BRAIN can be more easily scrubbed for latent faults during operation than central or local guardians. Central guardians may additionally introduce architectural constraints, for example, by restricting the order of component power-up. Therefore, a core goal of the BRAIN was to remove the need for any dedicated guardian components.

The BRAIN was conceived as a broadcast flooding network targeting network bandwidth on the order of 5–20 Mbit/s. At these speeds, the intranode propagation delay is minimal, comprising only a few bits of elasticity delay encountered at each link as the message floods around the segmented medium. A global, time-triggered, *a priori* agreed schedule coordinates the transmission sequencing, in a manner conceptually similar to the media access of a typical time-triggered bus, that is, time-division multiple access (TDMA). For targeting very-low-end applications, the BRAIN can use half-duplex instead of full-duplex BRAIN links. The half-duplex BRAIN sends data in both directions on each link medium, while the full-duplex BRAIN sends data through unidirectional link media. Half-duplex operation is described in [3]. The half-duplex configuration uses less physical layer hardware, at the expense of cutting effective bandwidth by about half (Figure 67.2).

Targeting medium- to high-performance applications, one recent development in the evolution of the BRAIN uses store-and-forward propagation to be able to more efficiently use emerging high-speed serial protocols, such as the gigabit per second (Gbs) Ethernet. However, the algorithms for this higher-speed variant of the BRAIN were still undergoing formal analysis at the time of this publication. Therefore, the details of this development are not discussed here.

### 67.1.1 Fault Tolerance and Fault Hypothesis

With point-to-point links, the BRAIN topology implicitly addresses the spatial and other physical layer damage issues that impact bus topologies. The BRAIN topology is able to tolerate complete loss of communications at any single geographic location on the ring. Similarly, any single node may fail and drop out from the BRAIN without adversely impacting the system-level communication (availability and integrity) guarantees. In addition to these passive failures, the BRAIN protocol also has been designed to tolerate an active malicious fault. The BRAIN mitigates such faults by leveraging bit-for-bit comparisons between the independent data paths that exist between the skip and direct links and/or the two opposing directions of traversing the ring (clockwise and counterclockwise) (see Section 67.2.1). In addition, the BRAIN can employ a *brother's keeper* guardian action, where each node may act as a guardian for its adjacent neighbors. Note that this is consistent with the original design goals, since it supports the deployment of guardian actions without incurring additional component overheads.

The BRAIN originally was designed to tolerate at least one faulty node.\* A node's failure mode may be either (1) passive (i.e., fail stop) on any combination of its ingress or egress links or (2) actively malicious, where the node acts actively to corrupt data and/or disrupt protocol operation, for example, by masquerading as another node or babbling. In practice, the connectivity of the BRAIN provides tolerance to many more benign faults, providing service under at least two passive node faults or link faults. However, to tolerate the active fault, the initial field-bus BRAIN requires the full connectivity of the nonfaulty nodes. A discussion of the BRAIN's sensitivity to node and link failures together with a comparison of the BRAIN's policies with other protocols is given in [4].

Note that, similar to SAFEbus, the BRAIN has not been designed to tolerate dual active colluding faults, that is, where two nodes act in a coordinated fashion to corrupt data flow and/or disrupt the system. This fault hypothesis is backed by two observations. First, statistical analysis shows that it is highly unlikely that two faults manifest in correlated active failure modes in two independent<sup>†</sup> devices within the very tight time window of self-checking action. Second, the combination of the self-checking forwarding action, the periodically scrubbed guardian function, and the potential reconfiguration actions of Section 67.3 are sufficient to tolerate an active fault for the time of exposure between scrubs.

### 67.1.2 Minimal Overhead Replication and Input Agreement

In Byzantine-tolerant real-time systems, the bandwidth and scheduling overheads associated with the Byzantine data exchange and agreement often constitute significant network, system, and software burdens. This observation created another design goal of the BRAIN, which was to provide a low-overhead framework to support task replication and data agreement. To this end, the BRAIN introduces additional mechanisms to contain Byzantine failures, for example, preventing a node from supplying different data on each of its outgoing directions. With such fault containment in place, an inconsistent omission fault model may be assumed for those messages needing agreement. This reduces the expenses of higher-level agreement exchanges required for such messages typically used in other Byzantine-tolerant protocols. In place of the fault message exchange and voting typically used in Byzantine agreement, a simpler agreement on reception status may be implemented. This is a hierarchical Byzantine agreement mechanism, similar to the one developed for SAFEbus. The BRAIN also encompasses hardware assistance mechanisms for this exchange that does not need software interaction (see Section 67.4.1).

## 67.2 Protocol Mechanisms and Services

---

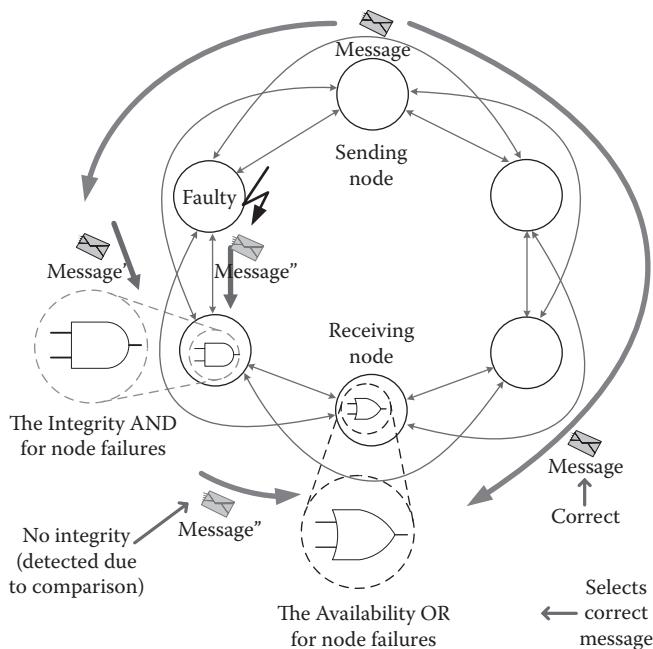

### 67.2.1 High-Integrity Data Propagation

The core service of the BRAIN is the fault-tolerant, high-integrity, high-availability broadcast distribution of data. This mechanism provides the foundation for all of the higher-level protocol services. Abstractly, the BRAIN data-propagation scheme is very simple and can be viewed independently of the higher-level protocol services. These techniques may also be applicable to other time-triggered protocols such as FlexRay (see Chapter 6 in KT), Time-triggered protocol (TTP) (see Chapter 5 in KT), or time-triggered Ethernet (see Chapter 42).

A conceptual representation of the BRAIN's high-integrity data propagation is illustrated in Figure 67.3. At a high level, the BRAIN is best viewed as offering two concurrent modes of data propagation, with both modes collaborating to maximize data integrity and data availability. The two modes are self-checking data relay and independent path data integrity reconstitution.

\* Later variants are targeting tolerance to two faults.

<sup>†</sup> This independence can be made arbitrarily large—separate boxes, separate power supplies, etc.

**FIGURE 67.3** Conceptual BRAIN operation for tolerating one arbitrary fault.

#### 67.2.1.1 Self-Checking Data Relay

The BRAIN's first propagation mode focuses on in-line integrity failure detection, that is, the possible corruption of data during a node's data relaying action and availability in the event of a single fault. As illustrated by the long outer arrows in Figure 67.3, a sending node transmits its message in both directions around the ring (*clockwise* and *counterclockwise*). Broadcasting a message in both directions provides availability. A message will be delivered successfully if either one of the directions is intact (the *Availability OR* in the figure). The independence of these two paths ensures that there will always be one success path available from any arbitrary sending node to any arbitrary receiving node, given a single fault.

If a receiving node gets two copies of a message (one from each direction) that are different, it must decide which one is good. This decision is supported by the use of message integrity status provided by an integrity scheme employed within each direction. This integrity scheme prevents a message from being undetectably corrupted in transit. For every potentially faulty component within the data-propagation path, there exists completely independent hardware, which checks that this component has not caused any corruption. If corruption is detected, the message is indelibly flagged as suspect (i.e., has lost its integrity guarantee). One instance of the mechanism supporting this scheme is shown in Figure 67.3 as the *Integrity AND* function for the *counterclockwise* direction. This is replicated for every node in both directions.

As a message traverses the ring, it tries to pass through every node using the direct links. Each node is also bypassed by a skip link. For the general case, in a particular direction, a node receives two inputs, one from the direct link and one from the skip link. Each node compares the data it receives from its direct link with the data it receives from its neighbor's neighbor via the skip link. This bit-for-bit comparison of all data transmitted ensures that any data corruption injected by a faulty node is immediately detected. For example, consider the node marked *faulty* of Figure 67.3 corrupting the message transmission from the sending node as it is being relayed. The erroneous data from the faulty node are immediately detected by the Integrity AND comparison function performed at the next downstream

node, which compares the direct link output from the faulty node with the original data (sending node) available on the skip link. This skip–direct comparison is performed by all nodes as the data are propagated around the ring. Hence, data corruption at any point can be immediately detected. The status of the propagation integrity comparison is signaled by setting the value of an indelible status flag at the end of the message. This flag must follow all of the bits within the message that are checked for integrity.

The implementation details for the integrity status flag depend on the particular physical layer technology used to implement the links (e.g., Ethernet) and whether the flag is equivalent to a single binary value (i.e., message integrity is intact vs. message integrity is not trusted) or is a vector of such binary values, one for each node through which the message passes. For vector implementations, the vector either can be a fixed length (with one element of the vector for each node in the ring) or can be variable length (growing in size by one element for every node through which the message passes). Vector implementations enable precise diagnostics to isolate where in the propagation path the errors are induced. However, it increases the message overhead and may not be compatible with some physical layer technologies. For the single binary implementations, an aggregate status of all upstream comparisons can be carried by a shared status flag.

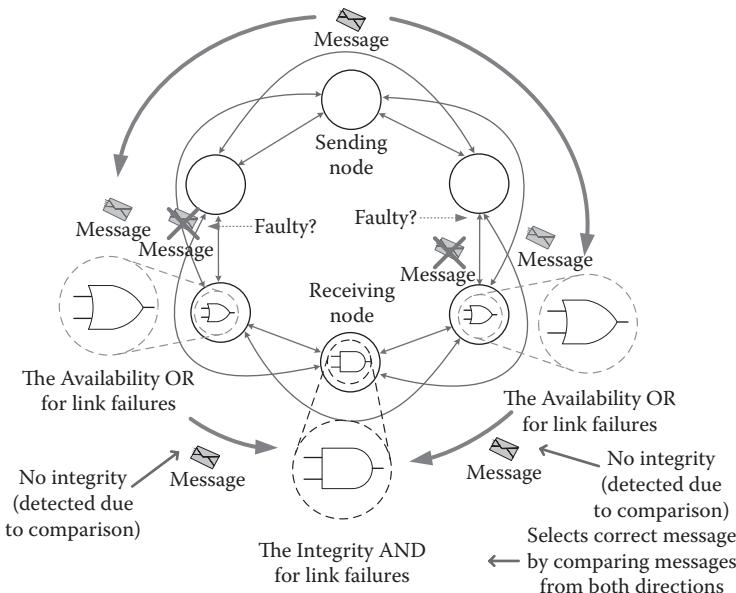

It is essential that the setting of the integrity status flag (single binary value or vector) by all repeating nodes is strictly one way indelible. That is, repeating nodes are limited to either propagating the current integrity status value or setting it to *not trusted*, that is, they are not allowed to change a nontrusted status back to one that says the message has integrity. To enforce this one-way behavior, the value of the integrity status is also checked in the direct–skip link comparison described earlier. If either link says that the message integrity is no longer trusted, the relayed message will have its integrity status flag say that the integrity is no longer trusted. In framed formats, such as Ethernet, the loss-of-integrity status can be signaled by truncating the frame (e.g., deleting the end-of-frame marker), forcing a detectable error at the end of the message (e.g., using the wrong disparity in 8B/10B encoding) or forcing a frame check sequence to be invalid (e.g., inverting Ethernet’s CRC field) that causes the frame to be detectability erroneous by the physical technology used to implement the links and consumes no bandwidth for this flag.

### 67.2.1.2 Independent Path Data Integrity Reconstitution

The BRAIN’s second propagation mode focuses on tolerating a second benign (fail-stop or omission) failure. The BRAIN is able to tolerate a benign second fault without any increase in redundancy. This provides the BRAIN an additional degree of fault tolerance. However, the first version of the BRAIN (described here) could not tolerate an active fault and an arbitrary benign fault at the same time. The first propagation mode provides for fail-op/fail-stop operation. The second propagation mode adds fail-op/fail-op/fail-stop operation for benign faults. This is worst case. The BRAIN can tolerate many more faults for most cases. For example, the BRAIN can tolerate any number of benign node failures, as long as no two or more failed nodes are adjacent when three or more nodes have failed.

This second propagation mode reverses the locations of the *Integrity AND* and *Availability OR* mechanisms. See Figure 67.4 and compare it to Figure 67.3. In this mode, the skip and direct links provide increased channel availability, while the *Integrity AND* is performed by comparing the data a node receives from each direction. If the data received from both directions match bit for bit and the data from neither direction violate the link data encoding nor framing checks, the integrity of the data received may be *reconstituted*. This allows the data to be used, despite having the integrity flags from both directions showing that integrity is suspect. The situation of getting a correct high-integrity message via integrity reconstitution may happen only if there are multiple benign node failures (fail-omission or broken links). By leveraging the reconstitution of integrity, a system may lose multiple skip and direct link connections yet still be able to deliver high-integrity data to the application.

In the second propagation mode, the *Availability OR* is implemented by each node selecting the data from either link to be forwarded, with the loss-of-integrity status signaled if the two incoming links do

**FIGURE 67.4** Conceptual BRAIN operation for a second benign failure.

not match bit for bit. This selection can be arbitrary in most cases. The exception rules for selection are discussed with the rules for the time sequenced guardian roles in Section 67.3.1.2.

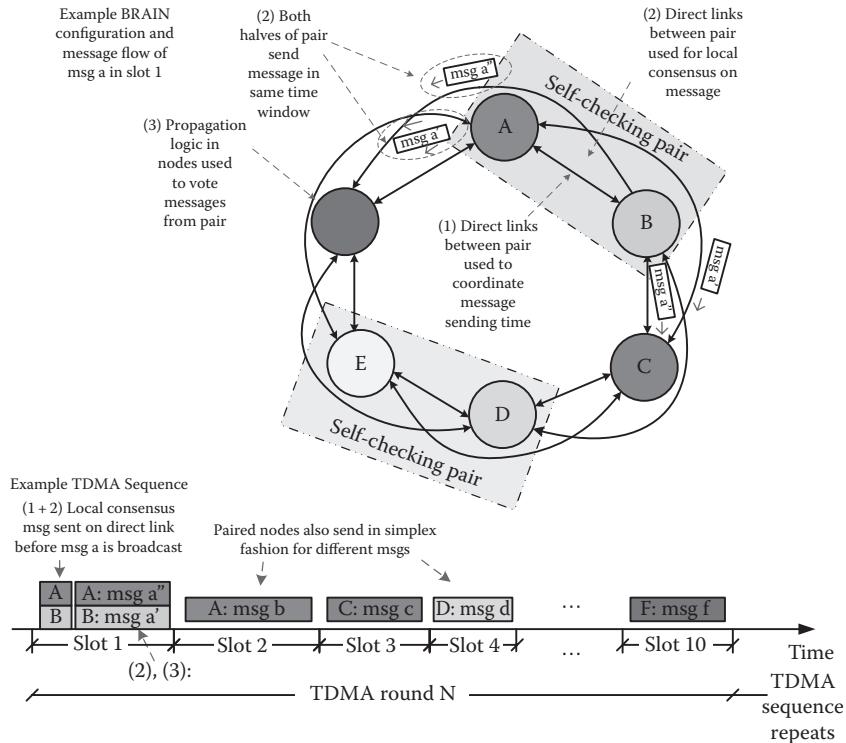

It is emphasized that both propagation modes of the BRAIN coexist simultaneously and there are not any specific mode selections nor additional bandwidth required to support them both. Therefore, there are three success propagations that may constitute a high-integrity data reception, either clockwise or counterclockwise with the in-line integrity status confirmed or the reconstituted path from the comparison of both directions.

### 67.2.1.3 Self-Checking Processor Pair Broadcast

The connectivity of the BRAIN that enables the data relaying policies of the BRAIN, as described earlier, also can be used to compare the output of two adjacent nodes. This allows for adjacent nodes to be configured into high-integrity *message-based SCPs*. Implementing paired transmissions is as simple as configuring the communication schedule to make the two halves of a pair transmit in a shared slot (the time allocated on the media to transmit one message). The synchronous nature of the BRAIN and the high-integrity forwarding mechanism ensure that the receiving nodes receive a single high-integrity message when the data sent from the two halves of the pair are identical. Such a configuration is depicted in Figure 67.5, where the copies of message *msg a* appears as the copies of a single message at all receivers.

Using the time-triggered network communication primitives to implement the high-integrity computational comparison presents significant advantages when contrasted with other self-checking approaches. Traditionally, high-integrity computational hardware platforms have required specialized design to *clock step* or *lock step* the processing platform. In modern processors, such lock-step comparisons can often introduce a significant run-time performance degradation. In addition, with the emergence of multicore processing engines, the complexity associated with such comparisons may impact the very feasibility of the lock-step approach. The loosely coupled time-triggered message-stepping comparison\* of the BRAIN does not suffer from performance degradation, since the comparison is made at the communication line

\* Integrity comparisons are done on a message-by-message basis rather than on every clock tick of the processor.

**FIGURE 67.5** SCPs.

rate as a by-product of the BRAIN's normal message propagation mechanisms. Additionally, the communications-based comparison approach may arguably offer superior fault coverage, since it detects failures that occur within the communication hardware itself. It should also be noted that the BRAIN message-stepping scheme enables nodes to selectively perform self-checking or non-self-checking message transmissions. As illustrated in Figure 67.5, nodes can operate as message-stepping pairs, during one TDMA slot (see nodes A and B in slot 1), and the same nodes can make independent simplex transmissions in other slots (node A in slot 2). This scheme may provide improved processing hardware utilization, since it provides the freedom to replicate only safety-relevant software tasks and does not require the full replication of all computation on the self-checking host.

There are advantages in reducing the tight redundancy coupling required for processor integrity mechanisms. For example, in missions and applications where spare resources are scarce or the logistics pipeline is expensive, system designers often strive for *generic sparing* strategies that enable common reconfigurable hardware to be used in more than one application or mission role. Hence, the ability to configure standard COTS processing hardware into high-integrity fail-silent computational pairs via a simple change of the TDMA schedule is very attractive. Additionally, each half of the pair may use dissimilar hardware, providing a path for generic design failure mitigation. A triple-modular redundant variant of the self-checking scheme is also possible, as presented in Figure 67.6. Using such a configuration, it may be possible to guarantee fail-operational behavior with a generic processing fault while using minimal hardware.

To implement the message-stepping pairs, input agreement is required between each half of the pair to ensure that a fault entering the two halves of the pair cannot force each half of the pair to diverge or disagree. To implement such agreement, the direct connections between the paired nodes may be used. Section 67.4.1 outlines the use of agreement hardware.

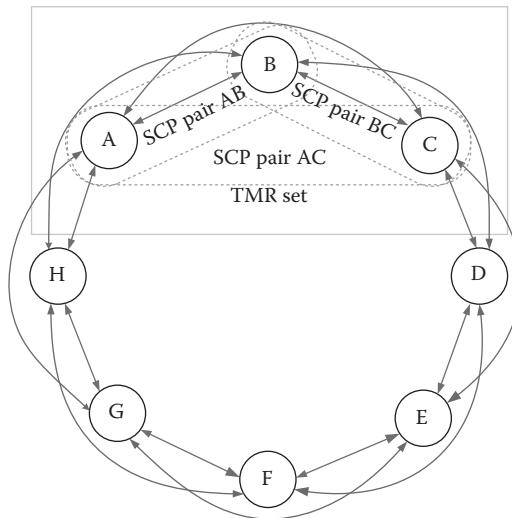

FIGURE 67.6 Triple-modular replication (TMR) deployed on BRAIN.

### 67.2.2 Clock Synchronization, Start-Up, and Clique Resolution

The self-checking data-propagation mechanism described earlier is extensively utilized by the BRAIN's clock synchronization and start-up protocols. Within a BRAIN network, adjacent nodes act as SCPs to send protocol synchronization messages. Unlike other protocols that utilize distributed algorithms to vote and converge output from multiple *peer* nodes, the BRAIN adopts a hierarchical protocol strategy. In place of a fault-tolerant convergence function, the BRAIN employs a fault-tolerant priority-based selection function to select a master-clock pair. The selection of a pair is performed once each synchronization interval. It is, therefore, tolerant to dynamic system membership changes and will reselect an alternative driving pair when the highest-priority selected master fails. Similarly, when the higher-priority pair recovers, the BRAIN protocol incorporates mechanisms to ensure that the recovering pair will assume the running timeline before it resumes its mastership. As is generally true for the creation of BRAIN SCPs, clock synchronization SCPs are created simply by including this information in the schedule tables. Nodes that are not configured to be in the set of potential SCP clock masters are called *slaves*. The protocol messages sourced from the SCPs are simple, comprising two fields as noted in Table 67.1. In the BRAIN, the same message format is used for synchronization and integration; hence, the messages are termed Synchronization-INTegration (SINT) messages.

Within the SINT message, the TDMA POSITION field enables nodes to agree and integrate on the TDMA schedule phase. The PRIORITY field is used to arbitrate among clock-pair masters, in the event that the pairs disagree on timing and/or schedule phase. The PRIORITY is statically allocated to pairs at design time and the pair with the highest priority wins. Following any detected contention, the highest-priority pair will continue running; the lower-priority pairs will yield and resynchronize according to the content of the higher-priority pair's SINT message. The timing of the highest-priority SINT messages also is used for global synchronization, with lower-priority pairs and slave nodes

TABLE 67.1 SINT Message Fields

Field	Description
TDMA position	The TDMA slot counter
Priority	The priority of the sending SCP

correcting their local timing with respect to the highest-priority master's SINT message arrival. There is a relationship between precision and drift of synchronized time. The more frequently an algorithm synchronizes, the tighter the precision, but frequent resynchronization may lead to a larger drift of the global time (affecting accuracy). The BRAIN master-/slave-based approach performs better than classical distributed algorithms because it maximizes accuracy (eliminates the integration of *read error* suffered by peer synchronization algorithms) and minimizes jitter impact. The time between scheduled SINT messages (the synchronization interval) is determined at design time as an engineering trade-off between better clock precision and minimizing bandwidth overhead, which can be different for every application.

### 67.2.2.1 Self-Checking Master Coordination

The accuracy and validity of the BRAIN's leader-elect master/slave synchronization approach is dependent on the fault coverage of the master clocks. For this reason, the BRAIN introduces special qualification logic to cross-check a pair's health prior to them initiating any protocol traffic. In the BRAIN, all SCPs are formed from adjacent nodes. Hence, each half of a master-clock pair is connected by the direct link (private link) that connects the nodes. The pairs use this link to initiate a pairing rendezvous. This rendezvous is performed by each pair once per synchronization interval and is scheduled to occur just prior to the sending of the associated pair's SINT frames. This ensures that the clocks are checked for accuracy before each half of the pair initiates SINT transmission. To achieve this, as part of a pair's rendezvousing action, each half of the pair monitors the timing of its other half. Subsequently, one half of a pair will not support a SINT transmission if the timing of its partner's clock fails beyond a configured tolerance.

To ensure clock correctness at start-up, the rendezvous procedure is also performed as part of the protocol start-up. On power-up, the nodes of each SCP perform a rendezvous prior to entering a listen-time-out period, that is, the period during which the nodes listen and wait to detect running TDMA traffic. If the SCP nodes complete the listen-time-out without detecting traffic, the nodes rendezvous again on completion of the listen period. Thus, the duration of the listen period constitutes the period over which the start-up clock frequency monitoring occurs. To ensure that the clocks are operating within the configured tolerance, both halves of the pair monitor and cross-check the duration of the listen period as indicated by its partner.

Should the listen activity result in a change of schedule phase, that is, following the reception of a SINT frame from another master, each half of the pair inhibits SINT transmission for the first synchronization interval following integration. This ensures that a full synchronization interval duration is

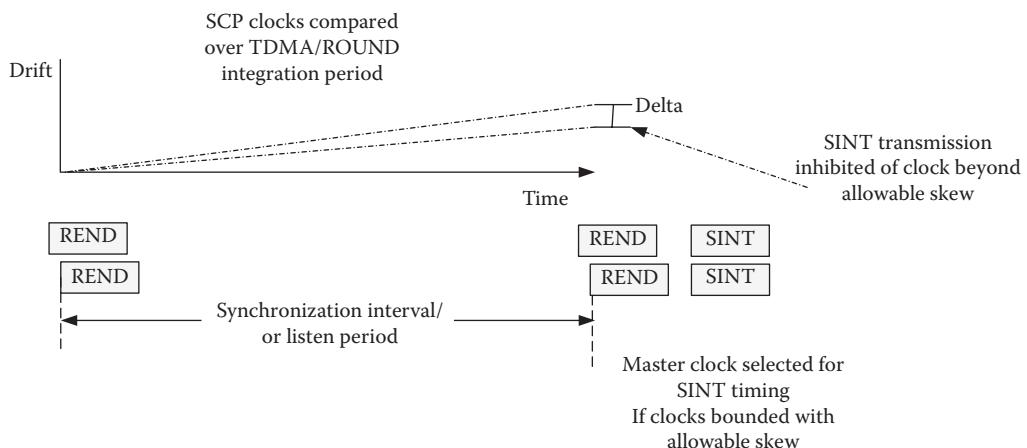

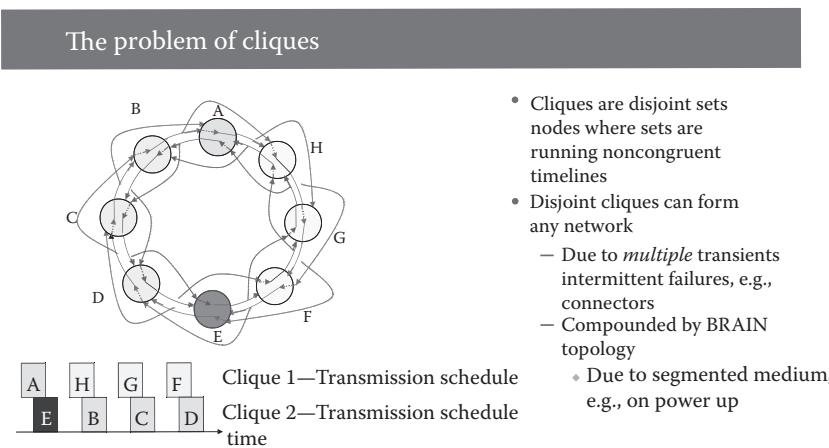

FIGURE 67.7 An SCP clock monitoring and rendezvous.

used for clock cross-checking prior to the pair sourcing of any coordinated SINT messages. Similarly, if one half of a pair has successfully integrated into running TDMA traffic, it will not support its partner in the establishment of a disjoint-phase clique. Figure 67.7 illustrates the rendezvous procedure, showing the sequence of SCP rendezvous (REND) messages used to align their respective timelines.

To maximize clock accuracy, the two halves of a pair do not perform mutual clock averaging. Instead, one of the pair's clocks is used as the master clock, and all protocol timing is derived from this single clock. The clock of the other half of the pair is used only for monitoring, to ensure that the master clock remains within the expected accuracy. This improves the clock accuracy.

### 67.2.2.2 Connectivity Building and Clique Aggregation

The self-checking leader-elect synchronization strategy described earlier is conceptually very simple. However, it is not sufficient, by itself, to address the multihop and segmented-media topology of the BRAIN architecture. Without mitigation, the segmentation of the BRAIN may cause start-up clique formation. This vulnerability is illustrated in Figure 67.8, which depicts a hypothetical scenario of how two cliques could be formed. If the skip links around nodes A and E have failed and these two nodes are powered on later than the other nodes, disjoint cliques can form on each side (because no messages can get past the locations of nodes A and E until they power up). Once either of these nodes power up, a communication path is created between the two cliques and clique resolution is required. As described in [5], existing clique resolution protocols (which are based on the properties of a globally perceived broadcast medium) cannot resolve such clique scenarios in all cases. This is because the disjoint phases of the nonaligned TDMA schedules can cause *collisions* that prevent nodes from one TDMA timeline from hearing messages sent by nodes on another TDMA timeline. For example, in Figure 67.8 the power-up timing of nodes A and E are such that node A joins the right-hand clique (H, G, and F) and node E joins the left-hand clique (B, C, and D). The nodes A, B, E, and F are called frontier nodes because they are the *outermost* nodes on their respective cliques. Frontier nodes belong to one clique, but they may hear messages from another clique. These messages are rejected because they do not meet the timeline constraints of the clique to which the frontier node belongs.

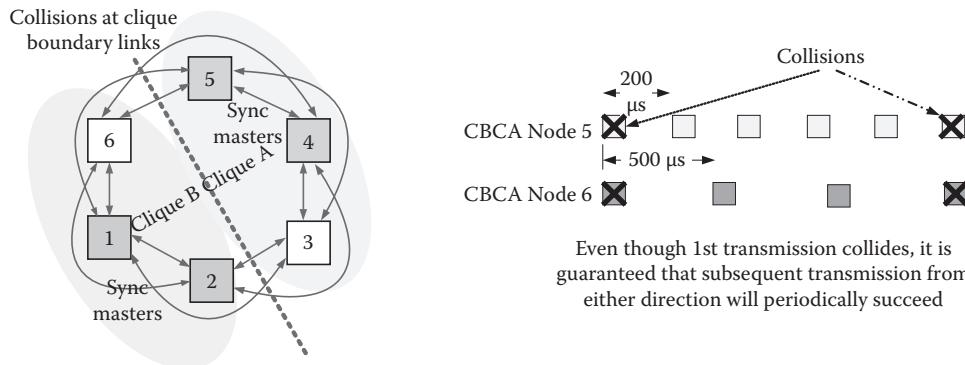

BRAIN requires an effective guaranteed clique recovery algorithm

Honeywell

BRAIN

**FIGURE 67.8** A BRAIN clique scenario.

**FIGURE 67.9** CBCA link arbitration resolves asynchronous TMDA clique boundaries.

To address these issues, the BRAIN approaches the start-up problem differently from previous clique resolution protocols. In place of a monolithic protocol that targets both synchronization and clique resolution, the BRAIN splits the protocol action into two layers. The BRAIN introduces a novel foundation layer in the form of a constructive connectivity-building and clique-aggregation (CBCA) algorithm that is used to build network connectivity and clique allegiance between adjacent frontier nodes. As such, the CBCA algorithm is conceived to run underneath the normal TMDA protocol activity. This means that it is unable to use, and does not need to use, the TDMA-coordinated activity to implement its signaling and/or link arbitration. For this reason, the foundation of the CBCA algorithm is a simple asynchronous medium arbitration mechanism. For half-duplex rings, nodes that share an adjacent link are configured with relatively prime periods of transmission, as illustrated in Figure 67.9. By using relatively prime periods, for example, 200 and 500  $\mu$ s as shown, it can be assured that should a collision occur during one transmission, the next transmission will be collision-free (in the fault-free case). Therefore, periodically successful transmissions will occur from each direction. For full-duplex rings, the *collisions* occur within frontier nodes, which receive messages that are out of sync with its TDMA timeline. This form of collision prevents these out-of-sync messages from being forwarded into the clique.

Similar to SINT messages, the CBCA messages leverage SCP protection, where adjacent nodes collaborate to signal the CBCA messages. Each frontier node and its nearest neighbor within the same clique form a pair for sending identical CBCA messages across the frontier.

The transmission of CBCA messages is timed relative to the SINT transmission schedule of the initiating clique. The decision to transmit CBCA messages is made by each node determining if it is on a frontier. The full procedure is illustrated in Figure 67.10.

In a simple start-up scenario (to illustrate the CBCA process), one master-clock SCP of nodes happens to start up before the other nodes, for example, nodes 4 and 5 in Figure 67.10. At the beginning of this scenario, these nodes are the master pair and the frontier nodes. The CBCA process is initiated from this pair, following the transmission of its SINT message. Because the nodes adjacent to the pair have not sent or relayed any messages indicating that they are in the same clique as the master pair, the master pair assumes that they are frontier nodes and initiate the coordinated CBCA transmissions, sending repetitive CBCA messages on both skip and direct links. The CBCA message comprises two fields as illustrated in Table 67.2. The TIME\_TO\_NEXT\_SINT field is updated for each CBCA transmission, relative to the sourcing-clique's clock master's SINT timing interval, with the values decrementing as the time of the next SINT transition approaches.

When a node adjacent to the master pair powers up and sees identical CBCA messages on both its direct and skip links, it joins the master's clique. If the newly connected node had already been part of a different clique (instead of this power-up scenario), the node would have compared the priority of the sending clique (as sent in its CBCA message's MASTER-PRIORITY field) with the priority of the clique to which it was already synchronized. If the CBCA message had a higher priority, the node would join

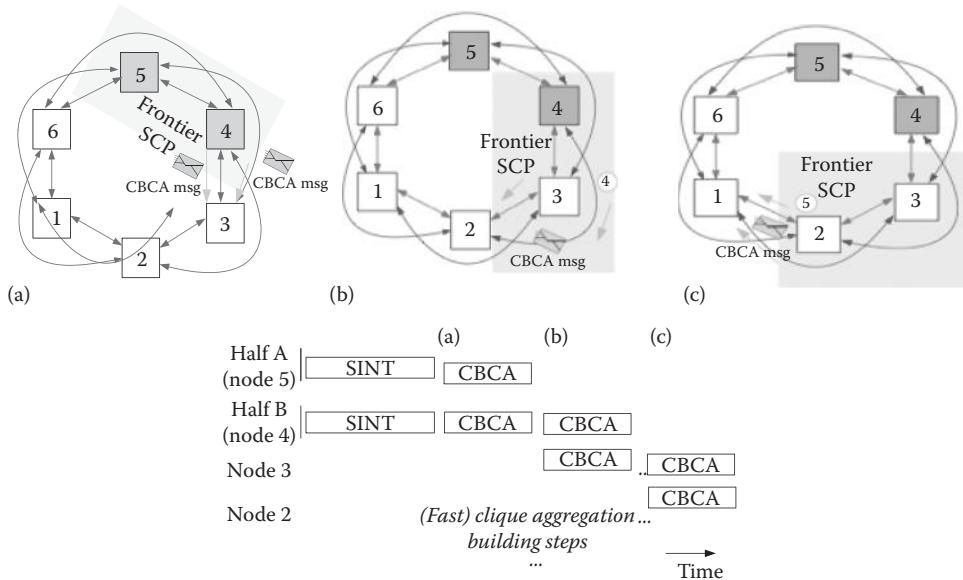

FIGURE 67.10 CBCA.

the higher-priority clique and synchronize to its schedule, that is, defecting from their previous clique/schedule. Following a node's defection or integration, it extends the self-checking frontier action with its immediate neighbor not already in the higher-priority clique. This propagates the clique status and associated priority to its neighbors, which expands the frontier out by one node. This CBCA action continues for a duration proportional to the value of the TIME TO NEXT SINT field received in the CBCA messages. All CBCA action is timed to cease before the next scheduled SINT message. During the CBCA propagation in frontier expansions, no other traffic is allowed on the newly converted links. Thus, prior to the next SINT message transmission, the media among all newly joined nodes is reserved to enable clean SINT message propagation through all of them. Note that, as the CBCA mechanism executes, each node records the status of which neighboring nodes have joined its clique. Then the nodes cease CBCA activity on those links that have indicated membership in its clique, following the next SINT transmission. Therefore, normal TDMA activity can commence between all nodes confirmed to be in the same clique, immediately following the next SINT message transmission.

### 67.2.2.3 Synchronous Mode Clique-Aggregation Breakthrough

The CBCA mechanism earlier is sufficient to mitigate all cliques given a BRAIN with a single node fault. However, to improve robustness, additional mechanisms have been added to resolve dual-link and dual-benign-node failure scenarios. In such scenarios, it is necessary to utilize the integrity reconstitution mechanisms of the BRAIN, to qualify integrity of the CBCA status information by using information received from the two different ring directions. To facilitate CBCA integrity reconstitution, special CBCA *breakthrough* slots are added to the normal TDMA schedule. In a breakthrough slot, each node at a frontier of the clique sends the received CBCA priority of the neighboring clique,

TABLE 67.2 CBCA Fields

Field	Description
Master_priority	The priority of clock master to which the frontier node is synchronized
Time_to_next_SINT	A countdown field that denotes time or number of remaining CBCA transmissions that may occur before the next scheduled SINT message

via this TDMA slot. Unlike normal TDMA data or synchronization slots, these slots are not assigned to individual nodes or pairs and are not protected by the Brother's Keeper Guardianship (see next section). Instead, all nodes are permitted to send in these slots. Hence, a suitable data authentication scheme is required to prevent a single maliciously faulty node from signaling erroneous clique activity. Such a scheme is described in Section 67.3.2.2.

Given suitable authentication of messages received during the CBCA breakthrough slot, all nodes can perform the CBCA priority comparison. If a higher-priority clique is detected via CBCA reconstitution, nodes yield by ceasing to execute their current schedule and prepare to receive the SINT message from the confirmed higher-priority SINT source. Therefore, by using the CBCA breakthrough mechanism, it is possible to resolve cliques even in the presence of two link faults or two benign node faults.

## 67.3 Fault Isolation

---

### 67.3.1 Time-Triggered Sequenced Guardian Roles

The basic high-integrity data-propagation mechanisms described in previous sections are sufficient to protect data during its transmission on the BRAIN fabric. However, additional mechanisms are required to qualify data as it enters the BRAIN, to ensure that the BRAIN's data integrity is consistent for all member nodes. These additional mechanisms can be viewed as guardian roles that cross-check and police data as it enters the BRAIN. The specific roles are selected in accordance with the TDMA schedule and are performed by the active transmitting nodes' immediate neighbors (direct links) and neighbors' neighbors (skip links). Hence, it is called Brother's Keeper Guardianship. In synchronous operation, the nodes adjacent to the currently scheduled transmitter implement guardian enforcement actions. Thus, guardianship can be pictured as moving around the ring as the TDMA communication sequence progresses, with Brother's Keeper Guardians only standing on either side of the currently transmitting node. Note that the guardian, being an independent neighboring node, ensures that guardian action is fully independent of the transmitter it is guarding, even if it is embodied in the communication controller hardware. This gives all the benefits of fully independent redundant guardian hardware, without requiring the addition of any redundant hardware components (such as central guardians or dedicated hardware components at each transmitter). Note that using the Brother's Keeper Guardian strategy, the early limitations restricting slot order and slot size for bus topology protocols such as TTP and FlexRay can be removed.

The generic guardian role implements the TDMA selection of the schedule transmitted, granting its neighbor access to initiate a transmission, during its assigned transmission slot. This mechanism prevents a node, disturbing traffic outside its schedule slot. Additional guardian roles, described later, may also be selected according to a node's relative placement to the active sender and/or self-checking senders and the data consistency requirements for the schedule slot.

#### 67.3.1.1 Directional Integrity Exchange

The directional integrity mechanism is illustrated in Figure 67.11. It is performed by nodes adjacent to an active simplex sender to ensure that the sender sends consistent data in each direction, that is, the copies of the data sent in each direction are identical. For a TDMA slot in which a simplex node is scheduled to transmit, each node on either side of the sender receives data from the sender via their direct links and immediately relays it to the partner guardian on the other side of the sending node via the skip links that connect them. The guardian nodes also perform an integrity comparison of the data transmitted directly from the sending node with the data reflected via the other guardian. Data integrity is signaled using the BRAIN's main data integrity mechanism, that is, by setting the integrity status trailing the transmission. This guardian action ensures that the transmitting node sends consistently in both directions. If the data sent in the two different directions are not identical, both copies of the transmitted data are marked with integrity loss.

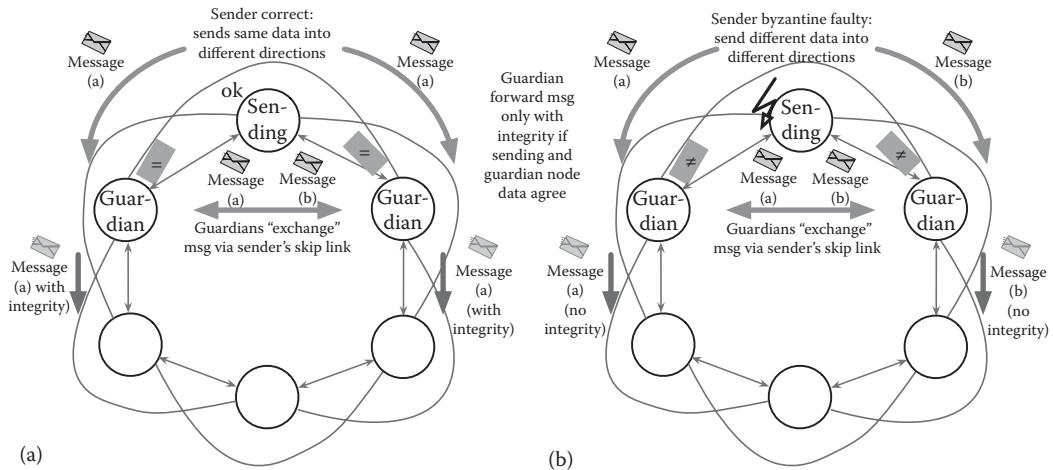

FIGURE 67.11 Consistent data guardian exchange. (a) Sender correct and (b) sender Byzantine faulty.

### 67.3.1.2 Skip Guardian Link Forwarding

The directional integrity mechanism described is sufficient to guarantee that data broadcast in both directions around the ring is the same. However, it has the disadvantage that it requires a guardian influence on the data transmissions in both directions of the BRAIN. Therefore, under guardian failure, the directional integrity mechanism may impact communication availability (but integrity *is* assured). For example, consider the faulty guardian (FG) in Figure 67.12. This guardian corrupts the data in both the clockwise and counterclockwise directions, that is, the data it is forwarding directly from the sender and the data it is reflecting to the adjacent guardian located on the other side of the sender. In this case, the integrity is flagged as lost in both directions. However, given that data integrity can be reconstituted, this situation can be mitigated by the nodes adjacent to the guardians. These nodes bias their selection of the data they forward such that in the event of data conflict/miscompare, the data from the skip link

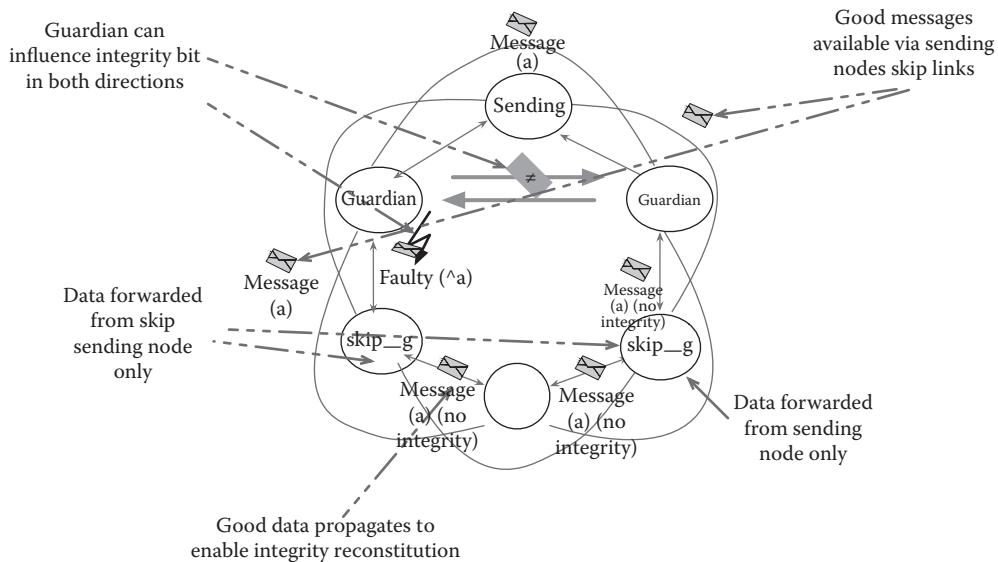

FIGURE 67.12 Skip guardian action mitigate.

are forwarded, that is, the data from the link directly connected to the sender. This action overrides the normal Availability OR selection of the standard high-integrity data-propagation logic.

As illustrated in Figure 67.12, this mitigation is performed by nodes on each side of the two guardians. Using this mechanism, the data from the sender propagate, even with an FG. If a consistent transmission is made in both directions, the data reconstitution mechanism performed by all nodes as part of data reception will accept the data as good, despite the loss-of-integrity status induced by the FG component.

### 67.3.1.3 Self-Checking Pair Neighbor Guardian

For the BRAIN's SCP assumptions to be valid, the output from each half of the pair must be cross-compared as part of any data validity evaluation. Therefore, the BRAIN needs to implement enforcement mechanisms to ensure that such an evaluation is always done. The required roles of SCP neighbors are illustrated in Figure 67.13. To ensure that data from each half of the pair can be utilized by the integrity reconstitution logic, the data flow from the pair is restricted such that the nodes adjacent to the SCP only propagate data from the direct links, with the data received from the skip links used solely for data integrity comparison. This data flow restriction exists even in the event of the direct link being *dead*, that is, indicating no data. As illustrated in Figure 67.13, this restriction prevents integrity reconstitution from evaluating the data from a single node (which would be a violation of the integrity separation guarantees for SCPs).

### 67.3.2 Asynchronous Guardian Roles

#### 67.3.2.1 Start-Up Enforcement

Prior to entering synchronous operation, the time-triggered guardian roles earlier are not applicable. Hence, the BRAIN deploys alternative enforcement actions to provide the protection during protocol start-up. Following power-up, the start-up guardian action is performed by all nodes. Before protocol start-up, the SINT message is the only message expected to flow around the BRAIN. As outlined earlier, the SINT message is a very small message, comprising the frame ID and clock master priority (as well as information to avoid a single node imitating a SCP, which is discussed later). Therefore, the guardian is only required to limit the size and rate of SINT message activity and ensure that no erroneous nodes send messages larger than the SINT message. The behavior is illustrated in Figure 67.14.

Initially, a node performs a race-based arbitration on skip and direct links in each direction. Once a link (i.e., direct or skip) is identified as the winner, the guardian enables data propagation for a window

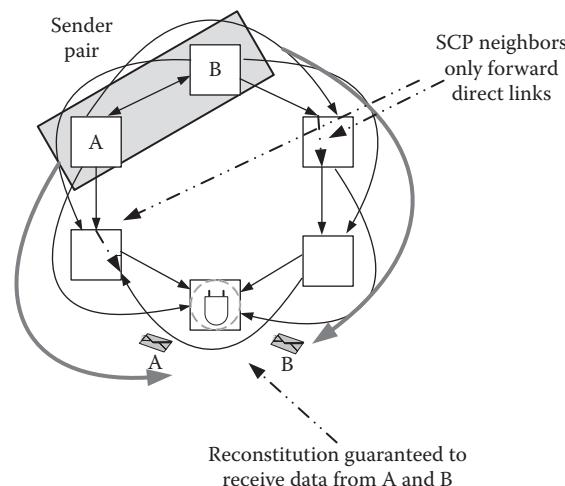

FIGURE 67.13 SCP guardian action.

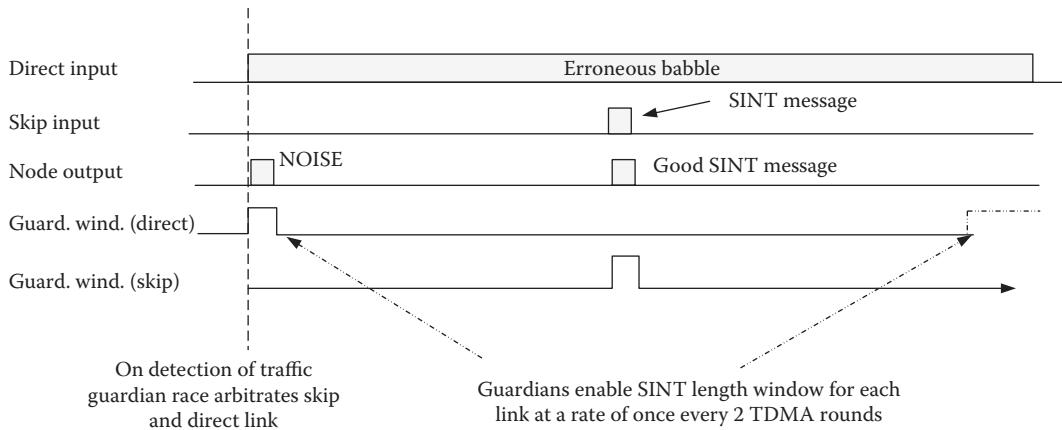

FIGURE 67.14 Start-up guardian action.

slightly larger than the SINT message. Once the SINT message window has expired, the guardian blocks the link, truncating any activity that is still in process. The winning link is then blocked for a period that is larger than two rounds of the minimum TDMA synchronization cycle. This blocking action can be viewed as a toggle-based enforcement where, during the blocking period, the guardian allows only the nonwinning link to take part in arbitration. Once the blocking time-out expires, the winning link is reenabled to take part in arbitration action.

### 67.3.2.2 Source Authentication

In the asynchronous start-up mode and/or in time-triggered slots where guardian action is disabled (e.g., the CBCA breakthrough slots of Section 67.2.2.3), an additional source authentication mechanism is required to prevent a node from masquerading as two independent sources. Without authentication, a faulty node would be able to unduly influence the system and potentially disrupt protocol operation. Many authentication schemes are possible. The key requirement for all schemes is to ensure that data from a single node are not used for both inputs in cross-checking. The initial authentication scheme of the BRAIN utilized a simple *port stamping* scheme. This mechanism required frontier nodes to write their ID into the message, together with the port of entry (i.e., skip or direct), upon reception. The topology of the BRAIN ensures that the port stamps are independently applied from each direction. Since all data used for integrity reconstitution are a function of two directions, this simple port stamping scheme is single-fault tolerant, requiring two nodes to agree before the data are validated. Alternative authentication algorithms in the BRAIN can be based on a hop count [1]. It should be noted that in all cases, only the port stamp or hop count data are used to implement the authentication, and no application data entering the BRAIN have influence on the authentication decision.

### 67.3.2.3 Additional Guardian Fault Containment Behavior

#### 67.3.2.3.1 Short-Circuit Detection

One vulnerability flow through guardian mechanisms, such as those used by the BRAIN, is undetected short circuits between links or within nodes, which may render the node's respective guardian ineffective (e.g., by the short circuit bypassing the blocking or flag-setting actions of a guardian). Although such failures may be mitigated by the active fault scrubbing of the guardian hardware, the overhead and system complications of in situ guardian testing is often nontrivial, potentially introducing significant software and system complications. The period of guardian scrubbing can also become a limit of system reliability. Therefore, the BRAIN implements continuous scrubbing. This scrubbing uses dissimilar link encoding, which is similar to the bus encoding of SAFEbus [6]. Each link that might short to another link in a way

that could bypass a guardian function is given a trivial *cryptographic key* that is different from the keys used by any of the other links to which it might short. These keys are used to *encrypt* each link's data streams using some trivial algorithms such as XOR. If the physical layer technology uses block-coded symbols, such as 8B/10B, the *encryption* is done before the block encoding, in order to maintain the desired spectral characteristics of the block encoding. Each encrypted signal that meets in some geographic locality must have a different key. Six keys are sufficient for most physical layouts of the BRAIN. This means a 3-bit key.

## 67.4 Diagnostic and Agreement Services

---

### 67.4.1 Host Task Set Agreement

The message-stepping SCP configuration of the BRAIN is an efficient scheme for software replication and output comparison. However, for such a scheme to be effective, the replicated task sets on both halves of the SCP processor need to be replica determinate. It is also important to prevent a fault from entering the pair and upsetting the pair's consistency (agreement of state between the two halves of the pair). Therefore, the BRAIN utilizes the direct link that connects configured self-checking nodes to implement input state agreement. Using this private link, both halves of the pair agree on the data they received. Given the inconsistent omission fault model of the BRAIN data exchange, this agreement mechanism is similar to the SAFEbus syndrome exchange, where the nodes simply agree on the received status. A full value exchange is not required. This mechanism ensures that any data not received consistently by both nodes are dropped by both nodes. Hence, data entering inconsistently are prevented from causing state divergence within the pair.

## 67.5 Validation and Verification Efforts

---

The braided-ring topology of the BRAIN is arguably optimal with respect to hardware and bandwidth usage for fault-tolerant systems. The reliability of braided-ring topologies has been investigated in the literature and research on this related to the BRAIN is described in [1]. Summarizing, the additional links provide significant additional reliability, especially for long mission times. In [4], the reliability of the braided ring is compared to dual-star topologies, evaluated in the context of extended dispatch scenarios very similar to the time-limited dispatch in engine control systems as described in ARP5107 [7]. The results are that braided rings significantly outperform dual stars in typical architectures and deployment scenarios with respect to reliability while using less hardware.

Certain aspects of the BRAIN, such as the BRAIN high-integrity forwarding logic, have been model checked using SRI's Symbolic Analysis Laboratory (SAL).

## 67.6 Example Configurations, Implementations, and Deployment Considerations

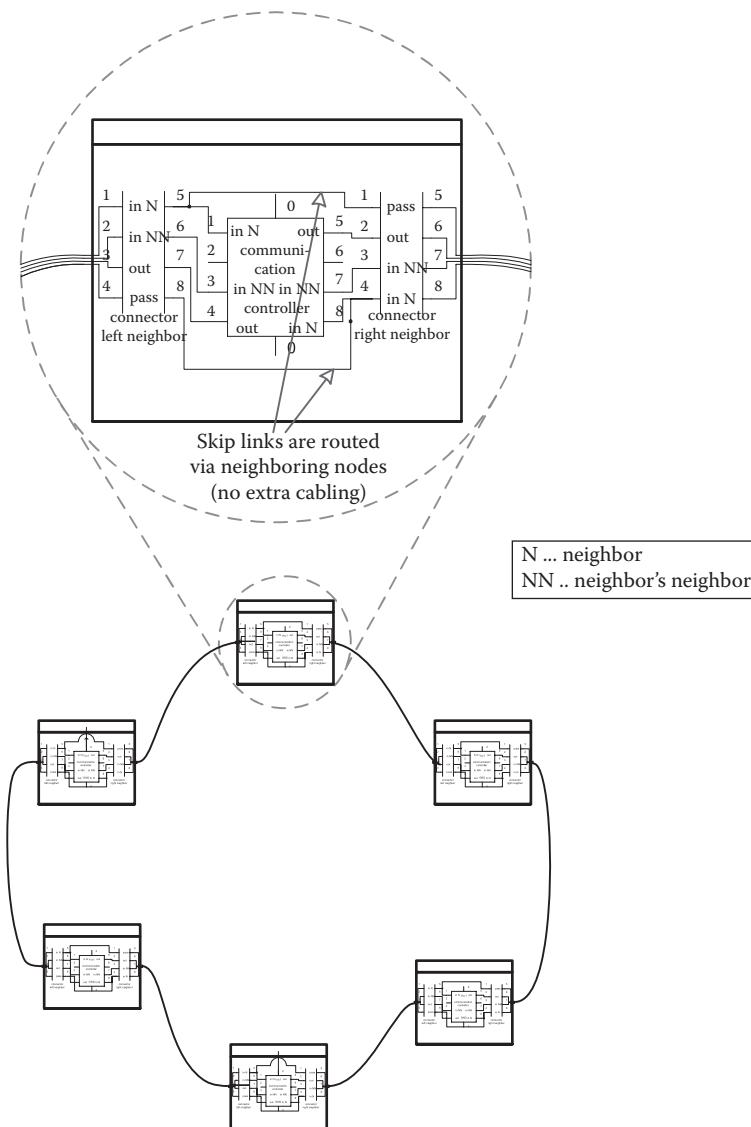

---

The BRAIN is still an evolving concept. It has a wide variety of possible implementations. It can use almost any physical layer technology to create its links. It can be half duplex or full duplex. The links within a single BRAIN can use multiple types of physical layer technologies, as long as the net speed and the type of duplexing are the same.

As discussed earlier, high-speed variants of the BRAIN are also under development. Targeting higher-speed protocols, such as 100 Mbs or Gbs Ethernet, these variants incorporate both store-and-forward and cut-through messaging. They are also targeted to tolerate multifault scenarios, that is, to be tolerant to multiple simultaneous active and benign node failures. Although many of the core protocol mechanisms of these BRAIN variants are the same as those discussed earlier, these new variants of the BRAIN replace the sequenced guardian roles of Section 67.3.1 with a more aggressive source authentication scheme. Such a strategy enables greater availability to be leveraged from the same BRAIN connectivity

and amount of hardware components while simultaneously reducing protocol complexity. Targeting full-duplex connectivity, these variants also remove the CBCA algorithm, since the possibility of store-and-forward messaging enables messages to propagate without regard for TDMA phase alignment.

A potential physical-layer BRAIN deployment option is an optimization that is possible with respect to BRAIN media routing. Often, the conceptual diagrams of the BRAIN lead readers to consider that it introduces a large cabling overhead. However, the cabling of the BRAIN does *not* have to be routed separately, and the BRAIN does not suffer any loss of dependability when cable layout is optimized. For example, consider the physical wiring of Figure 67.15. Here the physical routing of skip links passes through the same shield as the direct links and the skip connections are routed through the neighboring nodes. This results in simple physical ring topology with respect to wiring and connections. It should also be noted that the number of connections for a BRAIN is equivalent to a dual-star despite the BRAIN's greater dependability.

**FIGURE 67.15** Cabling of BRAIN routed within neighboring nodes.

The BRAIN has yet to be deployed in series production or completely prototyped within a full-up system. However, the efficiencies offered by the BRAIN approach is beneficial to high-integrity control architectures. In addition, as Ethernet and time-triggered Ethernets become more pervasive, hybrid approaches of mixed BRAIN and COTS technology present advantages, for example, by allowing a high-dependability by-wire infrastructure to coexist with noncritical Ethernet. This would allow generic Ethernet to be used for system maintenance and loading, allowing for the use of COTS and standard laptop- or desktop-derived test equipment while still providing very strong assurance and fault tolerance guarantees for the by-wire backbones. In addition, the BRAIN's ability to support message-stepping SCPs, together with its guaranteed inconsistent omission fault handling for data exchange, also allows for significant reduction of software complexity and associated overheads. With its various flavors and forms, a version of the BRAIN can be chosen to fit a wide variety of cost and performance targets while providing a guaranteed level of fault tolerance with the least amount of hardware possible.

SECOND EDITION

# Industrial Communication Technology Handbook

Featuring contributions from major technology vendors, industry consortia, and government and private research establishments, the **Industrial Communication Technology Handbook, Second Edition** provides comprehensive and authoritative coverage of wire- and wireless-based specialized communication networks used in plant and factory automation, automotive applications, avionics, building automation, energy and power systems, train applications, and more.

## New to the Second Edition:

- 46 brand-new chapters and 21 substantially revised chapters
- Inclusion of the latest, most significant developments in specialized communication technologies and systems
- Addition of new application domains for specialized networks

The **Industrial Communication Technology Handbook, Second Edition** supplies readers with a thorough understanding of the application-specific requirements for communication services and their supporting technologies. It is useful to a broad spectrum of professionals involved in the conception, design, development, standardization, and use of specialized communication networks as well as academic institutions engaged in engineering education and vocational training.
